Bogart (2021) (170) *nouveau* Étude transversale É.-U. Nov.-déc. 2020	207 personnes de race noire ont été sélectionnées dans le groupe RAND American Life Panel (ALP) représentatif au niveau national et ont été interrogées en ligne afin d'évaluer les associations entre la méfiance envers la médecine, les intentions de se faire vacciner et la réticence à se faire vacciner. Sujets des questions : 1) Intentions de se faire vacciner Outils de sondage disponibles? Non Des recherches formatives ont-elles été menées? Non Sondage prétesté? Non	• Les minorités sexuelles ou de genre ne permettaient pas de prédire statistiquement une intention négative ou positive de se faire vacciner (intention positive P = 0,56 et intention négative P = 0,41).
Teixeira da Silva (2021) (167) Étude transversale ÉTATS-UNIS Octobre à décembre 2020	Un sondage en ligne effectué aux États-Unis a évalué l'acceptation des vaccins chez 1 350 personnes appartenant à des minorités sexuelles et de genre. Sujets des questions : 1) Intentions en ce qui concerne les vaccins Outils d'enquête disponibles? Non Recherches formatives effectuées? Non Enquête prétestée? Non	• Sur une échelle de 10 points, 10 signifiant « très probable » et 1 « très improbable », l'intention de se faire vacciner était moyennement élevée (score moyen = 7, écart-type = 3,12). • Comparativement aux homosexuels, les participants regroupés dans la catégorie « Autre » identité sexuelle étaient moins susceptibles d'avoir l'intention de se faire vacciner (β = 1,102, P = 0,047). Il n'y avait pas d'autres différences selon l'identité sexuelle (bisexuelle, queer, identités multiples, amour du même sexe). • Comparativement aux participants blancs, les Noirs (β = 0,681, P < 0,001), les Amérindiens/Autochtones de l'Alaska (β = 2,482, P < 0,001) et les participants s'identifiant à une autre race (β = 1,174, P < 0,001) étaient plus disposés à vouloir se faire vacciner. Les participants asiatiques (β = 0,718, P = 0,018)

		étaient plus susceptibles d'avoir l'intention de se faire vacciner que les Blancs. • L'acceptation du vaccin a été associée négativement à davantage de préoccupations sociales concernant le vaccin (β = 0,10, p < 0,001) et de méfiance médicale (β = 0,06, p < 0,05) et associée positivement à des motivations altruistes (β = 0,60, p < 0,001).
Phillips (2021) (169) *nouveau* Étude transversale É.-U. Avril-août 2020	Les différences entre les minorités sexuelles/de genre et les personnes vivant avec le VIH dans l'adoption d'un vaccin contre la COVID-19 ont été mesurées par un sondage en ligne auprès de 932 adultes (plus de 18 ans). Sujets des questions : 1) Intentions de se faire vacciner Outils de sondage disponibles? Non Des recherches formatives ont-elles été menées? Non Sondage prétesté? Non	• 91.8 % envisageraient de se faire vacciner contre la COVID-19 et 8,2 % ne le feraient pas. • Les répondants bisexuels et pansexuels avaient une probabilité significativement plus élevée d'envisager un vaccin contre la COVID-19 (OR 1,69, IC à 95 % : de 1,01 à 2,82) par rapport aux répondants gais ou lesbiennes qui étaient de genre non-binaire (OR 4,38, IC à 95 % : de 1,33 à 14,4) par rapport aux répondants ayant une identité sexuelle masculine ou transgenre (OR 2,30 IC à 95 % : de 1,08 à 4,88) par rapport aux répondants non transgenres. • Les personnes séropositives étaient significativement moins susceptibles d'envisager de se faire vacciner contre la COVID-19 (OR 0,40, IC à 95 % : de 0,23 à 0,67) par rapport aux répondants séronégatifs.
Melin (2021) *préimpression* (168) Étude transversale ÉTATS-UNIS Juillet 2020	Un sondage en ligne a été utilisé pour évaluer les facteurs associés à l'intention de se faire vacciner contre la COVID-19 chez 1 016 adultes (âgés de 21 ans et plus) vivant à Porto Rico. Sujets des questions : 1) Intentions en ce qui concerne les vaccins 2) Hésitation par rapport à la vaccination	• Dans l'analyse bidirectionnelle, les identités sexuelles homosexuelle (81,8 %), bisexuelle (85,7 %) et autre (90,9 %) étaient toutes associées à une intention accrue de se faire vacciner comparativement à l'identité sexuelle hétérosexuelle (66,4 %), P < 0,001. • Après ajustement dans l'analyse de régression multivariée, cette relation n'était pas significative (homosexuel : RCa = 0,9, P = 0,72; bisexuel : RCa = 2,1, P = 0,08; autre identité sexuelle : RCa = 3,4, P = 0,25).

PARENTS		
CANADA		
Gouvernement du Manitoba (2021) *Non publié* (11) *nouvelle* Étude longitudinale Canada Mai 2021	Un groupe de recherche en ligne composé de 600 Manitobains a été interrogé pour comprendre les attitudes envers le vaccin et les mesures incitatives possibles pour augmenter le taux de participation. Sujets des questions : 1) Intentions de se faire vacciner 2) Perception des vaccins Outils de sondage disponibles? Non Des recherches formatives ont-elles été menées? Non Sondage prétesté? Non	• Dans un groupe de 70 parents ou tuteurs d'enfants âgés de 12 à 17 ans, 15 % sont incertains de faire vacciner leurs enfants et 13 % ne le feront pas. • Les parents qui n'avaient pas l'intention de faire vacciner leurs enfants faisaient partie de ménages dont le revenu était inférieur à 40 000 dollars, ne se feraient pas vacciner eux-mêmes et ne pensaient pas que les adultes devaient recevoir tous les vaccins habituels.
McKinnon (2021) *préimpression* (18) Étude transversale Canada Janvier à avril 2021	La volonté de faire vacciner les enfants selon leur niveau de scolarité, leur quartier et leur appartenance à une minorité visible a été évaluée lors d'un sondage en ligne effectué auprès de 380 parents ayant des enfants âgés de 2 à 17 ans à Montréal. Sujets des questions : 1) Intentions en ce qui concerne la vaccination 2) Hésitation par rapport à la vaccination	• 61 % des parents ont dit qu'il était très probable qu'ils fassent vacciner leur enfant, 25 % ont dit que c'était assez probable, 9,2 % ont dit qu'il était peu probable qu'ils le fassent alors que 4,5 % ont dit qu'il était très peu probable qu'ils fassent vacciner leur enfant. • Les préoccupations au sujet du manque d'information sur l'innocuité du vaccin et les effets secondaires possibles étaient la raison la plus courante de la réticence (48 %). • Si l'on compare les parents membres d'une minorité visible aux parents non membres d'une minorité visible, 30,3 % comparativement à 66,6 % d'entre eux étaient très susceptibles de

	Outils d'enquête disponibles? Non Recherches formatives effectuées? Non Enquête prétestée? Non	faire vacciner leurs enfants, 36,8 % comparativement à 23,9 % étaient plutôt susceptibles de le faire et 32,9 % comparativement à 9,5 %, respectivement, n'étaient pas susceptibles de faire vacciner leurs enfants.
Vallis (2021) (164) Étude transversale Canada Juin à octobre 2020	Les attitudes et les préoccupations à l'égard de la vaccination contre la COVID-19 chez les personnes en surpoids et atteintes d'obésité ont été évaluées par un sondage en ligne. Deux échantillons ont été utilisés : 1) un échantillon représentatif de 1 089 personnes en surpoids et atteintes d'obésité, et 2) un échantillon de proximité de 980 personnes recrutées auprès de services cliniques ou d'organisations de patients en obésité. Sujets des questions : 1) Intentions en ce qui concerne les vaccins 2) Hésitation par rapport à la vaccination Outils d'enquête disponibles? Non Recherches formatives effectuées? Oui Enquête prétestée? Non	• 64,6 % des personnes atteintes d'obésité se sentaient à l'aise de recevoir un vaccin alors que 35,4 % hésitaient. • Les personnes étaient moins à l'aise avec le fait que leurs enfants se fassent vacciner (58,5 % étaient à l'aise alors que 41,6 % hésitaient, $P < 0,001$).
Drouin (2021) *préimpression* (151) Étude transversale	L'intention des parents de faire vacciner leur enfant souffrant d'asthme contre la COVID-19 a été évaluée au moyen d'un sondage en ligne auprès de 305 parents. Sujets des questions :	• 63 % des parents étaient susceptibles de faire vacciner leur enfant, 19,1 % ont dit qu'il était peu probables qu'ils le fassent et 17 % étaient incertains. Pour eux-mêmes, 64 % des parents ont dit qu'ils se feraient probablement vacciner, 21 % ont dit que cela était peu probable et 15,1 % étaient incertains. Il y avait un lien étroit entre l'intention des parents de faire vacciner leurs

Canada Août 2020	1) Intentions en ce qui concerne les vaccins 2) Hésitation par rapport à la vaccination Outils d'enquête disponibles? Non Recherches formatives effectuées? Non Enquête prétestée? Non	enfants et l'intention de la personne de se faire vacciner. • Les facteurs associés de façon importante à la décision d'un parent de faire vacciner son enfant comprenaient un niveau de scolarité plus élevé, un emploi, le sexe de l'enfant (femme), la présence d'autres maladies chroniques, la vaccination antérieure contre la grippe, l'anxiété parentale et la consultation d'un professionnel de la santé.
Lackner (2021) (189) Étude transversale Canada Mai et juin 2020	Les facteurs démographiques, expérientiels et psychologiques associés à la probabilité et à la rapidité prévues de recevoir un vaccin contre la COVID-19 ont été examinés dans 455 familles (857 enfants). Sujets des questions : 2) Intentions en ce qui concerne les vaccins Outils d'enquête disponibles? Non Recherches formatives effectuées? Oui Enquête prétestée? Non	• Les facteurs associés à une plus grande probabilité de faire vacciner les enfants comprennent l'âge plus avancé des parents, la vie dans les Prairies (comparativement au centre du Canada), des antécédents de vaccination plus complets pour les enfants et les parents, des attitudes positives à l'égard des vaccins en général, un plus grand évitement psychologique de la pandémie et une plus grande tendance à prioriser les risques de la maladie comparativement aux risques des effets secondaires. • Dans certains modèles, le risque perçu de COVID-19 et les niveaux plus élevés d'anxiété au pays étaient associés à une probabilité accrue de faire vacciner les enfants. • Les facteurs ci-dessus étaient également des prédicteurs de la vitesse plus rapide de la vaccination prévue. Toutefois, un statut socio-économique plus élevé était un prédicteur de tendance.
À L'ÉCHELLE MONDIALE		
Skjefte (2021) (135) Étude transversale 16 pays : Australie,	Un sondage en ligne a été utilisé pour évaluer le niveau d'acceptation de la vaccination contre la COVID-19 chez 5 294 femmes enceintes et 12 562 mères d'enfants de moins de 18 ans. Sujets des questions :	• 69,2 % de toutes les femmes avaient l'intention de faire vacciner leurs enfants. Les niveaux d'acceptation étaient supérieurs à 85 % en Inde, au Mexique, au Brésil et en Colombie et inférieurs à 52 % aux États-Unis, en Australie et en Russie. • Pour les mères, les raisons les plus courantes de refuser un vaccin étaient la crainte que l'approbation du vaccin soit précipitée pour des

Afrique, Argentine, Brésil, Chili, Colombie, Inde, Italie, Mexique, Nouvelle-Zélande, Pérou, Philippines, Russie, Espagne, Royaume-Uni, États-Unis. Octobre et novembre 2020	1) Intentions en ce qui concerne les vaccins 2) Hésitation par rapport à la vaccination Outils d'enquête disponibles? Non Recherches formatives effectuées? Non Enquête prétestée? Non	raisons politiques (39,8 %), le manque de données sur l'innocuité et l'efficacité chez les enfants (32,7 %) et les préoccupations au sujet de l'innocuité et des effets secondaires (28,4 %).
UNITED KINGDOM		
Office for National Statistics (2021) & Office of National Statistics (2021) *non publiée* (43, 140) Étude transversale ROYAUME-UNI Février à avril 2021	Les réponses provenant de quatre vagues de résultats recueillis dans le cadre du sondage en ligne Opinions and Lifestyle Survey (130) ont été mises en commun pour mettre l'accent sur les associations démographiques spécifiques et la réticence à se faire vacciner. Le nombre de personnes handicapées ou extrêmement vulnérables au niveau clinique n'a pas été déclaré. Février et mars : 17 201 réponses ont été mises en commun Mars et avril : 16 362 réponses ont été mises en commun Sujets des questions : 1) Intentions en ce qui concerne les vaccins 2) Hésitation par rapport à la vaccination	**Mars et avril** • L'hésitation à se faire vacciner est la plus forte chez les parents ayant des enfants de 0 à 4 ans (12 %) comparativement à 8 % chez les parents dont les enfants sont âgés de plus de 5 ans (8 %) et à 6 % chez les personnes qui ne vivent pas avec des enfants à charge. L'hésitation par rapport à la vaccination a diminué depuis le dernier sondage. • Chez les personnes ayant des enfants âgés de 0 à 4 ans, la réticence à se faire vacciner était plus prévalente chez les femmes que chez les hommes (16 % comparativement à 8 %). Ce nombre a cependant diminué depuis le dernier sondage. • Le sentiment positif à l'égard de la vaccination est le plus fort chez les parents qui ont des enfants de 0 à 4 ans (88 %) comparativement à 92 % chez ceux dont les enfants ont de plus de 5 ans et à 94 % chez les personnes qui ne vivent pas avec des enfants à charge. **Février et mars** • La principale raison pour hésiter portait sur les effets secondaires et cette préoccupation était la même pour les deux groupes de parents.

	Outils d'enquête disponibles? Oui Recherches formatives effectuées? Oui Enquête prétestée? Oui	
Skirrow (2021) *préimpression* (19) Étude de prévalence et qualitative ROYAUME-UNI Août à octobre 2020	Un sondage en ligne et des entrevues semi-structurées ont été menés auprès d'un groupe de 1 181 femmes enceintes (âgées de 16 ans et plus) afin de déterminer leurs points de vue sur l'acceptabilité du vaccin contre la COVID-19 pour elles-mêmes lorsqu'elles sont enceintes ou non enceintes, ainsi que pour leur bébé. Sujets des questions : 1) Intentions en ce qui concerne la vaccination 2) Hésitation par rapport à la vaccination Outils d'enquête disponibles? Non Recherches formatives effectuées? Oui Enquête prétestée? Non	• 81,2 % des femmes ont déclaré qu'elles accepteraient certainement un vaccin ou auraient tendance à le faire si elles n'étaient pas enceintes. L'acceptation du vaccin était beaucoup plus faible pendant la grossesse (62,1 %, P < 0,005), ainsi que pour leurs bébés (69,9 %, p < 0,005). • Comparativement aux femmes de race blanche, les femmes de minorités ethniques étaient deux fois plus susceptibles de refuser un vaccin pour elles-mêmes lorsqu'elles n'étaient pas enceintes, étaient enceintes et pour leur bébé (P > 0,005). • Les personnes de ménages à faible revenu, âgées de moins de 25 ans et provenant de certaines régions géographiques étaient plus susceptibles de refuser un vaccin lorsqu'elles n'étaient pas enceintes, enceintes et pour leurs bébés. • Les femmes non vaccinées contre la coqueluche pendant la grossesse étaient plus de quatre fois plus susceptibles de refuser un vaccin lorsqu'elles n'étaient pas enceintes, enceintes et pour leur bébé. • L'analyse thématique a révélé que les raisons les plus courantes de réticence étaient l'innocuité du vaccin et une méfiance plus grande à l'égard des vaccins en général.
Bell (2020) (185) Étude transversale Angleterre	Un sondage en ligne a été utilisé pour évaluer l'acceptabilité d'un futur vaccin auprès d'un groupe de 1 252 parents et tuteurs (âgés de 16 ans et plus et ayant un enfant de moins de 18 mois). À la fin du sondage en ligne, on a demandé aux participants s'ils	• Les Noirs, les Asiatiques, les Chinois, les personnes d'ethnicité mixte ou les autres groupes ethniques étaient presque trois fois plus susceptibles de refuser le vaccin contre la COVID-19 pour eux-mêmes et leurs enfants que les Britanniques blancs, les Irlandais blancs et les autres participants blancs.

Avril et mai 2020	voulaient participer à une entrevue téléphonique de suivi. Dix-neuf personnes ont pris part à l'entrevue. Sujets des questions : 1) Intentions en ce qui concerne les vaccins 2) Hésitation par rapport à la vaccination Outils d'enquête disponibles? Oui Recherches formatives effectuées? Oui Enquête prétestée? Oui	• 55,8 % des répondants ont l'intention de se faire vacciner et 34,3 % étaient incertains, mais tendaient vers le oui. • En ce qui concerne leurs enfants, 48,2 % étaient prêts à accepter que leurs enfants se fassent vacciner alors que 40,9 % étaient incertains, mais tendaient vers le oui.
NOUVELLE-ZÉLANDE		
Horizon Research (2021) *non publiée* (15, 195, 232) Étude longitudinale Nouvelle-Zélande Mar-Mai 2021	Une enquête en ligne a été menée auprès des adultes (16 ans et plus) pour mesurer le taux d'utilisation du vaccin. Mar-Avr, n=1,350 Avr-Mai, n=1387 Mai, n=1,234 *nouvelle* Sujets des questions : 1) Intentions en ce qui concerne les vaccins 2) Hésitation par rapport à la vaccination Outils d'enquête disponibles? Oui Recherches formatives effectuées? Non Enquête prétestée? Non	**Mai** • 55 % des parents ou des personnes qui s'occupent d'enfants âgés de 12 à 15 ans sont susceptibles de faire vacciner leurs enfants, soit une baisse de 1 % par rapport à avril. • Les principales raisons sont les suivantes : désir d'obtenir des garanties quant à l'innocuité du produit chez les enfants (59 %), inquiétude quant aux effets à long terme chez les enfants (50 %) et désir d'attendre pour voir s'il y a des effets secondaires (28 %). **Avril-mai** • 56 % des parents ou des personnes qui s'occupent d'enfants âgés de 12 à 15 ans autoriseront leurs enfants à recevoir un vaccin. Les parents qui étaient disposés à se faire vacciner eux-mêmes étaient plus susceptibles de faire vacciner leurs enfants que ceux qui ne le feraient pas (85 % contre 6 %). • Les principales préoccupations des personnes incertaines ou peu susceptibles de faire vacciner

		leurs enfants sont le besoin d'avoir des garanties d'innocuité (60 %) et l'incertitude quant aux effets à long terme (43 %).
Horizon Research (2021) *non publiée* (187) Étude transversale Nouvelle-Zélande Septembre 2020	Un sondage en ligne a été réalisé auprès de 1 451 adultes (âgés de 18 ans et plus) pour mesurer le niveau d'acceptation des vaccins pour eux-mêmes et leurs enfants après l'annonce de la disponibilité des vaccins. Sujets des questions : 2) Intentions en ce qui concerne les vaccins Outils d'enquête disponibles? Oui Recherches formatives effectuées? Non Enquête prétestée? Non	• Les parents pasifika et indiens étaient les plus susceptibles de faire vacciner leurs enfants (72 % et 68 %) alors que les Māori et autres Européens étaient les moins susceptibles (40 % et 41 %).
Horizon Research (2021) *non publiée* (94) Étude transversale Nouvelle-Zélande Décembre 2020	Un sondage effectué en ligne auprès de 1 438 adultes (âgés de 18 ans et plus) visait à évaluer les intentions, les connaissances et les perceptions relatives au vaccin. Sujets des questions : 1) Intentions en ce qui concerne les vaccins 2) Perception des vaccins 3) Connaissance des vaccins Outils d'enquête disponibles? Oui Recherches formatives effectuées? Non	• 40 % des parents étaient prêts à faire vacciner leurs enfants après l'approbation du vaccin, 33 % ont dit que c'était peu probable qu'ils les fassent vacciner et 24 % ont dit être incertains. Les parents les moins susceptibles de faire vacciner leurs enfants étaient les Pasifika (39 %) et les autres Européens (29 %), suivis des Māori (39 %), des Européens/Pakeha de Nouvelle-Zélande (41 %), des Asiatiques (45 %) et des Indiens (62 %).

	Enquête prétestée? Non	
ÉTATS-UNIS		
Teasdale (2021) *préimpression* (16) *nouveau* Étude transversale É.-U. Mars-avril 2021	Un sondage en ligne a été mené auprès de 1 119 parents ou personnes qui s'occupent (18 ans et plus) d'enfants de moins de 12 ans à New York afin de déterminer les intentions de faire vacciner leur plus jeune enfant. Sujets des questions : 1) Intentions de se faire vacciner Outils de sondage disponibles? Non Des recherches formatives ont-elles été menées? Non Sondage prétesté? Non	• 61,9 % avaient l'intention de vacciner leur plus jeune enfant (âge moyen de 4,7 ans), 23,3 % étaient incertains et 14,8 % n'avaient pas l'intention de le faire. • L'intention de faire vacciner augmentait lorsque les enfants étaient plus âgés et de race blanche non hispanique et que les parents étaient âgés de 30 à 44 ans, de sexe masculin et de race blanche non hispanique. Dans la modélisation multivariée, seuls les parents de sexe féminin (aPR 0,72, IC à 95 % : de 0,61 à 0,85) et les parents noirs non hispaniques (aPR : 0,79, IC à 95 % : de 0,63 à 0,99) étaient associés à une diminution des intentions de se faire vacciner. • Les parents étaient plus susceptibles de vacciner leur enfant s'ils n'avaient pas d'assurance maladie, si leur enfant fréquentait une garderie plus d'une fois par semaine, s'ils avaient deux enfants de moins de 12 ans, s'ils avaient terminé des études universitaires ou plus, si le revenu du ménage était de 100 000 dollars et s'ils vivaient à Manhattan. • Dans le modèle ajusté, seul le fait que les enfants fréquentent la garderie plus d'une fois par semaine était associé à une augmentation des intentions (aPR 1,23, IC à 95 % : de 1,05 à 1,45). • 20,2 % des parents avaient reçu un vaccin, 47,1 % avaient l'intention de se faire vacciner, 20,6 % étaient incertains et 9,1 % ont déclaré ne pas avoir l'intention de se faire vacciner (3,0 % ont refusé de répondre). • Parmi les parents qui prévoient de se faire vacciner ou qui ont été vaccinés, 82,4 % feront vacciner leur enfant, contre 25,4 % des parents incertains et 4,5 % des parents qui ne prévoient pas de se faire vacciner.

Teasdale (2021) *préimpression* (14) Étude transversale États-Unis Mars 2021	Afin d'évaluer les intentions des parents (âgés de 18 ans et plus) de faire vacciner leurs enfants (âgés de 12 ans ou moins), un sondage en ligne a été mené auprès de 2 074 adultes aux États-Unis. Sujets des questions : 2) Intentions en ce qui concerne la vaccination 3) Hésitation par rapport à la vaccination Outils d'enquête disponibles? Non Recherches formatives effectuées? Non Enquête prétestée? Non	• 49,4 % ont dit avoir l'intention de faire vacciner le plus jeune enfant de leur ménage (âge médian de l'enfant : 4,8 ans, EI : 4,5 à 5,1) lorsqu'un vaccin pédiatrique sera approuvé, 25,6 % ont dit qu'ils n'accepteraient pas de faire vacciner leur enfant, et 25 % étaient incertains. Les parents étaient plus susceptibles de faire vacciner les enfants âgés de 7 à 12 ans (56,5 %) que ceux qui avaient entre 2 et 6 ans (48 %) et 2 ans et moins (37,2 %). • Parmi les parents qui avaient reçu un vaccin ou qui avaient l'intention de se faire vacciner, 85,2 % ont dit qu'ils feraient vacciner leurs enfants, 4,8 % ne le feraient pas et 10 % ont dit être incertains. Seulement 5,7 % des parents qui ne se sont pas fait vacciner ont déclaré qu'ils prévoyaient faire vacciner leur enfant. • Parmi les raisons associées à la réticence à se faire vacciner, mentionnons des préoccupations possibles quant à l'innocuité ou à l'efficacité (78,2 %), la croyance que les enfants n'avaient pas besoin d'être vaccinés (23 %), des raisons médicales (11,2 %) et des raisons religieuses (8,5 %). • Les parents asiatiques étaient plus susceptibles de dire qu'ils voulaient faire vacciner leurs enfants que les Blancs non hispaniques (RCa 1,38, IC à 95 % : 1,19 à 1,60). • Les parents sont moins susceptibles d'avoir l'intention de faire vacciner leurs enfants s'ils sont de sexe féminin (RCa 0,69, IC à 95 % : 0,62 à 0,77), étaient moins instruits (RCa 0,73, IC à 95 % : 0,62 à 0,86) et avaient des revenus plus faibles (RCa 0,75, IC à 95 % : 0,64 à 0,88).
Czeisler (2021) *préimpression* (17) Étude longitudinale	Un sondage en ligne a été utilisé pour évaluer l'intention de se faire vacciner contre la COVID-19 et la réticence à se faire vacciner chez des adultes (18 ans et plus) américains, tant pour eux-mêmes	• En mars, 66,0 % des gens ont dit qu'ils se feraient certainement ou fort probablement vacciner le plus rapidement possible, 20 % ont dit qu'ils refuseraient le vaccin et 14 % étaient indécis. En décembre, 63,7 % ont dit qu'ils se feraient

États-Unis Décembre 2020 à mars 2021	que pour leurs enfants. En décembre 2020, 5 188 adultes ont répondu au sondage alors que 5 256 adultes y ont répondu en mars 2021. Sujets des questions : 1) Intentions en ce qui concerne la vaccination 2) Hésitation par rapport à la vaccination Outils d'enquête disponibles? Non Recherches formatives effectuées? Non Enquête prétestée? Non	vacciner, 17,5 % ont dit qu'ils refuseraient le vaccin et 18,8 % étaient indécis. • Les intentions en ce qui concerne la vaccination pour les enfants et les vaccins de rappel étaient semblables aux intentions en ce qui concerne les vaccins personnels. Dans le cadre du sondage réalisé en mars, chez les 2 160 personnes qui vivaient avec des enfants de 2 à 18 ans ou qui s'occupaient, 60,4 % des personnes ont dit qu'elles feraient vacciner ces enfants, 21,4 % ont refusé le vaccin et 18,1 % étaient indécis. • Parmi ceux qui feraient vacciner leurs enfants, 93,5 % ont dit qu'eux aussi se feraient vacciner. Parmi ceux qui ne feraient pas vacciner leurs enfants, 56,5 % ont dit qu'ils refuseraient également de se faire vacciner. • La réticence à se faire vacciner était beaucoup plus fréquente chez les adultes plus jeunes (RCa 3,88, IC à 95 % : 2,02 à 7,46), les femmes (RCa 1,51, IC à 95 % : 1,16 à 1,96), les Noirs (RCa 1,60, IC à 95 % : 1,10 à 2,33), les personnes très conservatrices sur le plan politique (RCa 3,58, IC à 95 % : 2,16 à 5,94), moins instruites (RCa 3,43, IC à 95 % : 2,11 à 5,59), celles qui portaient moins souvent le couvre-visage (RCa 3,92, IC à 95 % : 2,52 à 6,10), celles qui se conformaient moins à la demande visant à éviter les rassemblements (RCa 2,65, IC à 95 % : 1,95 à 3,60), étaient plus méfiantes envers les médecins (RCa 2,11, IC à 95 % : 1,10 à 4,07) ou n'avait pas reçu de vaccin contre la grippe en 2020 (RCa 4,11, IC à 95 % : 3,05 à 5,54).
McCabe (2021) *préimpression* (166) Étude transversale	Une enquête nationale distribuée par voie électronique a été menée auprès de 34 470 travailleurs de la santé et d'adultes de la population générale afin de mesurer l'intention de recevoir un vaccin et les facteurs liés à l'acceptation et au refus. Le	• Dans l'analyse multivariable, les parents hésitaient davantage à se faire vacciner que les non-parents (RR ajusté 1,24, IC 95 %) : 1,13 % à 1,36 %).

É.-U. Décembre 2020 à février 2021	nombre de travailleurs de la santé n'a pas été indiqué. Sujets des questions : 1) Intentions de se faire vacciner 2) Hésitation à se faire vacciner Outils d'enquête disponibles? Oui Des recherches formatives ont-elles été menées? Non Enquête prétestée? Oui	
Milan (2021) (13) Étude transversale États-Unis Décembre 2020	Pour déterminer l'incidence du trouble de stress post-traumatique (TSPT) et des antécédents de traumatisme sur les croyances et les intentions des mères de se faire vacciner et de faire vacciner leurs enfants, un sondage en ligne a été mené auprès de 240 mères aux États-Unis ayant des antécédents de maladie mentale et des enfants âgés de 3 à 18 ans. Sujets des questions : 1) Intentions en ce qui concerne la vaccination 2) Hésitation par rapport à la vaccination Outils d'enquête disponibles? Non Recherches formatives effectuées? Oui Enquête prétestée? Non	• Un historique du diagnostic de TSPT et des événements potentiellement traumatisants sont en corrélation significative et positive avec toutes les mesures du vaccin. • Il existe une forte corrélation entre l'intention de la mère et de l'enfant de se faire vacciner ($r = 0,90$, $p < 0,001$). • Parmi les mères ayant des antécédents de TSPT, 40 % hésitaient à se faire vacciner comparativement à 23,9 % des mères sans de tels antécédents, X^2 ($df = 1$, $N = 238$) = 6,45, $P < 0,01$ et pour leurs enfants, 38,7 % des mères ayant des antécédents de TSPT hésitaient comparativement à 25,8 % sans de tels antécédents, X^2 ($df = 2$, $N = 238$) = 4,08, $P < 0,05$. • Les motifs de réticence les plus courants incluaient les préoccupations à propos des effets secondaires (31 %) et le besoin d'avoir plus d'information et d'observations (24 %). • On a observé des différences dans la réticence à se faire vacciner entre les personnes ayant déjà reçu un diagnostic de TSPT et celles qui n'en avaient pas reçu. Les mères qui avaient des antécédents de TSPT étaient moins susceptibles de dire qu'elles

		croyaient en la science et plus susceptibles de dire que leur enfant avait des problèmes de santé particuliers. • Les mères ont indiqué que les facteurs les plus importants pour augmenter la confiance dans le vaccin seraient la lecture, par elles-mêmes, d'essais et de recherches et les recommandations d'un pédiatre.
Catma (2021) (241) Étude transversale États-Unis Novembre 2020	Les perceptions des parents à l'égard d'un vaccin contre la COVID-19 et leur volonté de payer pour un vaccin pour eux-mêmes et leurs enfants de moins de 18 ans ont été évaluées dans un sondage en ligne effectué aux États-Unis. Sujets des questions : 1) Intentions en ce qui concerne la vaccination Outils d'enquête disponibles? Non Recherches formatives effectuées? Non Enquête prétestée? Oui	• Les parents étaient d'accord pour payer entre 228 $ et 291 $ US pour un vaccin pour eux-mêmes et entre 243 $ et 321 $ US pour leurs enfants. • Le revenu était associé positivement à la volonté de payer des adultes pour un vaccin, tant pour eux-mêmes que pour leurs enfants. • À mesure que le nombre d'enfants augmentait dans un ménage, la volonté de payer pour le vaccin des enfants augmentait. • 72 % des parents croyaient que les vaccins étaient importants pour prévenir la maladie.
Haeder (2021) (242) Étude transversale É.-U. Octobre à novembre 2020	Les réponses de 2 404 adultes ont été recueillies dans le cadre d'une enquête en ligne visant à étudier les attitudes à l'égard des vaccins obligatoires. Sujets des questions : 1) Attitudes à l'égard des vaccins Outils d'enquête disponibles? Non Des recherches formatives ont-elles été menées? Non	• Les ménages avec enfants étaient moins favorables à l'obligation de vaccination dans les crèches et à l'université, mais pas dans les écoles maternelles et primaires. • Le fait d'avoir des enfants dans le foyer permet de prédire les attitudes favorables à l'égard des mandats contre la COVID-19 lorsque les attitudes à l'égard des mandats de vaccination généraux sont soustraites pour la garderie, la maternelle à la 12e année et l'université.

	Enquête prétestée? Non	
Marques (2021) (243) *nouveau* Étude transversale É.-U. Sept.-nov. 2020	99 parents et personnes s'occupant d'enfants (âgés de 24 à 63 ans) ont été approchés en personne dans des salles de soins dentaires pour répondre à un sondage concernant leur intention de faire vacciner leurs enfants contre la COVID-19. Sujets des questions : 1) Intentions de se faire vacciner 2) Réticence à se faire vacciner Outils de sondage disponibles? Non Des recherches formatives ont-elles été menées? Non Sondage prétesté? Oui	• 21,6 % des parents disent qu'ils autoriseraient leur enfant à être vacciné contre la COVID-19, 39,2 % sont incertains et 42,3 % n'autoriseraient pas leur enfant à être vacciné. • 19,6 % des parents disent eux-mêmes qu'ils se feront vacciner, 38,1 % sont incertains et 42,3 % ne se feront pas vacciner. • 77, 6 % des parents ont déclaré que l'âge de leurs enfants n'avait pas influencé leur décision de se faire vacciner contre la COVID-19 lorsqu'il était disponible. • L'intention de faire vacciner son enfant augmentait si l'on connaissait une personne atteinte de COVID-19 (OR 0,47, IC à 95 % : de 0,24 à 0,93). • 40 % des parents qui font vacciner leur enfant contre la grippe chaque année autoriseraient leur enfant à être vacciné contre la COVID-19. • 52,2 % des parents seraient influencés par la recommandation d'un médecin pour se faire vacciner contre la COVID-19, contre 42,4 % qui ont déclaré que personne n'influencerait leur décision.
Rhodes (2021) (184) Étude transversale ÉTATS-UNIS Juillet et août 2020	Un sondage en ligne comportant des questions ouvertes a été utilisé pour mesurer l'hésitation à l'égard de la vaccination chez 1 381 parents hésitants à l'égard de la vaccination (âgés de 18 ans et plus) qui ont au moins un enfant de moins de 4 ans aux États-Unis. Sujets des questions : 2) Intentions en ce qui concerne les vaccins 3) Hésitation par rapport à la vaccination Outils d'enquête disponibles? Non	• Les parents se sont dits légèrement hésitants en ce qui concerne leur intention de faire vacciner leurs enfants (moyenne = 3,55) et eux-mêmes (moyenne = 3,58). • Les personnes ayant un niveau de scolarité supérieur étaient plus susceptibles d'accepter un vaccin pour elles-mêmes et leurs enfants. • Les sources les plus courantes d'information sur les vaccins pour les parents étaient les travailleurs de la santé, la recherche personnelle (ressources en ligne et traditionnelles), les croyances et l'expérience personnelles, et les collègues experts. • Les réponses ouvertes indiquent également l'influence de sources de santé non traditionnelles comme les docteurs en naturopathie et en médecine alternative, ainsi que de sources comme

	Recherches formatives effectuées? Non Enquête prétestée? Non	les forums, les blogueurs, l'intuition personnelle et les expériences d'amis ou de membres de la famille.
Davis (2020) *préimpression* (188) Étude transversale ÉTATS-UNIS Juin 2020	Les facteurs associés à la probabilité que 1 008 parents se fassent vacciner et fassent vacciner leurs enfants contre la COVID-19 ont été examinés dans un sondage en ligne. Sujets des questions : 1) Intentions en ce qui concerne les vaccins Outils d'enquête disponibles? Non Recherches formatives effectuées? Non Enquête prétestée? Non	• Comparativement aux parents hispaniques, blancs non hispaniques et noirs, les parents qui se sont identifiés comme Autres étaient plus susceptibles de se faire vacciner. • 63 % des parents ont déclaré qu'ils étaient susceptibles de faire vacciner leurs enfants contre la COVID-19 et 60 % ont dit qu'il était probable qu'eux aussi se fassent vacciner. • Les facteurs fortement associés à la probabilité de faire vacciner leurs enfants et de se faire vacciner comprennent l'âge, le sexe masculin, le fait d'être marié, ainsi que le niveau de scolarité et de revenu plus élevés.
Thunstrom (2021) (186) Essai clinique randomisé ÉTATS-UNIS Mars 2020	Un sondage en ligne effectué auprès de 3 133 adultes sur leurs intentions de se faire vacciner et de faire vacciner leurs enfants contre la COVID-19. Les participants ont été répartis aléatoirement en huit groupes de traitement de l'information. Chaque groupe a vu des messages précis dans lesquels la probabilité d'infection, le taux de mortalité conditionnelle de la COVID-19 et la question de savoir si les différentes autorités sanitaires des États-Unis fournissaient des renseignements cohérents sur les risques variaient. Sujets des questions :	• 19,5 % des participants ont dit qu'ils ne se feraient pas vacciner. • Sur les 1 156 participants ayant des enfants, 19,7 % ne feraient pas vacciner leurs enfants.

	1) Intentions en ce qui concerne les vaccins 2) Hésitation par rapport à la vaccination Outils d'enquête disponibles? Non Recherches formatives effectuées? Non Enquête prétestée? Non	
AFFILIATIONS RELIGIEUSES		
AUSTRALIE		
Edwards (2021) (244) & Biddle (2021) *préimpression* (179) Étude longitudinale Australie Août 2020 et janvier 2021	Les changements dans l'intention de se faire vacciner au fil du temps et les raisons de ce changement ont été évalués dans deux sondages en ligne et téléphoniques. En août, 3 061 adultes (âgés de 18 ans et plus) ont répondu au sondage, puis 3 459 adultes ont répondu à un sondage semblable en janvier. Les deux sondages ont été remplis par 2 377 personnes. Sujets des questions : 1) Intentions en ce qui concerne les vaccins Outils d'enquête disponibles? Non Recherches formatives effectuées? Non Enquête prétestée? Non	• Ceux qui avaient des visions plus populistes et des niveaux de religiosité plus élevés étaient moins susceptibles d'avoir l'intention de se faire vacciner. • Les personnes les plus religieuses étaient moins susceptibles d'avoir l'intention de se faire vacciner (coefficient de vraisemblance du vaccin -0,022). •
Smith (2021) (182) Étude transversale	L'intention de se faire vacciner et les raisons pour hésiter à accepter la vaccination ont été évaluées au moyen d'un sondage en ligne	• Dans l'analyse bivariée, les personnes moins religieuses étaient plus susceptibles d'avoir l'intention de se faire vacciner que les personnes religieuses (P > 0,004). Cette variable n'était pas significative dans l'analyse multivariée.

Australie s.d. 2020	effectué auprès de 1 200 adultes (âgés de 18 ans et plus). Sujets des questions : 1) Intentions en ce qui concerne la vaccination 2) Hésitation par rapport à la vaccination Outils d'enquête disponibles? Non Recherches formatives effectuées? Oui Enquête prétestée? Non	
ROYAUME-UNI		
de Figueiredo (2021) *préimpression* (20) *nouveau* Étude transversale R.-U. Avril 2021	Ce sondage national en ligne mené auprès de 17 611 adultes (18 ans et plus) a utilisé une régression bayésienne à plusieurs niveaux pour estimer l'incidence des passeports vaccinaux sur l'intention de se faire vacciner contre la COVID-19 parmi les répondants qui n'ont pas encore reçu deux doses de vaccin. Sujets des questions : 1) Intentions de se faire vacciner Outils de sondage disponibles? Oui Des recherches formatives ont-elles été menées? Non Sondage prétesté? Non	• Dans une régression à plusieurs niveaux contrôlant l'intention initiale de se faire vacciner, la probabilité de se faire vacciner en cas d'introduction de passeports vaccinaux pour les voyages nationaux était significativement plus élevée chez les personnes déclarant être de confession chrétienne (RCa 1,23, IC à 95 % : de 1,08 à 1,41) par rapport aux athées ou aux agnostiques. • Si des passeports vaccinaux étaient mis en place pour les voyages internationaux, la foi chrétienne était significativement associée à une intention accrue de se faire vacciner (RCa 1,22 IC à 95 % : de 1,07 à 1,39) par rapport aux athées ou aux agnostiques.
Rahman (2021) *préimpression* (245)	Cette enquête en ligne visait à améliorer les activités de promotion du vaccin en recueillant des informations sur les	• Les scores d'attitude à l'égard du vaccin étaient modérément positifs dans chaque mosquée (62 % et 69 %).

Étude transversale ROYAUME-UNI Janvier 2021	connaissances, les attitudes et les pratiques concernant la COVID-19 auprès de 151 participants à deux mosquées. Sujets des questions : 1) Attitudes à l'égard des vaccins Outils d'enquête disponibles? Non Des recherches formatives ont-elles été menées? Oui Enquête prétestée? Non	• Les questions ouvertes concernant les améliorations à apporter à la participation et aux expériences relatives à la mise en place du vaccin englobent largement le souhait d'accroître l'accessibilité de l'information et des sites de vaccination, et d'entendre directement les membres de la communauté. • Les principales sources d'information sur les vaccins étaient les sites web du National Health Service ou du gouvernement, suivis par les médecins généralistes.
de Figueiredo (2020) *préimpression* (178) Étude transversale ROYAUME-UNI Septembre et octobre 2020	À l'aide des méthodes statistiques bayésiennes et d'un sondage national en ligne effectué auprès de 17 684 adultes (âgés de 18 ans et plus), on a estimé l'adoption du vaccin et déterminé les obstacles à cette adoption. Sujets des questions : 1) Intentions en ce qui concerne les vaccins Outils d'enquête disponibles? Oui Recherches formatives effectuées? Non Enquête prétestée? Non	• Ceux qui ont déclaré l'hindouisme ou le judaïsme comme religion étaient plus susceptibles que les athées ou les agnostiques d'accepter un vaccin (RC = 1,66, HPDI à 95 % : 1,11 à 2,43) et ceux qui ont déclaré que leur religion était musulmane (RC = 0,75, HPDI à 95 % : 0,57 à 0,96) ou autre (RC = 0,72, HPDI à 95 % : 0,62 à 0,82), étaient moins susceptibles d'avoir l'intention de se faire vacciner.
Chadwick (2021) (246) Étude transversale ROYAUME-UNI	Cette enquête en ligne menée auprès de 5 114 adultes a exploré la relation entre la consommation de médias, les données sociodémographiques, les attitudes sociales et politiques, et la probabilité de promouvoir ou de	• La religiosité était associée à l'encouragement de la vaccination ($\beta = -0{,}032$, $p < 0{,}001$).

Septembre à octobre 2020	décourager la vaccination sur les médias sociaux. Sujets des questions : 1) Attitudes à l'égard des vaccins Outils d'enquête disponibles? Non Des recherches formatives ont-elles été menées? Non Enquête prétestée? Non	
Garry (2020) (176) Étude transversale ROYAUME-UNI Juillet 2020	L'intention de se faire vacciner a été évaluée à l'aide d'un sondage en ligne effectué auprès de 2 057 adultes. Les répondants ont été répartis en groupes ayant des options de réponse différentes (asymétrie positive – plus d'options positives, asymétrie négative – plus d'options négatives et équilibrées – autant d'options positives que négatives) pour étudier l'impact des théories de conspiration sur le vaccin. Sujets des questions : 1) Intentions en ce qui concerne les vaccins 2) Perception des vaccins Outils d'enquête disponibles? Oui Recherches formatives effectuées? Non Enquête prétestée? Non	• Les répondants plus jeunes, qui avaient un revenu plus faible, qui vivaient dans une région urbaine et qui étaient religieux étaient moins susceptibles de se faire vacciner.
Murphy (2021) (174)	Un sondage en ligne effectué auprès de 1 041 adultes (âgés de 18 ans et plus) en Irlande et de	• En Irlande, le groupe des personnes qui hésitaient à se faire vacciner et résistaient au vaccin était plus susceptible d'avoir des niveaux plus élevés de

Étude transversale Irlande et Royaume-Uni Mars 2020	2 025 adultes au Royaume-Uni a évalué la volonté de se faire vacciner contre la COVID-19 et les raisons de l'hésitation à se faire vacciner. Sujets des questions : 1) Intentions en ce qui concerne les vaccins 2) Hésitation par rapport à la vaccination Outils d'enquête disponibles? Non Recherches formatives effectuées? Oui Enquête prétestée? Non	croyances conspirationnistes (d = 0,21) et religieuses (d = 0,20).
ÉTATS-UNIS		
Viskupic (2021) *préimpression* (21) *nouveau* Étude quasi expérimentale É.-U. Avril 2021	709 électeurs inscrits non vaccinés du Dakota du Sud ont reçu des messages identiques encourageant la vaccination, émanant d'un leader religieux, politique ou médical, afin d'évaluer l'incidence du messager sur l'intérêt envers la vaccination. Un groupe témoin a reçu un message sans rapport avec la COVID-19. Sujets des questions : 1) Intentions de se faire vacciner Outils de sondage disponibles? Oui Des recherches formatives ont-elles été menées? Non Sondage prétesté? Non	• L'intérêt moyen envers la vaccination était de 1,86 (IC à 95 % : de 1,61 à 2,11) dans le groupe témoin. • Un messager religieux a suscité un intérêt moyen envers la vaccination de 2,32 (IC à 95 % : de 1,94 à 2,71, P<0,05) qui était le seul messager présentant une différence statistique d'intérêt. • Tous les messagers ont eu des effets statistiquement significatifs sur les répondants s'identifiant comme chrétiens évangéliques, l'effet le plus fort étant observé avec un messager religieux. • Un messager religieux a également eu un effet statistique chez les répondants de moins de 65 ans.

King (2021) *préimpression* (181) Étude longitudinale É.-U. Janvier à mars 2021	Dans le cadre d'une enquête nationale continue mensuelle sur la COVID-19, des questions visant à mesurer l'acceptation des vaccins et les facteurs connexes d'acceptation ont été recueillies auprès d'échantillons d'adultes (âgés de 18 à 64 ans). Le nombre de travailleurs de la santé n'a pas été communiqué. Enquête de janvier : n = 791 716 Enquête de février : n = 710 529 Enquête de mars : n = 732 308 Sujets des questions : 2) Hésitation à se faire vacciner Outils d'enquête disponibles? Oui Des recherches formatives ont-elles été menées? Non Enquête prétestée? Non	• Dans un sous-ensemble d'individus de cette enquête (n = 143 297) par catégories professionnelles présentant le plus fort pourcentage d'hésitation, 6,7 % des individus ont déclaré la religion comme raison de leur hésitation à se faire vacciner. Il s'agit notamment des professions de la construction, de l'installation, de l'agriculture, de la sylviculture et de la pêche, et des transports.
Carmody (2021) (183) Étude transversale États-Unis Décembre 2020 à janvier 2021	Un sondage sur papier a été utilisé pour évaluer les attitudes et les intentions à l'égard de la vaccination chez 102 adultes juifs Haredi (ultra-orthodoxes) (âgés de 18 ans et plus) de New York. Sujets des questions : 1) Intentions en ce qui concerne la vaccination 2) Attitudes à l'égard des vaccins 3) Hésitation par rapport à la vaccination	• 12 % des répondants ont dit qu'ils accepteraient un vaccin pour eux-mêmes et les membres de leur famille, 47 % hésitaient fortement et 41 % étaient indécis. • 70 % ont convenu que les vaccins de routine étaient essentiels. • L'appréhension en ce qui concerne la nouvelle technologie associée aux vaccins était la préoccupation la plus courante en ce qui concerne la vaccination. • Il y avait également un manque de confiance dans le gouvernement et les responsables de la santé, et seulement 17 % des gens ont dit les mandats

	Outils d'enquête disponibles? Non Recherches formatives effectuées? Oui Enquête prétestée? Non	adoptés par le ministère de la Santé local les obligeraient à accepter un vaccin. • Les prédicteurs indépendants d'une forte hésitation à se faire vacciner étaient les suivants : 1) la croyance que l'infection naturelle était meilleure que le vaccin pour développer l'immunité (RCa 4,28, IC à 95 % : 1,23 à 14,86, P = 0,022), l'idée selon laquelle l'infection antérieure au SRAS-CoV-2 qui a laissé des anticorps n'oblige pas à porter un couvre-visage ou un masque ou à respecter la distanciation sociale (RCa 4,1, IC à 95 % : 1,22 à 13,77, P = 0,022) et la perte de confiance envers les médecins à la suite de la pandémie (RCa 5,01, IC à 95 % : 1,05 à 23,96, P = 0,044).
Clark (2020) *préimpression* (171) Étude transversale ÉTATS-UNIS Novembre et décembre 2020	Un sondage en ligne mené auprès de 655 adultes de l'Oregon a évalué leur intention de se faire vacciner et les raisons de leur hésitation en mettant l'accent sur la comparaison des résidents ruraux et urbains. Sujets des questions : 1) Intentions en ce qui concerne les vaccins 2) Hésitation par rapport à la vaccination Outils d'enquête disponibles? Non Recherches formatives effectuées? Non Enquête prétestée? Non	• Les personnes qui signalent des préoccupations personnelles ou religieuses et celles qui croient que la COVID-19 n'est pas grave sont 9,5 et 10 fois plus susceptibles de refuser un vaccin, respectivement.
Graupensperger (2021) (180) Étude transversale	Les intentions et les attitudes à l'égard du vaccin de 647 étudiants d'une grande université publique du nord-ouest des États-Unis ont	• 91,6 % des étudiants ont déclaré avoir l'intention de se faire vacciner contre la COVID-19. • 2,78 % des élèves étaient d'avis qu'un vaccin contre la COVID-19 était incompatible avec leurs croyances religieuses.

ÉTATS-UNIS Novembre 2020	été évaluées au moyen d'un sondage en ligne. Sujets des questions : 1) Intentions en ce qui concerne les vaccins 2) Hésitation par rapport à la vaccination Outils d'enquête disponibles? Non Recherches formatives effectuées? Oui Enquête prétestée? Non	
Parente (2021) (126) *nouveau* Étude transversale É.-U. Août 2020	Les associations avec l'adoption des vaccins ont été évaluées en ligne pour un vaccin hypothétique en tenant compte des périodes de retard (de 1 à plus de 12 mois après l'approbation) chez 3 347 travailleurs de la santé du Kentucky. Sujets des questions : 1) Intentions de se faire vacciner 2) Réticence à se faire vacciner Outils de sondage disponibles? Non Des recherches formatives ont-elles été menées? Oui Sondage prétesté? Oui	• 7,4 % des répondants ont mentionné des raisons personnelles religieuses ou éthiques comme raisons de vouloir retarder ou refuser de se faire vacciner.
Olagoke (2020) (177)	La relation entre la religion et l'intention de se faire vacciner a été examinée dans un sondage en	• Il y avait un lien très négatif entre l'intention de se faire vacciner et la religion (β = -0,15, IC à 95 % : -0,23 à -0,08, p < 0,0001) et le locus de contrôle

Étude transversale ÉTATS-UNIS Mars 2020	ligne réalisé auprès de 501 adultes (âgés de 18 ans et plus). Sujets des questions : 1) Intentions en ce qui concerne les vaccins Outils d'enquête disponibles? INSPQ (2020), INSPQ (2021), INSPQ (2021), INSPQ (2021) *non publiée* (86, 88, 91, 95) Étude longitudinale Canada Avril 2020 à avril 2021	L'analyse de l'acceptabilité de la vaccination contre la COVID-19 a été évaluée à l'aide d'un sondage en ligne réalisé auprès d'adultes et de travailleurs de la santé au Québec. Le nombre de participants n'a pas été indiqué de façon claire (environ 3 300 par période de collecte). Il y a eu plusieurs périodes de collecte, soit en avril-mai 2020, en septembre et en décembre 2020, et en avril 2021 *nouvelle*. Ces articles sont en français. Sujets des questions :	L'intention était la plus faible dans les villages de moins de 10 000 habitants (76 %) comparativement à ceux de Montréal (79 %), dans les villages de 10 à 100 000 habitants (80 %) et dans les zones entourant la grande région de Montréal (81 %).

	1) Intentions en ce qui concerne les vaccins 2) Hésitation par rapport à la vaccination Outils d'enquête disponibles? Non Recherches formatives effectuées? Non Enquête prétestée? Non	
Lang (2021) (87) Étude transversale Canada Août 2020	Une enquête en ligne a été menée auprès de 60 adultes (18 et +) de l'Alberta pour évaluer leur intention de se faire vacciner. Sujets des questions : 1) Intentions de se faire vacciner Outils d'enquête disponibles? Oui Des recherches formatives ont-elles été menées? Non Enquête prétestée? Non	• L'intention de se faire vacciner était plus faible dans les autres centres urbains (29 %) et dans les zones rurales de l'Alberta (50 %) que dans les villes de Calgary (75 %) et d'Edmonton (80 %), (P = 0,030).
ROYAUME-UNI		
Sethi (2021) (247) Étude transversale ROYAUME-UNI Septembre à octobre 2020	Pour comprendre les facteurs de participation et de perception des essais de vaccination contre la COVID-19, 4 884 adultes ont été interrogés en ligne. Sujets des questions : 1) Intentions de se faire vacciner 2) Perception à l'égard des vaccins Outils d'enquête disponibles? Oui	• 41,4 % des répondants étaient intéressés par la participation à des essais de vaccins, 27,6 % n'étaient pas intéressés et 31,1 % étaient incertains. • Le plus grand pourcentage de répondants qui ne souhaitaient pas participer se trouvait dans les villages (pop. > 7 500) alors que les petites villes (pop. 7 500 à 24 999) étaient les plus incertains quant à leur participation. • La probabilité de ne pas participer est 0,66 fois celle des répondants des villages et 0,54 fois celle des petites villes. • 88 % des répondants des petites villes et 91 % des répondants des villages âgés de 50 à 59 ans

	Des recherches formatives ont-elles été menées? Non Enquête prétestée? Oui	n'étaient pas intéressés par la participation à des essais.
Garry (2020) (176) Étude transversale ROYAUME-UNI Juillet 2020	L'intention de se faire vacciner a été évaluée à l'aide d'un sondage en ligne effectué auprès de 2 057 adultes. Les répondants ont été répartis en groupes ayant des options de réponse différentes (asymétrie positive – plus d'options positives, asymétrie négative – plus d'options négatives et équilibrées – autant d'options positives que négatives) pour étudier l'impact des théories de conspiration sur le vaccin. Sujets des questions : 1) Intentions en ce qui concerne les vaccins 2) Perception des vaccins Outils d'enquête disponibles? Oui Recherches formatives effectuées? Non Enquête prétestée? Non	• Les répondants plus jeunes, qui avaient un revenu plus faible, qui vivaient dans une région urbaine et qui étaient religieux étaient moins susceptibles de se faire vacciner.
Murphy (2021) (174) Étude transversale Irlande et Royaume-Uni Mars 2020	Un sondage en ligne effectué auprès de 1 041 adultes (âgés de 18 ans et plus) en Irlande et de 2 025 adultes au Royaume-Uni a évalué la volonté de se faire vacciner contre la COVID-19 et les raisons de l'hésitation à se faire vacciner. Sujets des questions : 1) Intentions en ce qui concerne les vaccins	• Les personnes qui hésitaient à se faire vacciner étaient plus susceptibles de résider en banlieue (RCa = 2,13, IC à 95 % : 1,01 à 4,49).

	2) Hésitation par rapport à la vaccination Outils d'enquête disponibles? Non Recherches formatives effectuées? Oui Enquête prétestée? Non	
ÉTATS-UNIS		
McCabe (2021) *préimpression* (166) Étude transversale É.-U. Décembre 2020 à février 2021	Une enquête nationale distribuée par voie électronique a été menée auprès de 34 470 travailleurs de la santé et d'adultes de la population générale afin de mesurer l'intention de recevoir un vaccin et les facteurs liés à l'acceptation et au refus. Le nombre de travailleurs de la santé n'a pas été indiqué. Sujets des questions : 1) Intentions de se faire vacciner 2) Hésitation à se faire vacciner Outils d'enquête disponibles? Oui Des recherches formatives ont-elles été menées? Non Enquête prétestée? Oui	• Les répondants des zones moins peuplées (densité de population 0 à 149) sont plus hésitants que ceux des zones peuplées (densité de population supérieure à 1000) (RR ajusté 1,31, IC 95 % : 1,16 % à 1,48 %).
Roess (2021) *préimpression* (175) Étude transversale États-Unis	Un sondage en ligne a été effectué aux États-Unis pour évaluer l'intention de se faire vacciner chez 1 181 parents et tuteurs âgés de 18 à 64 ans qui ont actuellement un enfant de moins de 18 ans à la maison aux États-Unis. Cette étude n'a pas évalué l'intention de faire vacciner leurs enfants.	• L'intention de se faire vacciner était plus élevée chez les personnes qui vivaient en milieux urbains (RCa 2,04, IC à 95 % : 1,24 à 3,09) et semi-urbains (RCa 1,45, IC à 95 % : 0,97 à 2,17) par rapport à celles qui vivaient dans des milieux ruraux.

Décembre 2020 à janvier 2021	Sujets des questions : 1) Intentions en ce qui concerne la vaccination Outils d'enquête disponibles? Non Recherches formatives effectuées? Non Enquête prétestée? Non	
Enwezor (2021) *préimpression* (115) Étude transversale États-Unis Décembre 2020 à janvier 2021	Un sondage en ligne a évalué l'intention de se faire vacciner chez 20 232 adultes (5 170 travailleurs de la santé et 15 062 autres personnes). 476 des participants avaient déjà reçu un diagnostic de COVID-19. Sujets des questions : 1) Intentions en ce qui concerne la vaccination Outils d'enquête disponibles? Non Recherches formatives effectuées? Non Enquête prétestée? Non	• Les résidents des banlieues (68 %) et des zones rurales (71,2 %) étaient moins susceptibles que ceux des zones urbaines (81 %) d'avoir l'intention de se faire vacciner (RRa 0,85, IC à 95 % : 0,83 à 0,88, P < 0,0001).
Clark (2020) *préimpression* (171) Étude transversale ÉTATS-UNIS Novembre et décembre 2020	Un sondage en ligne mené auprès de 655 adultes de l'Oregon a évalué leur intention de se faire vacciner et les raisons de leur hésitation en mettant l'accent sur la comparaison des résidents ruraux et urbains. Sujets des questions : 1) Intentions en ce qui concerne les vaccins	• L'intention de se faire vacciner était plus élevée chez les résidents urbains que chez ceux qui vivent dans les régions rurales (47 % contre 41 %). • Les personnes qui signalent des préoccupations personnelles ou religieuses et celles qui croient que la COVID-19 n'est pas grave sont 9,5 et 10 fois plus susceptibles de refuser un vaccin, respectivement.

	2) Hésitation par rapport à la vaccination Outils d'enquête disponibles? Non Recherches formatives effectuées? Non Enquête prétestée? Non	
Kuter (2021) (109) Étude transversale ÉTATS-UNIS Novembre et décembre 2020	Pour évaluer l'intention de se faire vacciner, un sondage en ligne a été mené dans deux grands hôpitaux universitaires de Philadelphie auprès de 12 034 employés. Sujets des questions : 1) Intentions en ce qui concerne les vaccins 2) Hésitation par rapport à la vaccination Outils d'enquête disponibles? Non Recherches formatives effectuées? Oui Enquête prétestée? Oui	• Les résidents des régions urbaines étaient beaucoup plus susceptibles d'avoir l'intention de se faire vacciner que les résidents des banlieues (RC = 0,71, IC à 95 % : 0,65 à 0,79) et des régions rurales (RC = 0,41, IC à 95 % : 0,30 à 0,54).
Haeder (2021) (242) Étude transversale É.-U. Octobre à novembre 2020	Les réponses de 2 404 adultes ont été recueillies dans le cadre d'une enquête en ligne visant à étudier les attitudes à l'égard des vaccins obligatoires. Sujets des questions : 1) Attitudes à l'égard des vaccins Outils d'enquête disponibles? Non Des recherches formatives ont-elles été menées? Non	• Les habitants des zones rurales sont moins favorables à la vaccination obligatoire des élèves en garderie (b = -0,418), des élèves de la maternelle à la 12^{e} année (b = -0,652) et des enseignants de la maternelle à la 12^{e} année (b = -0,360). • Les habitants des zones rurales étaient moins favorables aux mandats contre la COVID-19 lorsque les attitudes à l'égard des mandats de vaccination générale étaient soustraites de la maternelle à la 12^{e} année.

	Enquête prétestée? Non	
Mora (2020) *préimpression* (173) Étude transversale ÉTATS-UNIS De juillet à novembre 2020	Des entrevues téléphoniques ont été effectuées auprès de 1 115 travailleurs agricoles adultes en Californie afin de déterminer leur intention de se faire vacciner et les raisons de leur hésitation. Sujets des questions : 1) Intentions en ce qui concerne les vaccins 2) Hésitation par rapport à la vaccination Outils d'enquête disponibles? Non Recherches formatives effectuées? Non Enquête prétestée? Non	• Le fait de vivre dans des régions plus rurales comme Greenfield était fortement associé à l'intention de ne pas se faire vacciner (RR = 1,19, IC à 95 % : 1,02 à 1,39).
Khubchandani (2021) (172) Étude transversale ÉTATS-UNIS Juin 2020	Un sondage en ligne a évalué l'intention de se faire vacciner et l'hésitation par rapport à la vaccination chez 1 878 adultes. Sujets des questions : 1) Intentions en ce qui concerne les vaccins 2) Hésitation par rapport à la vaccination Outils d'enquête disponibles? Non Recherches formatives effectuées? Non Enquête prétestée? Non	• Dans les analyses non ajustées, la réticence à se faire vacciner était plus élevée chez les habitants des régions rurales (29 %) que chez leurs homologues.
JEUNESSE		

Afifi (2021) (213) *nouveau* Étude transversale Canada Nov.-déc. 2020	Grâce aux répondants de l'étude longitudinale Well-Being and Experiences (2017-2020), les intentions de se faire vacciner ont été consignées pour les adolescents de Winnipeg âgés de 16 à 21 ans et leurs soignants/parents à l'aide d'un sondage en ligne. Sujets des questions : 1) Intentions de se faire vacciner 2) Réticence à se faire vacciner Outils de sondage disponibles? Non Des recherches formatives ont-elles été menées? Non Sondage prétesté? Non	• 65,4 % des répondants ont l'intention de se faire vacciner, 26,1 % sont incertains et 8,5 % ne sont pas disposés à le faire. • Les parents ayant fréquenté une école de métiers, un collège communautaire ou ayant une éducation inférieure, ayant un revenu inférieur à 49 999 $, ayant subi une certaine pression financière à cause de la COVID-19, ayant déclaré avoir une faible connaissance de la COVID-19 étaient associés à de plus faibles intentions de se faire vacciner. • Le fait d'avoir un problème de santé autodéclaré était associé à des intentions plus élevées d'accepter un vaccin. • Après correction pour tenir compte du genre, de l'âge et du revenu du ménage, les enfants qui n'avaient jamais reçu de fessée (RRa 0,33, IC à 95 % : de 0,17 à 0,62), jamais connu de victimisation par les pairs (RRa 0,49, IC à 95 % : de 0,25 à 0,96), jamais connu de toxicomanie dans le ménage (RRa 0,41, IC à 95 % : de 0,20 à 0,83), n'ayant jamais eu de contact avec une famille d'accueil ou un bureau de protection de l'enfance (RRa 0,34, IC à 95 % : de 0,16 à 0,72), et n'ayant eu aucun risque que leur ménage soit à court d'argent (RRa 0,45 IC à 95 % : de 0,21 à 0,97) étaient plus disposés à se faire vacciner. • Le fait de déclarer n'avoir eu aucune expérience négative durant l'enfance au sein du foyer est associé à la volonté de se faire vacciner (RRa 0,45, IC à 95 % : de 0,20 à 0,99). • Les principaux motifs de réticence à accepter un vaccin sont l'innocuité du vaccin (64,5 %), le manque de connaissances sur le vaccin (60,6 %) et le fait de ne pas penser que le vaccin serait efficace (23,4 %).
Brandt (2021) (190) Étude transversale	Un sondage par message texte a été réalisé auprès de 911 jeunes âgés de 14 à 24 ans à travers les États-Unis afin d'évaluer les	• 42 7 % et 33,3 % ont déclaré une volonté inconditionnelle ou une volonté conditionnelle de se faire vacciner, respectivement, dont 80,7 % ont déclaré être prêts à se faire vacciner s'il est prouvé que la vaccination est sûre et recommandée.

É.-U. Octobre 2020	obstacles et les facilitants à la vaccination contre la COVID-19. Sujets des questions : 1) Intentions de se faire vacciner 2) Hésitation à se faire vacciner Outils d'enquête disponibles? Non Des recherches formatives ont-elles été menées? Oui Enquête prétestée? Non	• Les raisons les plus courantes de se faire vacciner sont la protection de soi (38,4 %), la protection des autres (24,9 %), l'importance du vaccin (14,3 %) et le retour à la normale (11,7 %). • Les effets secondaires (36,2 %), l'efficacité (20,1 %), l'approbation précipitée (18,8 %) et la sécurité (16,2 %) étaient les préoccupations les plus courantes concernant le vaccin. • Par rapport aux jeunes blancs, les jeunes noirs (RR = 3,31) étaient plus susceptibles de refuser la vaccination et les jeunes asiatiques (RR = 0,46) étaient moins susceptibles de refuser la vaccination (P < 0,001). • Les CDC ou l'OMS (42,3 %) étaient les sources préférées d'information sur les vaccins, suivis des prestataires et établissements de santé (31,75 %), d'Internet (17,8 %), des responsables de la santé (8,4 %), des médias d'information (7,8 %) et des médias sociaux (2,5 %).
IMMIGRANTS		
INSPQ (2020), INSPQ (2021), INSPQ (2021), INSPQ (2021), INSPQ (2021) *non publiée* (86, 88, 90, 91, 95) Étude longitudinale Canada Avril 2020 à mai 2021	L'analyse de l'acceptabilité du vaccin contre la COVID-19 a été évaluée à l'aide d'un sondage en ligne auprès d'adultes et de travailleurs de la santé au Québec. Le nombre de participants n'a pas été clairement indiqué (~3 300 par période de collecte). Il y a eu plusieurs périodes de collecte, une en avril-mai 2020, une en septembre et en décembre 2020, une en avril et en mai 2021 *nouvelle*. Articles en français. Sujets des questions : 1) Intentions de se faire vacciner 2) Hésitation à se faire vacciner	• Les immigrants étaient plus hésitants et plus incertains à l'idée de se faire vacciner que les non-immigrants.

	Outils d'enquête disponibles? Non Des recherches formatives ont-elles été menées? Non Enquête prétestée? Non	
Australia Bureau of Statistics (2021) *Non publié* (141) *nouveau* Étude longitudinale Australie Avril 2020-mai 2021	Le sondage sur les impacts sur les ménages est un sondage mensuel qui recueille des données en ligne et par téléphone auprès d'un groupe d'adultes (18 ans et plus) sur des sujets liés à la COVID-19, y compris les attitudes envers les vaccins. Mai : n=3 371 Sujets des questions : 1) Intentions de se faire vacciner Outils de sondage disponibles? Non Des recherches formatives ont-elles été menées? Non Sondage prétesté? Non	• Les personnes nées à l'étranger étaient plus susceptibles de déclarer leur intention de se faire vacciner que celles nées en Australie (70,7 % contre 67,2 %). Cela est plus évident pour celles qui sont arrivées au cours des dix dernières années (74,6 %) que pour celles qui sont arrivées il y a plus de dix ans (69,1 %). • Le facteur le plus important dans la décision de se faire vacciner était une recommandation de leur médecin généraliste (25,8 %). • 68,1 % des immigrants étaient préoccupés par les effets secondaires possibles.
Deal (2021) (248) Étude transversale ROYAUME-UNI Septembre 2020 à mars 2021	Des entretiens téléphoniques approfondis ont été menés avec 32 immigrants récents (moins de 10 ans) ayant un statut d'immigration précaire afin de définir les barrières et les perceptions à l'égard de la vaccination ainsi que de générer des stratégies pour augmenter la participation.	• 28 % déclarent qu'ils se feront certainement vacciner, 31 % sont incertains et penchent vers l'affirmative, 22 % sont incertains, 19 % sont incertains et penchent vers la négative, et 6 % ne se feront certainement pas vacciner. Parmi les deux participants qui refuseraient définitivement, l'un a indiqué que c'était en raison du manque d'essais cliniques et l'autre pour des raisons religieuses. • L'intention variait fortement entre les personnes interrogées plus tôt (intentions plus faibles

	Sujets des questions : 3) Intentions de se faire vacciner 4) Perception à l'égard des vaccins 5) Hésitation à se faire vacciner Outils d'enquête disponibles? Non Des recherches formatives ont-elles été menées? Oui Enquête prétestée? Oui	d'accepter un vaccin) et celles interrogées plus tard (intentions plus élevées de se faire vacciner). • Parmi les hésitants, les inquiétudes portent sur les effets secondaires potentiels et l'insuffisance des tests du vaccin. • Trois barrières communes à la vaccination ont été déterminées : les problèmes d'accès (tels que la langue, la confiance et la perception d'un manque de droit), le manque de confiance (mauvais traitement de la part du Service national de santé, être facturé pour des soins, ou d'éventuels contrôles d'immigration), et le sentiment d'être abandonné pendant la pandémie causant une tension mentale et physique. • Les sans-papiers étaient particulièrement préoccupés par le fait qu'ils n'étaient pas enregistrés dans un cabinet de médecin généraliste et qu'ils manqueraient le déploiement des vaccins. Les migrants indiquent que les organisations caritatives et les cliniques sans rendez-vous sont fréquemment utilisées. • D'autres difficultés ont été relevées : les migrants n'étaient pas au courant des annonces selon lesquelles la vaccination n'entraînerait pas de contrôles d'immigration. • Pour augmenter l'adoption du vaccin, les migrants ont indiqué qu'il était plus facile de se faire vacciner en déployant le vaccin dans les cliniques sans rendez-vous et les organisations caritatives, en fournissant des informations sur les effets secondaires dans leur propre langue, en indiquant clairement où et comment les vaccins seraient disponibles et en soulignant que le vaccin serait fourni gratuitement.
Statistics Canada (2020) & Statistics Canada (2021)	Un sondage en ligne mené par Statistique Canada dans le cadre de l'Enquête sur la santé dans les collectivités canadiennes (ESCC) a évalué les comportements des	• Les immigrants étaient légèrement moins susceptibles de se faire vacciner (74,6 %), mais cela variait grandement entre les immigrants plus âgés et les plus jeunes (73,2 % pour les 12 à 64 ans et 81,1 % pour les 65 ans et plus).

non publiée (65, 80) Étude longitudinale Canada Septembre à décembre 2020	Canadiens pour protéger leur propre santé et celle des autres. Une question sur les intentions de vaccination a été ajoutée au sondage de septembre. Le plus récent rapport fait état de 20 000 réponses reçues de personnes âgées de 12 ans et plus. Sujets des questions : 1) Intentions en ce qui concerne la vaccination Outils d'enquête disponibles? Oui Recherches formatives effectuées? Oui Enquête prétestée? Oui	•
Knights (2021) (192) Étude qualitative ROYAUME-UNI Juin à novembre 2020	Des entretiens téléphoniques semi-structurés approfondis ont été menés auprès de 17 migrants de moins de 10 ans, 48 professionnels de la santé et 16 membres du personnel administratif à travers trois phases d'échantillonnage (intentionnel, de convenance et sondage cumulatif) afin d'obtenir des informations sur l'accès aux vaccins. Sujets des questions : 1) Perception à l'égard des vaccins 2) Hésitation à se faire vacciner	• La numérisation accrue des rendez-vous et des informations sur la santé a été ressentie différemment par les professionnels des soins primaires et les migrants ayant des problèmes d'accès à la technologie. Les professionnels des soins primaires ont indiqué que la numérisation a augmenté l'exclusion des groupes marginalisés tout en amenant des patients plus jeunes et plus en forme. Inversement, la numérisation a également été signalée comme une opportunité de communiquer avec des messages ciblés traduits. • Les migrants ont signalé que les barrières linguistiques se sont accrues en raison d'un accès plus faible à des amis qui traduiraient, alors que les médecins généralistes s'inquiétaient de la confidentialité lors des consultations virtuelles. • Les migrants et les professionnels des soins primaires ont estimé qu'il y avait un manque d'informations sur les messages relatifs à la santé publique et le vaccin ciblant les migrants. Cette situation est liée à des problèmes de faibles

		connaissances en matière de santé, de manque de compréhension des changements de politique, de méfiance à l'égard du gouvernement ou de la science, et a donné lieu à une désinformation et à la recherche d'informations sur les médias sociaux à propos de la COVID-19 et du vaccin. • Les problèmes susmentionnés et les croyances liées aux vaccins, comme le fait que la COVID-19 soit une « maladie occidentale », la peur d'être un cobaye et la dépendance aux remèdes maison, constituent également des obstacles à l'adoption du vaccin. • Les migrants et les professionnels des soins primaires ont noté qu'il était important d'établir la confiance entre les pratiques cliniques et les individus, ce qui a été un défi pendant la pandémie. Lesmigrants ont noté la tendance à rechercher les conseils de la religion ou des pairs dans la prise de décision. • Les migrants notent que l'approche « même pour tous » adoptée pendant la pandémie s'est avérée inflexible pour traiter les problèmes de la communauté liés à la numérisation et aux défaillances de la communication.
Allen (2021) *préimpression* (249) *nouveau* Étude transversale É.-U. Juillet-août 2020	Les intentions de se faire vacciner ont été mesurées chez 364 immigrants brésiliens vivant aux États-Unis par l'intermédiaire d'un sondage en ligne. Sujets des questions : 1) Intentions de se faire vacciner 2) Réticence à se faire vacciner Outils de sondage disponibles? Non	• 70,9 % des personnes interrogées ont déclaré qu'elles se feraient vacciner contre la COVID-19, 18,1 % étaient incertaines et 11 % ne se feraient pas vacciner. • Les réponses ouvertes des personnes ne prévoyant pas de se faire vacciner ont révélé qu'elles craignaient que le vaccin n'ait pas été testé (30,9 %), qu'il puisse entraîner des effets secondaires (17,6 %) ou qu'il ne soit pas efficace (8,8 %). Les autres préoccupations étaient liées au manque de confiance envers les industries impliquées dans son développement (10,3 %), le gouvernement (8,8 %) et les vaccins en général (8,8 %).

	Des recherches formatives ont-elles été menées? Non Sondage prétesté? Non	• 3,8 % des personnes qui ont passé moins de quatre ans aux États-Unis n'avaient pas l'intention de se faire vacciner, contre 27,3 % de celles qui sont nées aux États-Unis. Plus de temps passé au pays était généralement associé à des intentions plus faibles et à des répondants plus incertains. • La perception de la pandémie de COVID-19 a également eu une incidence significative sur l'intention de se faire vacciner : 75,9 % des personnes qui la considèrent comme un problème majeur souhaitent un vaccin, contre 52,6 % qui la considèrent comme un problème mineur. • Les personnes qui faisaient confiance aux professionnels de la santé (73,9 %) et aux agences de santé publique (76,8 %) avaient des intentions plus élevées que celles qui se fiaient aux réseaux sociaux (63,6 %), aux réseaux privés (62,2 %) ou qui n'avaient pas de réponse de source fiable (61,9 %).
INFECTION PASSÉE AU SARS-COV-2		
Enwezor (2021) *préimpression* (115) Étude transversale États-Unis Décembre 2020 à janvier 2021	Un sondage en ligne a évalué l'intention de se faire vacciner chez 20 232 adultes (5 170 travailleurs de la santé et 15 062 autres personnes). 476 des participants avaient déjà reçu un diagnostic de COVID-19. Sujets des questions : 1) Intentions en ce qui concerne la vaccination Outils d'enquête disponibles? Non Recherches formatives effectuées? Non Enquête prétestée? Non	• Les personnes qui n'avaient pas reçu de diagnostic antérieur de COVID-19 étaient plus susceptibles d'avoir l'intention de se faire vacciner que celles qui avaient reçu un diagnostic antérieur de COVID-19 (76,6 % comparativement à 60,9 %, RRa 1,20, IC à 95 % : 1,11 à 1,28, P < 0,0001).
Olanipekun (2021) (193)	119 Afro-Américains ont été interrogés après la guérison et la sortie de l'infection à la COVID-19	• 54 % n'avaient pas l'intention de se faire vacciner, 30 % le feraient et 16 % étaient incertains.

Étude transversale É.-U. Avril à mai 2020	pour évaluer l'acceptation d'un vaccin sûr et efficace. Sujets des questions : 1) Intentions de se faire vacciner Outils d'enquête disponibles? Non Des recherches formatives ont-elles été menées? Oui Enquête prétestée? Non	• La principale raison invoquée par ceux qui n'ont pas l'intention de se faire vacciner est une grande méfiance à l'égard de l'efficacité des vaccins et des industries pharmaceutiques (78,1 %). Les autres principales raisons sont le manque de confiance dans l'efficacité du vaccin (68,8 %) et la peur des effets secondaires (64,1 %).

Emerging Evidence on COVID-19

Evergreen Rapid Review on COVID-19 Vaccine Attitudes and Uptake in Canada – Update 9

Introduction

What is the evidence on COVID-19 vaccine attitudes and uptake in Canada?

The purpose of this evergreen rapid review is to identify and summarize literature on COVID-19 vaccination uptake and attitudes to better understand the factors associated with vaccine uptake in Canada. This report focuses on Canadian evidence on uptake and attitudes up to August 1, 2021. All studies included in this review were conducted in Canada or were multinational studies with Canadian specific data. Previous versions of this report (updates 1-8) included evidence up to July 1, 2021 on vaccine uptake and attitudes in Canada, global evidence on vaccine uptake, and vaccine attitudes in pre-defined priority populations from Australia, New Zealand, USA, and UK to complement areas where there was little Canadian research. These can be requested at phac.ocsoevidence-bcscdonneesprobantes.aspc@canada.ca. The What's New section below focuses on highlighting important findings from the most recently conducted studies (within the last four months).

What's New

- This update identified 9 new studies or updates to existing studies on COVID-19 vaccination uptake and attitudes in Canada. New studies are indicated throughout the tables as *new* and all tables are located in the appendices to assist readers in navigating the document.

Intentions to Vaccinate

- Two surveys conducted in July indicate that 86-91% of Canadians have either received a vaccine or wish to get a vaccine as soon as possible, an increase from May and June surveys (1, 2).
- A longitudinal study in Quebec demonstrated that 87% of parents intend to vaccinate their children, up 1% from June (1).
- Non-permanent residents in Canada were less likely to vaccinate (11%) compared to non-immigrants (5%), and immigrants living in Canada for more than 10 years (4%) (3). Another study in Saskatchewan indicated those who were born outside of Canada and living in Canada less than 20 years were more vaccine hesitant compared to those born in Canada (RRR 3.14, 95% CI: 1.56-6.34) (4).
- A study conducted in May-June 2021 exploring the relationship between ethnicity/race and intention to vaccinate in Canada found higher levels of vaccine hesitancy among Black (33%) and non-Black visible minorities (25%) compared to Whites (19%). Black Canadians aged 25-34 had the highest levels of vaccine hesitancy (54%). Drivers of vaccine hesitancy among Black Canadians were the ability to take paid time off, concern that vaccines cause autism, and vaccine safety concerns (5).

- Vaccine hesitancy was higher amongst Black and non-Black Canadians born in Canada compared to those born outside of Canada in study conducted in June 2021 (5).
- Those having Indigenous status in Saskatchewan were more vaccine hesitant compared to non-Indigenous status (RRR 1.65, 95% CI: 1.01-2.70) (4).

Incentives to Vaccinate

- A survey across Canada revealed that 50% of respondents supported vaccine incentives such as lotteries, 36% opposed incentives, and 14% were unsure. Support for incentives was highest in Quebec and among those aged 18-34, and lowest among those aged 55+ and rural residents (6).

Vaccine Attitudes

- 66% of Canadians wanted full vaccination (two doses) as a requirement to allow people to cross the USA-Canada border (6). Another survey indicated that 69% wanted to wait until at least 75% of Canadians were fully vaccinated before opening the Canada-USA border (7).
- Support for mandatory vaccination was 53% for the general population and 81% for healthcare workers. The highest support was demonstrated among those aged 55+ (6).

Vaccine Behaviors

- 76% of those who were unwilling or unsure about vaccination were planning on resuming everything they did before with no hesitation compared to 34% of those after their first dose and 27% of those after two doses (8).
- 53% of respondents agreed that people vaccinated against COVID-19 should be able to gather and no longer wear masks in public, 41% disagreed, and 6% did not know (9).

Key Points

- There have now been 62 studies on COVID-19 vaccine uptake and attitudes conducted in Canada (Tables 1-9). The majority of studies have been conducted on the general population and focused on intention to vaccinate. There is a severe lack of studies on high-risk and underserved populations in Canada such as Indigenous, youth, those with substance abuse disorders, LGBTQ+, and the homeless. Since vaccine rollout began in December 2020, only one study has evaluated vaccine uptake in HCWs.

Vaccine Uptake

- The one study on vaccine uptake and factors associated with uptake in HCWs from Montreal was conducted in December 2020 (Table 1). Of the HCWs offered a vaccine, 80.9% accepted and 19.1% refused. The most common reasons for refusal were the newness of the vaccine, a preference for others to get vaccinated first, lack of information, and not having enough time to make a decision.
- Increasing age and male gender were positively associated with vaccine uptake. These trends are similar to those reported in the global literature and mirror the trends seen in intention to vaccinate.

Vaccine Intentions

- The most recent studies from July 2021 report intention to vaccinate is increasing and currently varies between 86-91% in the general public. Intention to vaccinate in HCWs varied between 80-82% but this

was from studies conducted in January 2021. Alberta and Saskatchewan currently have the highest percentage of the population who do not intend to vaccinate.

Facilitators and Barriers to Vaccine Intention

- The most common factors positively associated with intention to vaccinate were male gender, older age, higher education, adequate knowledge or health literacy, trust in experts and government, history of a prior influenza vaccine, higher socioeconomic status, and heightened worry or concern about COVID-19.
- Three studies demonstrated that LGBTQ2+ were 6-11% more willing to accept a vaccine compared to non-LGBTQ2+.
- Partisanship was associated with intention to vaccinate. Those who voted liberal/democrat expressed intention to vaccinate at higher rates than those who voted for other parties.
- A recommendation to get the vaccine by a healthcare provider (e.g., doctor) had a positive impact on vaccine intention.
- Intention to vaccinate varied widely by race/ethnicity, with White ethnic groups more likely to vaccinate compared to other ethnic groups such as Black and Hispanic.
- Parents had lower intentions to vaccinate their children compared to themselves. Parental and child vaccine intentions were highly correlated with each other, with parents who were intending to take a vaccine being more likely to intend to vaccinate their children.
- Religion and belief in conspiracy theories were associated with vaccine hesitancy.
- Concerns about vaccine safety and effectiveness were the two most cited reasons for vaccine hesitancy. Other commonly cited reasons include newness of the vaccine, and the belief that a COVID-19 vaccine is unnecessary.
- Rural participants were slightly less likely to accept a vaccine compared to urban and suburban participants.
- Immigrants were slightly less likely to accept a vaccine compared to non-immigrants.
- Facilitators and barriers in Canada are similar to those reported in the global literature.

Overview of the Evidence

Sixty-two studies pertaining to COVID-19 vaccine uptake and attitudes were identified and included in this review. Of these, nine are preprints and 32 are reports which have not completed the peer-review process. This report focuses on evidence on COVID-19 vaccine uptake and attitudes in Canada.

The publications reporting on COVID-19 vaccine uptake and attitudes are mainly observational studies with a few quasi-experimental studies exploring factors associated with intention to vaccinate and the impact of messaging on these intentions. The outcomes in the experimental studies did not assess prevalence, but rather were designed to inform what may be most effective across a range of options.

A formal risk of bias evaluation was not conducted. Across observational studies the reliability of the outcome is based on obtaining a representative sample of the target population that is sufficiently large to obtain a representative spectrum of results. Studies frequently did not demonstrate the representativeness of their samples to the target population in both unpublished and published studies. Longitudinal studies where a target population was sampled more than one time to monitor changes in vaccine attitudes and uptake over time were the strongest observational study design identified. Most observational studies were cross-sectional online surveys of a target population at a single point in time. These study designs are at moderate/high risk of bias and thus, are considered medium-low quality depending on the sample size and whether the sample represents the target population as well as how well the survey tool can measure the outcome(s) of interest (e.g., was it informed by formative research, validated and pretested prior to implementation). For most of the included studies the outcomes are self-reported, which can be biased by response and social desirability biases. Other biases considered in these studies include response rate and missing data. Most studies captured in this rapid review did not report and/or account for one or more of the criteria listed above either due to conduct or reporting of the study. While there are many studies that show similar trends, the conclusions could change with additional research, larger sample size, different sampling strategies, data collection tools, and progression through the pandemic.

A key knowledge gap in this research are studies that address vaccine intentions and reasons for hesitancy and refusal rates in high-risk and unserved populations. The majority of studies used online surveys, and to a lesser extent telephone surveys, which may limit segments of population due to lack of access. Although the vaccine rollout has been underway for over half a year, there have been minimal studies released on vaccine refusal and the knowledge and attitudes associated with actually rejecting or accepting a vaccine. This information is crucial to determine why people are accepting or refusing vaccinations to continue developing strategies to encourage vaccine uptake in those who are hesitant.

CONTENTS

COVID-19 VACCINE UPTAKE

Vaccine uptake and factors associated with uptake in health-care workers (HCWs) was evaluated in one study (10). Only studies where it is has been established or can be inferred that the entire group was offered a vaccine prior to measuring uptake were included. This includes studies from the beginning of the vaccine rollout (December 2020 onwards). High level points are listed below and detailed outcomes for each study are located in the Appendix (Table 1).

- In a December survey conducted in Montreal, Canada, 80.9% of HCWs offered a vaccine accepted and 19.1% refused. 74.1% of those that declined a vaccine reported they will accept a vaccine in the future with 53.2% wanting to delay a few months and 31.9% wanting to wait a year (10). The most common reasons for refusal were the newness of the vaccine (82%), preference that others get vaccinated first (77%), felt they lacked information about the vaccine (74%), and that they did not have enough time to make a decision (60%) (10).
- Vaccine uptake was positively associated with increasing age and male gender (10).
- These trends are similar to those reported in the global literature (11) and mirror the trends seen in intention to vaccinate.

COVID-19 VACCINE ATTITUDES OF THE GENERAL PUBLIC

The majority of research on COVID-19 vaccine attitudes has been conducted on the general public. Forty-five studies were specific to the Canadian population, of which 29 were unpublished and three were preprints. High level points from January 2021 onwards are listed below and detailed outcomes for each study are located in the Appendix (Table 2).

Intentions to Vaccinate

- According to the most recent Canadian studies from June-July 2021, intention to vaccinate is between 84-91% (1, 8, 12, 13). Alberta and Saskatchewan populations currently have the lowest intentions to vaccinate (3, 8, 12-14).
- Three longitudinal studies demonstrate that intention to vaccinate continues to rise in Canada from baselines measured between September-December 2020 (8, 12, 15).
- In June, 89% of Canadians who had one dose reported they intend to receive a second dose, 9% have already had their second dose, 1% probably will not, and 1% were unsure (12).

- Vaccine hesitancy dropped dramatically in Alberta from 45% in January to 25% in April to 17% in May (16).
- 71% of youth aged 12-17 intended to receive a vaccine in a survey conducted in January-February 2021 (17).
- There has been one study conducted in 2021 (May-June) exploring the relationship between ethnicity/race and intention to vaccinate (5). 21% of Canadians were vaccine hesitant with higher levels among Black (33%) and non-Black visible minorities (25%) compared to Whites (19%). Black Canadians aged 25-34 had the highest levels of vaccine hesitancy (54%). Drivers of vaccine hesitancy among Black Canadians were the ability to take paid time off, concern that vaccines cause autism, and vaccine safety concerns (5).
- Five studies conducted in 2020 demonstrated that compared to White ethnicity, visible minorities are less likely to accept a vaccine (18-22).
- Intention to vaccinate among Indigenous respondents ranged between 68-71% in two studies conducted in March 2021 (23, 24). In one of the studies, 74.2% of First Nations living off reserve were willing to vaccinate compared to 67.8% of Métis and 72.5% of Inuit (23). Older Indigenous people (65+) were more likely to want a vaccine compared to younger individuals (74.9% vs 71.3%) (23).
- Those having Indigenous status in Saskatchewan were more vaccine hesitant compared to non-Indigenous status (RRR 1.65, 95% CI: 1.01-2.70) (4).
- In Canada, those who voted Liberal or NDP in the 2019 election were more likely to indicate the intention to vaccinate compared to those who voted for other parties (25-28).
- Rural participants were less likely to accept a vaccine compared to urban and suburban participants in three studies (12, 29, 30).
- Men were more likely to intend to vaccinate than women across 12 studies (17, 18, 20, 22, 25, 31-37).
- The most common factors positively associated with intention to vaccinate were older age, higher education, adequate knowledge or health literacy, trust in experts and government, higher socioeconomic status, history of receiving an influenza vaccine, and heightened worry or concern about COVID-19.
- Concerns about vaccine safety and effectiveness were the two most cited reasons for vaccine refusal. Other commonly cited reasons include newness of the vaccine, and the belief that a COVID-19 vaccine is unnecessary.
- A recommendation to get the vaccine by a healthcare provider (e.g., doctor) had a positive impact on vaccine intention in five studies (15, 22, 24, 38, 39).
- Conspiracy beliefs were associated with decreased intentions to vaccinate (26, 33, 40, 41).

Vaccine Preferences

- 48% of Canadians were uncomfortable about receiving a different brand of vaccine as their second dose, whereas 46% were comfortable and 6% were unsure. Of those who received AstraZeneca as

their first dose, 50% preferred to receive AZ as their second dose, 32% preferred another brand as their second dose, and 18% were unsure (12).

- A study in May 2021 demonstrated that most felt comfortable with the Pfizer (93%) and Moderna (89%) vaccines while less were comfortable with Johnson and Johnson (49%) and AstraZeneca (35%) vaccines. Women and those aged 55+ were more uncomfortable with the AstraZeneca (AZ) and Johnson and Johnson (J&J) vaccines compared to men and those <55. Of those who were uncomfortable with the AZ and J&J vaccines, 40% of women and 31% of men reported they would still accept these vaccines if offered (16).

Incentives to Vaccinate

- Financial incentives (monetary, vouchers, complimentary items, draws for prizes, discounts) were not reported to increase the likelihood of accepting a vaccine in a study conducted in Manitoba (between 7-84% of respondents stating the incentive would not make them more likely to vaccinate). However, 70% would be concerned if only vaccine hesitant individuals received large ($50-100) incentives (42).
- A second survey conducted across Canada demonstrated that 50% of respondents supported vaccine incentives such as lotteries, 36% opposed incentives, and 14% were unsure. Support for incentives was highest in Quebec and among those aged 18-34 and lowest among those aged 55+ and rural residents (6).

Vaccine Attitudes

- Vaccine passports have high support in Quebec with 72-73% of residents in favor (9, 43).
- 61% of respondents now agree that Canada should have vaccine passport, an increase from 54% in April (44).
- Four studies demonstrated high support for showing proof of vaccination when traveling by plane (71-82%), events with large crowds (67-75%), attending in-person university (71%) and lower support for showing proof of vaccination to stay in a hotel (68%), go to work (55-68%), or go to public places such as restaurants, bars, and movie theatres (35-64%) (6, 8, 9, 45).
- Of those who were vaccine hesitant, 7-18% of respondents across two surveys reported they could be swayed by the ability to travel, attend sporting or cultural events, or visit loved ones (11%) (45, 46).
- Of those who received an AstraZeneca vaccine, 2% fully regret getting it and 66% have serious second thoughts or doubts (16).
- 66% of Canadians wanted full vaccination (two doses) as a requirement to allow people to cross the USA-Canada border (6). Another survey indicated that 69% wanted to wait until at least 75% of Canadians were fully vaccinated before opening the Canada-USA border (7).
- Support for mandatory vaccination was 53% for the general population and 81% for healthcare workers. The highest support was demonstrated among those aged 55+ (6).
- 51-55% believed that Canada has done a good job procuring vaccine doses (13, 29).
- 71% of respondents were comfortable with how the Manitoba government was determining priority groups for early vaccination in January 2021 (47).

- Approval of the overall vaccine rollout in Alberta was split, 48% were satisfied and 43% were dissatisfied in study conducted in January 2021. For the order of priority groups established by the government, 64% were satisfied and 28% were dissatisfied (48).
- There is currently no evidence on attitudes or interest in a booster or third dose of the vaccine.

Post-Vaccine Behaviors

- 76% of those who were unwilling or unsure about vaccination were planning on resuming everything they did before with no hesitation compared to 34% of those with their first dose or 27% with both doses (8).
- 53% of respondents agreed that people vaccinated against COVID-19 should be able to gather and no longer wear masks in public, 41% disagree, and 6% did not know (9).

COVID-19 VACCINE ATTITUDES OF HEALTHCARE WORKERS

Evidence on COVID-19 vaccine attitudes of healthcare workers (HCWs) was identified in seven studies. All studies targeted HCWs including nurses, doctors, and personal support workers. The most recent studies were conducted in January 2021. High level points are listed below and detailed outcomes for each study are located in the Appendix (Table 3).

- The two most recent studies conducted in January 2021 showed that intention to vaccinate in HCWs ranged between 80-82% (49, 50).
- A participants' acceptance or rejection of a COVID-19 vaccine was not different between those employed within the healthcare sector compared to those not in the healthcare sector in one study (32).
- Three studies demonstrated that male HCWs are more likely to intend to vaccinate than female HCWs (19, 32, 50).
- The proportion of those likely to get the COVID-19 vaccine was directly related to older age (19, 32, 49, 50), the likelihood of receiving an influenza vaccine (19, 50, 51), higher education (49), and an individuals' perceived risk of COVID-19 infection (50).
- The main concerns about vaccination include safety, efficacy, insufficient knowledge about the vaccine, side-effects, speed of vaccination development, and believing that vaccination was not necessary (19, 32, 49-51).
- A study of social service employees supporting individuals with intellectual disabilities in Ontario found that Indigenous, First Nations, and Metis (aOR 1.73, 95% CI: 0.67- 4.43), Latin (aOR 1.22, 95% CI: 0.21-7.24), and mixed ethnicities (aOR 1.11, 95% CI: 0.27-4.55) were more likely to refuse a vaccine compared to European ethnicity (50).
- In a study of 8634 non-physician HCWs in Ontario, 80.4% stated they intend to vaccinate. HCWs were more likely to intend to vaccinate if direct financial supports such as paid sick days were provided (49). Those who identified as Filipino (OR 1.07, 95% CI: 0.41-2.76, P<0.001), Caribbean (OR 3.20, 95% CI: 1.52-6.75, P<0.001), or other (OR 1.44, 95% CI: 0.93-2.22, P<0.001) ethnicity were more likely to refuse a vaccine compared to those who identified as European (49).

- In a 2020 study of personal support workers, 64.2% of respondents intend to vaccinate when it is available, 16.2% refuse to vaccinate, 10.7% are unsure, and 8.9% will only take the vaccine if it's mandatory. The majority (71.7%) do not believe there is enough clear education on the vaccine (52).

COVID-19 VACCINE ATTITUDES OF HIGH-RISK POPULATIONS

It is important to develop evidence-based strategies to target high-risk populations for vaccination. This includes older individuals, those with substance use disorders, those who are pregnant or breastfeeding, people experiencing homelessness, and vulnerable communities. One study was identified on COVID-19 vaccine attitudes in older adults conducted in May 2020. High level points are listed below and detailed outcomes for the study are located in the Appendix (Table 4).

- There is a severe lack of evidence on high risk populations in Canada. Previous versions of this report included studies on high risk populations from the other Five Eye countries (Australia, New Zealand, UK, USA) to complement the lack of Canadian studies (11).
- Intention to vaccinate was high (79.5%) in one study conducted in May 2020 looking at older adults (65+) (35).
- Willingness to receive a COVID-19 vaccination was positively associated with male gender and having at least one chronic condition ($P<0.05$) (35).

COVID-19 VACCINE ATTITUDES OF LGBTQ+ INDIVIDUALS

Four studies were identified on COVID-19 vaccine attitudes in LGBTQ+ individuals. All four studies were conducted between August-December 2020, prior to vaccine rollout. High level points are listed below and detailed outcomes for the studies are located in the Appendix (Table 5).

- Four studies demonstrated that LGBTQ2+ were more willing to accept a vaccine compared to non-LGBTQ2+ (20, 22, 37, 53).
- LGBTQ2+ individuals were 6-11% more willing to accept a vaccine compared to non-LGBTQ2+ (20, 53). The third study from British Columbia indicated that non-binary, pansexual, gender queer, agender, two-spirit or other were significantly more likely (OR 3.04, 95% CI: 1.08-8.55, $P<0.04$) to receive a vaccine compared to heterosexual women (22).

COVID-19 VACCINE ATTITUDES OF PARENTS

Vaccine attitudes in parents were explored in seven studies. Three of the studies were conducted in the first half of 2021 and the remaining three in 2020. High level points are listed below and detailed outcomes for the studies are located in the Appendix (Table 6).

- Two studies reported parents were more willing to accept a COVID-19 vaccine for themselves than for their children (54, 55).

- A longitudinal study in Quebec revealed that 87% of parents intend to vaccinate their children, up 1% from June (1).
- In a survey conducted in May 2021 of 70 parents or guardians of children aged 12-17, 15% were not sure if they would vaccinate their children, and 13% would not vaccinate their children (42).
- A study of 380 parents with children aged 2-17 in Montreal revealed that parents were 61% very likely, 25% somewhat likely, 9.2% somewhat unlikely, and 4.5% very unlikely to have their child vaccinated. Visible minority parents were more likely to reject a vaccine for their children compared to non-visible minority parents (32.9% vs. 9.5%) (56).
- Parental and child vaccine intentions are highly correlated with each other, with parents who were intending to take a vaccine more likely to intend to vaccinate their children (42, 54). Similar to the general population, parents from lower-income households (42, 57), who are younger (58), less educated (57), and have a history of not accepting other vaccines (57, 58) were less likely to intend to vaccinate their children.

COVID-19 VACCINE ATTITUDES OF IMMIGRANTS

Evidence on COVID-19 vaccine attitudes of immigrants was identified in six studies. Two were conducted in 2020 and four in 2021. High level points from 2021 studies are listed below and detailed outcomes are located in the Appendix (Table 7).

- Vaccine hesitancy was higher amongst Black and non-Black Canadians born in Canada compared to those born outside of Canada (5).
- Non-permanent residents were more unlikely to vaccinate (11%) compared to non-immigrants (5%), immigrants living in Canada for more than 10 years (4%), and among immigrants living in Canada for less than 10 years (3%) (3).
- A study conducted in Saskatchewan revealed those who were born outside of Canada and living in Canada less than 20 years were more vaccine hesitant compared to those born in Canada (RRR 3.14, 95% CI: 1.56-6.34) (4).

COVID-19 VACCINE ATTITUDES OF INDIVIDUALS WITH COMORBIDITIES

One study with evidence on COVID-19 vaccine attitudes in individuals with comorbidities in Canada was identified. High level points from this study with evidence from October 2020 are listed below and detailed outcomes for this study are located in the Appendix (Table 8).

- There is a severe lack of evidence on individuals with comorbidities in Canada. There was a range of comorbidities found in literature from the other Five Eye countries (Australia, New Zealand, UK, USA) including obesity, hypertension, chronic respiratory or autoimmune diseases, HIV, and intellectual and developmental disabilities. Previous versions of this report can be accessed for more information on these populations to complement the lack of Canadian studies (11).

- In October 2020, 64.6% of those who are overweight or obese were comfortable receiving a vaccine and 35.4% were hesitant (55). Comfort levels in receiving the vaccine were positively associated with male gender, having more comorbidities, having lower depression scores, not practicing physical distancing, and past acceptance of influenza vaccinations (55).

COVID-19 VACCINE ATTITUDES IN CANADA COMPARED TO THE GLOBAL POPULATION

The comparison of COVID-19 vaccine attitudes in the general population across different countries around the world was reported in six articles. Only studies that included Canada and reported outcomes by country were included. The most recent studies were conducted in January 2021. High level points from the most recent studies are listed below and detailed outcomes for all other studies are located in the Appendix (Table 9).

- As of January, countries with the highest intentions to vaccinate (63-77%) included the UK, Denmark, and the Netherlands. Intention to vaccinate in Canada was 55% (59).
- Increases in intention to vaccinate between November and January were seen in Spain (24.1%), UK (23.2%), Sweden (22.7%), Finland (20.4%), Netherlands (18.5%), Italy (15.4%), Norway (14.6%), France (14.2%), Denmark (13.3%), Germany (13.0%), Canada (11%), and Japan (0.8%) (59).
- In 11/15 countries there was a significant decrease in the proportion of individuals who reported concern about the side-effects of a vaccine. In Canada, this worry decreased from 53.3% in November to 47.9% in January (59).

Methods

Prior to the initiation of this rapid review, a pre-defined rapid review protocol was developed to ensure the methods were reproducible, transparent, and consistent. The protocol is available upon request. This rapid review will be kept evergreen and updates will contain key research articles published up to the latest search date.

Publications and Pre-prints

A daily scan of the literature (published and pre-published) is conducted by the Knowledge Synthesis team in the Emerging Science Group, Public Health Agency of Canada. The scan has compiled COVID-19 literature since the beginning of the outbreak and is updated daily. Searches to retrieve relevant COVID-19 literature are conducted in Pubmed, Scopus, BioRxiv, MedRxiv, ArXiv, SSRN, Research Square, and COVID-19 information centers run by Lancet, BMJ, Elsevier, Nature and Wiley. The cumulative scan results are maintained in a Refworks database and an excel list that can be searched. Details on this search strategy are available upon request. From this database and excel list, article titles and summaries will be systematically searched for the following key words: ("vaccin*" OR "immuni*") AND ("accept*" OR "hesitan*" OR "preference" OR "confidence" OR "intent*" OR "willing*" OR "readiness" OR "behavio*" OR "knowledge" OR "attitude*" OR

"belief*" OR "believe*" OR "perception" OR "influence*" OR "reject*" OR "refus*" OR "oppos*" OR "consent*" OR "fear" OR "motiv*" OR "anti vax*" OR "antivax*" OR "trust*" OR "mistrust*" OR "anti vaccin*" OR "pro vaccine*" OR "provax*" OR "pro vax" OR "decision*" OR "decid*" OR "uptake"). The original search was conducted on October 16, 2020. The first update was conducted on November 30, 2020, the second update on January 5, 2021, the third on February 3, 2021, the fourth on March 2, 2021, the fifth on April 2, 2021, the sixth on May 3, 2021, the seventh on June 3, 2021, the eighth on July 2, 2021, and the ninth on August 4, 2021.

Grey Literature

A grey literature search was conducted to compliment the database search. In prior versions the grey literature search was extended to include research from Australia, New Zealand, the United States, and the United Kingdom. The grey literature search is now exclusively focused on Canadian research. A detailed list of websites searched is available in the protocol. The original grey literature search was conducted on November 5-6, 2020. The first updated grey literature search was conducted on December 9-10, 2020, the second on January 4, 2021, the third on February 1-2, 2021, the fourth on March 7, 2021, the fifth on April 13-22, 2021, the sixth on May 3-7, 2021, the seventh on June 9-11, 2021, the eighth on July 28-30, 2021, and the ninth on July 27-30, 2021.

Quality of Survey Instrument

Three criteria which determine the quality of the survey instrument were reported. These include the availability of the survey tool in the report, the use of formative research to design the survey, and evidence of pre-testing the survey. A yes or no was provided for each criteria. If the information was not reported, the answer no was selected. These criteria evaluate the degree to which the survey items evaluate the theoretical concepts the survey is focused on, are comparable to other surveys and whether the instrument was comprehensive, clear and valid when applied to the target population. There is an increased risk of bias when these features are missing (60).

Peer-review

This document underwent peer-review by a subject matter expert, and editorial and science to policy review by the Office of the Chief Science Officer.

Prepared by: Tricia Corrin and Austyn Baumeister, NML, Emerging Science Group, PHAC.

APPENDIX: EVIDENCE TABLES

VACCINE UPTAKE

Table 1. Evidence of vaccine uptake (n=1)

STUDY	METHODS & SURVEY TOOLS	KEY KAB OUTCOMES
VACCINE UPTAKE		
HEALTHCARE WORKERS		
Dzieciolowska (2021) (10) Cross-sectional study Canada Dec 2020	Vaccine uptake was evaluated through an online survey in 2,761 nurses, physicians, orderlies, hospital administration working in 17 health institutions in Montreal to determine factors that are predictive on uptake. All HCWs were offered a vaccine. Question Topics: 1) Vaccine uptake 2) Vaccine hesitancy	• 80.9% of those offered a vaccine accepted and 19.1% refused. • Multivariate analysis revealed that men (aOR 1.62, 95% CI: 1.16-2.26), those aged 50-59 (aOR 1.62, 95% CI: 1.07-2.44) or 60+ (aOR 3.28, 95% CI: 1.74-6.18), had occupational contact with COVID-19 patients (aOR 3.88, 95% CI: 2.29-6.58), or worked in rehabilitation centers (aOR 1.76, 95% CI: 1.17-2.66) were more likely take a vaccine when offered. • The most common concerns or reasons for refusal among those who did not accept a vaccine were the newness of the vaccine (82%), preferred that others get vaccinated first (77%),

	Survey tools available? Yes Formative research conducted? No Survey pre-tested? No	felt they lacked information about the vaccine (74%), and that they did not have enough time to make a decision (60%). • 74.1% of those that declined a vaccine reported they will accept a vaccine in the future with 53.2% wanting to delay a few months and 31.9% wanting to wait a year. • Those who never plan on accepting a vaccine were more likely to cite not trusting experts or pharmaceutical companies, preferring natural immunity, belief that the risk of vaccination outweighed risk of COVID, or that they had a past poor vaccine reaction.

CANADIAN GENERAL POPULATION

Table 2. Evidence of vaccine attitudes of the general public (n=45)

STUDY	METHODS & SURVEY TOOLS	KEY KAB OUTCOMES
Longitudinal studies (n=9)		
Leger (2021) *unpublished* (6, 12, 44, 61-67) Longitudinal study Canada & USA Nov 2020 & Jan-Jul 2021	An online survey of Canadian and American adults (18+) was conducted to evaluate vaccine perceptions and intentions to vaccinate. Wave 1: Nov 2020, 1516 Canadians and 1002 Americans Wave 2: Jan 2021, 1516 Canadians and 1003 Americans Wave 3: Feb 2021, 1535 Canadians and 1002 Americans Wave 4: Feb 2021, 1,532 Canadians and 1002 Americans Wave 5: Apr 2021, 1,504 Canadians and 1,002 Americans Wave 6: Apr 2021, 1,548 Canadians and 1,003 Americans Wave 7: May 2021, 1,529 Canadians, 1,003 Americans	**Wave 14** • In a July 2021 survey, 66% of Canadians want full vaccination (two doses) as a requirement to allow people to cross the USA-Canada border. • 50% of respondents supported vaccine incentives such as lotteries, 36% opposed incentives, and 14% did not know. • Support for incentives was highest in QC and among those aged 18-34 and lowest among those aged 55+ and rural residents. • Most (66%) Canadians believed that those who are medically able to be vaccinated have a responsibly to be vaccinated and should have greater freedoms than those who do not get vaccinated, whereas 26% believe that it would be unfair to place restrictions on the unvaccinated even if medically able to get vaccinated. • 53% think COVID-19 vaccines should be mandatory with the highest support among those aged 55+ and lowest in AB and those aged 18-34.

	Wave 8: May 2021, 1,529 Canadians, 1,003 Americans Wave 9: May 2021, 1,624 Canadians and 1,002 Americans. Wave 10: May 2021, 1,624 Canadians and 1,002 Americans. Wave 11: June 2021, 1,539 Canadians, 1,004 Americans Wave 12: June 2021, 1,542 Canadians and 1,001 Americans Wave 13: July 2021, 1,518 Canadians, 1,003 Americans *new* Wave 14: July 2021, 1,529 Canadians, 1,001 Americans *new* Question Topics: 1) Vaccine intentions 2) Vaccine perceptions Survey tools available? No Formative research conducted? No Survey pre-tested? No	• Most respondents feel comfortable going to outdoor gatherings (73%), eating on patios (72%), going to outdoor shows or sporting events (65%), going to work (56%), indoor gatherings with family/friends (55%), and eating in a dining room of a restaurant (51%) with the possibility of unvaccinated persons present. • Fewer respondents were comfortable going to in person class (48%), going to spas (47%), going to the cinema (45%), indoors shows or sports (41%), using public transit (40%), the gym (38%), fly on an airplane (37%), or go to a bar/nightclub (32%) with unvaccinated persons. • 81% respondents support mandatory vaccination for healthcare professionals or hospital employees with highest support among QC residents and those aged 55+. • 71% want vaccine passports for air travel. • 35% would like a vaccine passport required for patio/terrace dining. • In general, 58% of support vaccine passports for essential and non-essential activities, 30% disagreed, and 13% did not know. **Wave 13** • 76% were either very or somewhat confident that vaccination will protect against variants including Delta with 9% not confident at all and 13% not very confident. • Confidence in the vaccine as protection against variants is highest among those aged 55+ and suburban residents. • The groups with lowest confidence in vaccines as protection against variants are those residing in AB, aged 35 to 64, and living in rural areas. **Wave 12** • Canadians intention to be vaccinated or who have been vaccinated increased to 88% from May. • The percentage of those who did not intend to vaccinate was highest in MB and SK (18%)

		followed by AB (16%), among those aged 18-34 (14%, decreased from 18% at last polling), and among rural residents (16%, decreased from 22% at last polling). • Belief that vaccines are dangerous stayed at 7% since May (81% believe vaccines are safe and 12% do not know). **Wave 11** • Canadians intention to be vaccinated or who have been vaccinated held steady at 86% (no change from May). • The percentage of those who did not intend to vaccinate was highest in AB (20%) followed by Atlantic Provinces (19%), among those aged 18-34 (18%), and among rural residents (22%). • 89% certainly or probably will receive a second dose, 1% probably will not, 9% already have received a second dose, and 1% were unsure. • 3% of those who reside in QC and 3% of those aged 18-24 indicated they either probably will not or certainly will not get a second dose. • 48% of Canadians were uncomfortable about receiving a different brand of vaccine as their second dose whereas 46% were comfortable and 6% were unsure. • Those in MB/SK (34%), those aged 35 to 55 (25%), and rural residents (26%) had the highest levels of not being comfortable with a different vaccine as a second dose. • 50% of those who had a first dose of Astra-Zeneca would prefer getting a second dose of Astra-Zeneca compared to 32% who would like a second dose of another brand, and 18% who did not know. • Belief that vaccines are dangerous increased 1% to 7% since May (82% believed vaccines are safe and 11% did not know). **Wave 10**

		• Canadians were split 50-50 on whether they were comfortable if some of their colleagues were not vaccinated. • Discomfort with unvaccinated coworkers was highest in BC (62%) and 60% of Atlantic Canada and MB/SK were comfortable. • Older (55+) Canadians were less comfortable with unvaccinated coworkers (52% uncomfortable) along with urban residents (53% uncomfortable) compared to rural residents (44% uncomfortable). **Wave 9** • 51% of respondents felt the vaccine campaign in their province was proceeding about the same as other provinces. QC residents felt they were doing better than other provinces whereas ON and AB felt vaccinations were slower. • Canadians had high support for showing proof of vaccination when traveling by plane (82%), attending events with large crowds (75%), attending in-person university (71%) and had lower support for going to their place of work (68%), staying in a hotel (68%), and dining in a restaurant (64%). Support for showing vaccination was consistently higher among those aged 55+. • Since earlier polling in May there was a 4% increase (to 86%) of those who had been vaccinated or intended to get a vaccine. • Provinces with the highest combined level of vaccination or intention to get a vaccine was in QC (90%), followed by AB (87%), Atlantic provinces (86%), BC (85%), and MB/SK (84%). • Belief that vaccines are safe and should be given has stayed steady at 81% but those who did not know increased 1% to 12%. • Waves 1-8 summarized in previous versions of this report.
Angus Reid (2021)	Vaccine intentions and perceptions were analyzed in Canadian adults (18+) using an online survey.	**Wave 12** • In a July 2021 survey, 69% of Canadians wanted to wait until at least 75% of Canadians were fully

unpublished (7, 8, 13, 16, 23, 24, 27, 28, 31, 68, 69) Longitudinal study Canada Jul, Sept, Dec 2020 & Jan-Feb and May-Jul 2021	Wave 1: Jul 2020, n=1519 Wave 2: Sep 2020, n=1660 Wave 3: Dec 2020, n=1603 Wave 4: Jan 2021, n=1580 Wave 5: Feb 2021, n=1201 Wave 6: Mar 2021, n=1748 Wave 7: Apr 2021, n=NR Wave 8: Apr 2021, n=1594 Wave 9: May 2011, n= 1,319 Wave 10: June 2021, n=4,948 Wave 11: July 2021, n= 2,040 *new* Wave 12: July 2021, n= 2,040 *new* Question Topics: 1) Vaccine intentions 2) Vaccine perceptions 3) Vaccine hesitancy Survey tools available? Yes Formative research conducted? No Survey pre-tested? No	vaccinated before opening the Canada-USA border, 38% would be okay with 50% of Canadians being vaccinated, and 22% say right away. • 53% of respondents reported they were not concerned about becoming sick but 9% reported they would feel less worried if 70% of eligible Canadians were vaccinated. • 54% felt the timing was right to remove the requirement for 2 weeks of isolation for returning double vaccinated Canadians, 25% felt it was too soon, and 21% felt it took too long. **Wave 11** • 86% of respondents reported they would get vaccinated right away or have had at least one dose, up 2% from June. • 8% would not get vaccinated down 1% since June. • Levels of those who are uncertain or would like to eventually get vaccinated but want to wait remained steady from last polling at 3%. • AB continued to lead the way in the levels of unwillingness to vaccinate at 22%, an increase of 5% since May. The next highest provinces are SK and MB both at 15% unwilling. • 52.9% of the 315 respondents who received a different brand to their first dose felt total comfortable with receiving different brands, 26.5% were fairly comfortable, 18.9% were a little uncomfortable, and 3.8% are very uncomfortable. • 23% reported they were very likely to spend time with someone who is unvaccinated, 31% were pretty likely, 30% were unlikely, and 16% very unlikely. Those aged 18-24 were more likely to report being very likely to spend time with the unvaccinated. • 49% of respondents felt comfortable asking about others vaccination status, 22% felt it was not okay, and 29% felt it depended on who it was. Those who were unwilling or unsure about vaccination, those who voted Conservative in the past, and

		those who were younger were less comfortable with asking about vaccination status. • 76% of those who were unwilling or unsure about vaccination were planning on resuming everything they did before with no hesitation compared to 34% of those their first dose or 27% with both doses. • Vaccine passport requirements had generally high support for activities like boarding a plane (75%), international travel (75%), travel to the US (73%), attending events (67%), at work (61%), and public places like restaurants (59%). **Wave 10** • 84% have received at least one shot or will get vaccinated as soon as possible (an increase of 2% from May), 4% will get a vaccine but wish to wait (down from 6%), 9% will not get a vaccine (no change), and 3% were unsure (no change). • Vaccine hesitancy remains highest in AB and SK (18%). This has increased 1% in AB and decreased 6% in SK since May. • 57% of respondents would like equal emphasis on distributing first and second doses, 26% would prefer priority of getting all eligible first doses administered, and 16% would like the focus to be on second doses and circling back to first doses. Support for focusing on administering first doses was higher among those waiting for vaccination (39%) and among those aged 18-24 (40%). • Canadians are supportive of continuing vaccinations until everyone in Canada has been vaccinated (72%) with 18% wanting to shift focus to at risk populations globally and 10% were unsure. • Respondents felt the second dose vaccinations were progressing as well as could be expected (49%) with nearly equal split between feeling it was taking too long (27%) and that it was going at great pace (24%). 55% of QC residents felt that

		things were going great whereas 40% of ON residents felt things were moving too slowly. • 51% felt Canada has done a good job of securing vaccine doses and 41% felt it had been a poor job. However, 60% and 69% still had confidence that the federal and provincial government can manage vaccine distribution, respectively. **Wave 9** • 82% of respondents have either received a vaccine or wish to get a vaccine as soon as possible, up from 71% in April. • Fewer respondents report being unsure about vaccinations (3% down from 13%), wanting to wait before receiving a vaccination (6% down from 13%), or report not wanting a vaccine (9% down from 13%) compared to April responses. • 53% of respondents have received at least one dose, an increase of 36% since April. • Vaccine hesitancy is highest in SK (24%) with the level remaining stable (22% in April and 26% in January. • Vaccine hesitancy dropped dramatically in AB from 45% in January to 25% in April to 17% in May. • Hesitancy in BC, MB, ON, QC, and the Atlantic provinces varied between 10-12% in May. • Vaccine hesitancy was highest in males aged 35-54 (18%) followed in by females aged 18-34 (15%). • Of those that received an AstraZeneca, 2% fully regret getting it and 66% have serious second thoughts or doubts. • Canadians remain very comfortable with Pfizer and Moderna (93% and 89%, respectively) but became less confident in AstraZeneca (52% in April to 35% in May) and Janssen (54% to 49%). • Unvaccinated men are more comfortable than women to receive AstraZeneca (29% vs 36% extremely uncomfortable) however 40% women

		would take a vaccine they are uncomfortable with compared to 31% of men. • Wave 1-8 summarized in previous versions of this report.
Engage Manitoba (2021) *unpublished* (46, 70) Longitudinal study Canada Jan-Jun 2021	A series of online surveys in Manitoba were implemented to assess vaccine intentions within the Safely Restoring Services in Manitoba Survey. Survey 1: Jan 10-15, n=73,351 Survey 2: Feb 4-9, n= 33,687 Survey 3: Feb 25-Mar 2, n=26,909 Survey 4: Mar 18-23, n=31,776 Survey 5: Jun 4-8, n= 33,904 Question Topics: 1) Vaccine intentions 2) Vaccine perceptions Survey tools available? Yes Formative research conducted? No Survey pre-tested? No	**Survey 5** • 86% have received at least one dose of a vaccine (up from 9% in survey 4). • 2% have booked their first dose appointment, 2% will get the vaccine but are in no rush (down from 13%), 4% are unsure if they will get a vaccine (down from 12%), and 5% will not get a vaccine (down from 10%). • Of those who were not sure or do not intend to be vaccinated, very few would be swayed by the ability to travel within Canada (9%), attend sporting events or cultural events (7-9%), visit facilities or events (10%), or visit loved ones (11%). **Survey 4** • 9.0% of respondents have already received a vaccination (up 4% since survey 3). • 56% intend to sign up for a vaccination as soon as they are eligible (up 1.9%). • 13% report that they want a vaccine but are not in a rush (down from 16.2%). • 12% are unsure if they will get a vaccine when it's available (down from 14.2%). • 10% would refuse a vaccine (down from 10.5%). • Approval of the Manitoba governments approach to vaccinations is high in the latest survey with 33% strongly approving, 47% somewhat approving, 13% somewhat disapproving, 7% strongly disapproving.
INSPQ (2020), INSPQ (2021), INSPQ (2021), INSPQ (2021),	Analysis of the acceptability of vaccination against COVID-19 was evaluated using an online survey of adults and healthcare workers in	**July** • In a July 2021 survey, 91% of respondents have either had one or both doses of vaccines, 2% intend to vaccinate, and 7% have no intention.

INSPQ (2021), INSPQ (2021), INSPQ (2021), INSPQ (2021), INSPQ (2021) *unpublished* (1, 9, 29, 32-34, 40, 43, 71) Longitudinal study Canada Apr 2020 – Jun 2021	Quebec. Number of participants was not clearly stated (~3300 each collection period). There were multiple collection periods, one in Apr-May 2020, Sep and Dec 2020, Apr-Jul 2021 *new*. Articles in French. Question Topics: 1) Vaccine intentions 2) Vaccine hesitancy Survey tools available? No Formative research conducted? No Survey pre-tested? No	• Of the unvaccinated, 18% intend to vaccinate, 69% have no intention, and 13% were unsure. • Among the unvaccinated, those who had no intention to vaccinate were more likely to be women (70%), aged 25-34 (73%) and 35-44 (70%), those with secondary or less (72%), workers in a healthcare environment (87%), full time workers (76%), households with minors (78%), non-immigrants (72%), others as compared to French (70%), those in the highest deprivation quintile (72%), rural villages (72%), those not worried about getting COVID-19 (76%), those who do not always follow preventative measures (72%), have conspiratorial world views (74%), and never check social media on COVID-19 (74%) or check several times a day (73%). • The top reasons to not vaccinate were concern about side effects (21%) followed by fear of its newness (17%) and lack of confidence in vaccines in general (17%). • Agreement over whether the COVID-19 vaccine is danger free was not clear cut with 63% agreeing that it is danger free and 26% disagreeing. • 7% reported that vaccination is incompatible with their religious beliefs but was slightly higher among those aged 18-24 (10%), 25-34 (12%), 35-44 (10%), and those with no intention to vaccinate (38%). • 56% are concerned about vaccine effectiveness against variants whereas 39% are not, and 5% are not sure with little difference among those with different vaccine intentions. • 53% of respondents agreed that people vaccinated against COVID-19 should be able to gather and no longer wear masks in public, 41% disagree, and 6% did not know. • 75% were in support of vaccine passports for access to events and places. • 71% (1% increase from June) disagreed that given vaccination rates and cases it's less important to

		follow preventative measure whereas 27% agreed, and 3% did not know. • Outcomes on parental intention to vaccinate is located in Table 6. **June** • 49% agreed that vaccinated adults should be able to gather without masks in private, 44% disagreed, and 6% were unsure. • Almost half of respondents felt that vaccinated people should be able to gather without masks in private (49%) but also agree that masks should be worn outside with people they don't live with (56%). • Vaccine passports have high support with 72% in favour (23% disagreed and 4% were unsure). • 73% of respondents disagreed that it is important to follow protective measures based on the rate of vaccination and the decrease in COVID-19 cases. **May** • 74% of respondents who have not been vaccinated yet intend to get a vaccine, a 3% drop since late April. 18% do not intend to get a vaccine (a 4% increase), and 8% do not know (1% decrease). • Intention to vaccinate was lowest in those aged 25-34, women, those without secondary education, who were unemployed, more deprived, were not worried about getting COVID-19, those with conspiratorial views, and those who check social media once a week or less. • Households with minors had lower intentions to vaccinate compared to single person households, and households without minors. • Immigrants were more hesitant and unsure about receiving a vaccine compared to non-immigrants. • The top three reasons among those who were not intending to vaccinate included worry about side effects, lack of confidence in vaccines in general, and the newness of the vaccine.

		• 28% of those who do not intend to vaccinate believe that it is incompatible with their religious beliefs or personal principles. **Earlier** • 77% of respondents who have not been vaccinated yet intend to get a vaccine, a 1% drop since early April. 14% do not intend to get a vaccine (no change), and 9% do not know (1% increase). Intention has increased 7% since December. • Intention to get a vaccine was higher among men compared to women (78% vs 76%), older respondents (79% for those 60+ vs 75% for those 18-25), and among those with university degree (85% of those with university, 78% with college). • Intention to vaccinate generally increased as communities increased in size, from living in small villages less than 10,000 (71%), towns 10,000 to 100k (73%), greater Montreal area (81%) and Montreal (79%). • 68% disagree with the statement "people vaccinated against COVID-19 should have the right to have private gatherings and no longer wear a mask in public" whereas 25% agreed and 7% were unsure. • In December those with low intentions to vaccinate were concerned about side effects (27%), the newness of the vaccine (24%), and not trusting vaccines in general (24%). • Those holding conspiratorial world views were less likely to accept a vaccine (51% vs. 76%). • Agreement with compulsory vaccination continues to trend downwards with 54% agreeing in December.
Government of Manitoba (2021) *unpublished* (42)	An online research panel of 600 Manitobans were surveyed to understand attitudes towards vaccination and possible incentives to increase uptake.	• 87% have received a vaccine or intend to be vaccinated (74% received and 13% intend), and increase of 11% from April. • 5% will get a vaccine but were not in a rush (down from 12%), 5% were unsure if they will get a

Longitudinal study Canada May 2021	Question Topics: 1) Vaccine intentions 2) Vaccine perceptions Survey tools available? No Formative research conducted? No Survey pre-tested? No	vaccine (down from 7%), and 4% will not get a vaccine (down from 5%). • From April to June there was an 18% drop in the number of people strongly approving of Manitoba's vaccine distribution (42% to 24%), 49% somewhat approve (up from 43%), 17% somewhat disapprove (up from 11%), and 10% strongly disapprove (up from 4%). • 31% of respondents felt much more positive about COVID-19 vaccine now then when first introduced, 19% felt slightly more positive, 45% felt the same, 3% felt slightly more negative, and 2% felt much more negative. • 55% felt that whether they got the vaccine or not should be a choice, 42% felt that it should not be a choice, and 3% were unsure. • Those who would promote vaccination tended to be younger than 30 or over 65 and believed that adults should have all their regular vaccines. • The types of information that were the most likely to influence decision to vaccinate included information about possible side effects (42%), being able to choose the vaccine (42%), information about testing (41%), and information about how the vaccine works (36%). • The least persuasive type of information was hearing stories from celebrities who got their vaccine (90% unlikely to impact). • Women would be the most influenced by being able to choose the vaccine. • Residents of Winnipeg were more influenced than those in rural areas by getting a vaccine from a family doctor/pharmacist, speaking to their family doctor/pharmacist, having someone come to their home, and hearing stories from celebrities. • Manitobans were largely not swayed by community incentives such as being able to travel without having to isolate (50% no more likely to vaccinate), being able to visit long term care homes without restrictions (52% no more likely),

		entry into provinces or countries (48% no more likely), being able to attend large events (60% no more likely), attend larger gathering (54% no more likely), certain businesses/facilities to those that are vaccinated (61% no more likely). • Those aged 30 to 44 were more likely to be influenced by being able to attend larger gatherings (community, faith, or personal). • Financial incentives (monetary, vouchers, complimentary items, draws for prizes, discounts) were not reported to increase the likelihood of accepting a vaccine (between 75% and 84% stating they are not more likely by any financial incentive). • 70% of respondents were concerned if only hesitant individuals received large ($50-$100) incentives. • Outcomes on intention to vaccinate in parents can be located in Table 6.
Statistics Canada (2020) & Statistics Canada (2021) *unpublished* (17, 53, 72) Longitudinal study Canada Sep 2020 – Feb 2021	An online survey conducted by Statistics Canada as part of the Canadian Community Health Survey (CCHS) assessed Canadians behaviors to safeguard their own health as well as the health of others. In the September survey, a question about vaccine intentions was added. The most recent report captures 25,321,400 responses from individuals aged 12+. Question Topics: 1) Vaccine intentions Survey tools available? Yes Formative research conducted? Yes Survey pre-tested? Yes	**Jan-Feb 2021** • 82.3% of respondents were very or likely to get a COVID-19 vaccine. • Vaccine intention was highest in those over 65 years (88.1%) with a decreasing level of intention in those aged 12-17 (71.0%). • Vaccine intention was similar between males and females (82.8% vs 81.9%, respectively). **Sept-Dec 2020** • Over the sampling period 77% were willing to receive a vaccine. This represents an increase from Sept (75.5%) to Oct (74.8%), and Nov/Dec (80.3%). • Vaccine intentions were highest in Prince Edward Island (89.1%), Nova Scotia (81.5%), and British Columbia (81.4%). Vaccine intention was lowest in Prairie provinces (75.2%) • Men were more likely to vaccinate then women (77.9% vs 75.8%). • The highest intentions among visible minorities were Japanese (86.5%), Korean (85.6%), South Asian (82.5%), Chinese (79.3%), visible minority not indicated/multiple (79.1%), Southeast Asian

		(78.3%), West Asian (78.3%), Filipino (75.1%), Arab (68.1%), Latin American (66.0%), and Black (56.6%). Non-visible minority's intention to vaccinate was 77.6%. • Older visible minorities were more likely to vaccinate than those 12-64 (77.4% vs 74.6%). • Intention to vaccinate among Indigenous respondents was 71.8% which was significantly less than Non-Indigenous respondents (77.1%). 74.2% of First Nations living off reserve were willing to vaccinate compared to 67.8% of Métis and 72.5% of Inuit*. • Older Indigenous people (65+) were more likely to want a vaccine compared to younger (74.9% vs 71.3%). • Outcomes on intention to vaccinate in LGBTQ+ and immigrants can be located in Tables 5&7. *Use with caution. Coefficient of variation (CV) from 15.1% to 35.0%.
Impact Canada (2020) *unpublished* (15) Longitudinal study Canada Apr 2020 – Feb 2021	Vaccine confidence and hesitancy in the Canadian context was explored through the implementation of the World Health Organization (WHO) Behavioural Insights (BI) Tool on COVID-19 in eight waves of adults (18+) using the same participants where possible. Wave 1: n=2023, Wave 2: n=2,098, Wave 3: n=2,000, Wave 4: n=2,152, Wave 5: n=2,169, Wave 6: n=2,141 , Wave 7: n=2,129, Wave 8: n=2,117, Wave 9: n=2,055, Wave 10: n=2,125, Wave 11: n= 2,037 Question Topics: 1) Vaccine intentions 2) Vaccine perceptions 3) Vaccine hesitancy	**Wave 11** • Intention to get vaccinated right away has increased to 58% (up from 49% in wave 10). 24% intend to vaccinate but would like to wait, 9% would not vaccinate, and 8% were unsure. • Those who plan to wait are mostly like to want to wait 1 to 2 months (33%). • 68% have made up their mind if they will or will not get a vaccine and 25% need more information before deciding. • The two most common reasons for vaccine hesitancy included a lack of testing or research (26%) and belief that the vaccine was not safe (15%). • 47% report that getting the most effective vaccine is the most important criteria for selecting a vaccine, followed by the vaccine that is available first (15%), and fewest side effects (12%).

	Survey tools available? Yes Formative research conducted? Yes Survey pre-tested? No	• 56% and 22% would like more information regarding the safety and effectiveness of the vaccine, respectively. • A vaccine recommendation from a healthcare provider would likely influence 45% of respondents. **Wave 10** • Vaccine acceptance rose slightly from wave 9 (61%) to wave 10 (65%). • Intention to get vaccinated right away has increased to 49% (up from 43% in wave 9). 31% intend to vaccinate but would like to wait, 11% would not vaccinate, and 8% were unsure. • Of those wanting to wait for a vaccine, 42% wanted to wait several months (up from 27% in wave 9). • The top reasons for wanting to wait were to ensure safety (80%) and efficacy (64%). • Those who would decline a vaccine were asked about hypothetical incentives. 58% would like assurances that the vaccine would not be a risk for exposure to COVID-19, 56% wanted a convenient booking system, and 52% wanted a convenient location. • 56% of participants stated they would vaccinate to be able to return to work, travel, or attend large gatherings. • 63% reported that their mind was made up whether to vaccine or not and 32% would like more information before they decide.
Dubé (2021) (41) *new* Longitudinal study Canada	During the first and second wave of the pandemic vaccine attitudes and intentions, and preventative behaviours were assessed in a weekly web panel of 3300 Quebec residents. This is a formal analysis of the INSPQ study with some additional information.	• In 2020, the intention to vaccinate started at 74% in April and grew to 76% until May, dropped to 66% in September before rebounding to 73% in December. • In multivariate analysis intention to vaccinate was higher in men (aOR 1.80, 95% CI: 1.56-2.06), those with college (aOR 1.37, 95% CI: 1.17-1.60) or university (aOR 2.01, 95% CI: 1.66-2.43), having or

Apr 2020-Dec 2020	Question Topics: 1) Vaccine intentions 2) Vaccine hesitancy Survey tools available? Yes Formative research conducted? Yes Survey pre-tested? No	living with someone chronic medical conditions (aOR 1.39, 95% CI: 1.18-1.63), and those that are afraid (aOR 1.58, 95% CI: 1.32-1.89) or moderately afraid (aOR 1.51,95% CI: 1.26-1.82) of COVID-19. • Increasing age was associated with higher intentions to vaccine (age 18-24: aOR 1.86, 95% CI: 1.46-2.36, age 45-59: aOR 1.29, 95% CI: 1.08-1.53, age 60-69: aOR 2.14, 95% CI: 1.73-2.65, age 70+: aOR 3.44, 95% CI: 2.57-4.58) compared to those aged 25-44. • Those who were less deprived were more likely to intend to vaccinate compared to those in the most deprived quintile (Q1: aOR 1.53, 95% CI: 1.20-1.94, Q2: aOR 1.34, 95% CI: 1.06-1.68, Q3: aOR 1.25, 95% CI: 1.00-1.58). • Those without conspiratorial world views were more likely to vaccinate (aOR 2.68, 95% CI: 2.28-3.14) compared to those who hold conspiratorial world views.
Saskatchewan Population Health and Evaluation Research Unit (2020) *unpublished* (73) Longitudinal study Canada May-Sep 2020	An online survey was used to evaluate intention to vaccinate in residents of Saskatchewan over time. Surveys were conducted from May-Sep. The number of individuals is not stated and it is unclear if they are the same participants over time. Question Topics: 1) Vaccine intentions Survey tools available? No Formative research conducted? No Survey pre-tested? No	• From May to Sep, intention to vaccinate dropped from 84.9% to 56.5%. • Intention to vaccinate is highest in those 65-74 years of age and lowest in those under 48 years of age.
Cross-sectional studies (n=31)		
Independent Polling System of Society (IPSOS) (2021)	An online survey of 1000 Canadians (18+) analyzed perceptions about COVID-19 vaccination in the face of emerging variants.	• 62% of respondents felt that vaccination would help avoid a fourth wave in Canada however 69% were still worried about a potential fourth wave.

unpublished (74) *new* Cross-sectional study Canada Jul 2021	Question Topics: 1) Vaccine perceptions Survey tools available? No Formative research conducted? No Survey pre-tested? No	• Belief that vaccination would prevent a fourth wave was highest in BC (66%) followed by SK/MB (64%), ON (63%), QC (62%), ATL (61%), and AB (59%).
Innovative Research Group (2021) *new* *unpublished* (5) Cross-sectional study Canada May-Jun 2021	An online poll of 2,838 adults with a specific over sampling of Black Canadians (n=502) was conducted to evaluate COVID-19 vaccine intentions and hesitancy. Question Topics: 1) Vaccine intentions 2) Vaccine hesitancy Survey tools available? No Formative research conducted? No Survey pre-tested? No	• 21% of Canadians were vaccine hesitant with higher levels among Black Canadians (33%) and non-Black visible minorities (25%) compared to White Canadians (19%). • Vaccine intentions were highest among non-Black visible minorities (32%) followed by Black Canadians (22%), and White Canadians (16%). • 60% of respondents overall have been vaccinated (65% of White Canadians, 45% Black Canadians, and 43% non-Black visible minorities). • Of those who have not received a vaccine, 48% of White Canadians would get vaccinated compared to 40% of Black and 56% of non-Black Canadians. • 54% of 25-34 old Black Canadians were vaccine hesitant. • Vaccine hesitancy was higher amongst Black Canadians and Non-Black Canadians born in Canada than those born outside of Canada. • The top reasons for hesitancy were a lack of trust/not enough testing (29%) followed by side effects/safety concerns (26%) which mirrored the top concerns of Black Canadians (21% and 23% respectively). The most dissimilar responses were seen for don't want it/my choice (7% among Black Canadians and 2% among White) and mixed messages/rumours (10% among Black Canadians and 1% among White). • Factor analysis finds trust in healthcare providers and vaccine makers, having a university education, being older than 55, confidence in how to get

		vaccinated, being able to take paid time off to get vaccinated, being in Atlantic Canada, feeling at high risk for COVID-19, and being male drive vaccine confidence for Black Canadians. • Drivers of not getting vaccinated among Black Canadians are the ability to take paid time off if they get COVID-19, concern that vaccines cause autism, and vaccine safety concerns. • 78% of Black Canadians and non-Black minorities were confident they knew how to get a vaccine but only 39% of Black and 38% non-Black minorities agree that they can take paid time off to get a vaccine. • 20% of Black and 17% non-Black minorities either strongly or somewhat agree that vaccines may cause autism compared to 9% of White Canadians.
Angus Reid (2021) *unpublished* (45) Cross-sectional study Canada May 2021	1601 Canadian adults were surveyed about their thoughts on vaccination policies (proof of and vaccine passports) online. Question Topics: 1) Vaccine intentions 2) Vaccine perceptions 3) Vaccine hesitancy Survey tools available? Yes Formative research conducted? No Survey pre-tested? No	• 79% Canadians were supportive of showing proof of vaccination for international travel (excluding the US), 78% support it for commercial flights, and 76% were supportive for traveling to the USA. • Less support was shown for having proof of vaccination for attending large public events (69%), public places such as restaurants, bars, and movie theatres (55%), and at places of work (55%). • Those who were vaccine hesitant had much lower support for proof of vaccination across all presented scenarios. • 18% of those not willing to get a vaccine would be swayed to get vaccinated if proof of vaccination was required in many scenarios.
Muhajarine (2021) *preprint* (4) *new* Cross-sectional study Canada	9,252 responses collected from 7,265 Saskatchewan adults (18+) were enrolled from landlines and online to complete an online survey regarding vaccine acceptance and hesitancy. Question Topics: 1) Vaccine intentions	• 76.1% of respondents had either been vaccinated or were willing to get vaccinated, 13.3% were vaccine hesitant, and 10.6% had refused a vaccine. • In multivariate analysis vaccine hesitancy was associated with women (RRR 2.16, 95% CI: 1.57-2.99), those with less education (no formal /completed high school RRR 2.45, 95% CI: 1.65-3.62), born outside of Canada and lived in Canada less than 20 years (RRR 3.14, 95% CI: 1.56-6.34),

Apr-May 2021	2) Vaccine hesitancy Survey tools available? No Formative research conducted? No Survey pre-tested? No	having Indigenous status (RRR 1.65, 95% CI: 1.01-2.70), those with unsecure financial situations (RRR 2.2, 95% CI: 1.67-2.91), and those slightly/hardly concerned about COVID-19 (RRR 2.46, 95% CI: 1.6-3.78) compared to their counterparts. Similar trends were seen with vaccine refusal.
Leger (2021) *unpublished* (75) Cross-sectional study Canada Apr 2021	An online survey of 1004 participants in British Columbia was conducted to assess views on vaccines, vaccine passports, and vaccine rollout. Question Topics: 1) Vaccine intentions 2) Vaccine perceptions Survey tools available? No Formative research conducted? No Survey pre-tested? No	• 16% reported they had received a vaccine. • 49% intend to tell everyone they know when they receive a vaccine, especially for respondents in urban areas (53%) compared to rural (40%). Fewer respondents would only tell immediate family and friends (42%). • 24% intend to share when they get a vaccine on social media. • Most don't feel they should be vaccinated before others (27%), or are jealous (25%), or anxious (25%) of others being vaccinated. • Vaccine passports had high support in international travellers coming to BC (77%) and BC travellers going abroad (75%). Support for passports for Canadians traveling within Canada (68%) and within BC (56%) was slightly lower. • Vaccine passports for any situation had higher support among those 55+. • 70% are happy with the order of vaccination prioritization in BC and 44% are satisfied with the rollout. • Support for health figures or leaders has decreased since Dec 2020 (Dr. Bonnie Henry: 65%, Adrian Dix: 58%, Dr. Theresa Tam: 53%, Justin Trudeau: 45%).
Statistics Canada (2021) *unpublished* (3, 76) Cross-sectional study	Vaccine intentions and perceptions were analyzed in the second round COVID-19 Vaccination Coverage Survey (CVCS) involving Canadian adults (18+) in the provinces using mail invites and computer assisted telephone interviews for non-responses.	**Round 2** • Vaccine coverage from highest to lowest (at least one dose) was: SK (54%), QC (47%), BC (46%), AB (46%), ON (45%), NL (43%), MB (42%), NB (40%), NS (36%), and PE (33%). • The highest levels of those unlikely to vaccinate were in MB (8%), SK (7%), BC and AB (6%), ON, QC, NB, NS, PE, NL (5%).

Canada Mar-May 2021	<u>Round 1:</u> n= 1,025 capital cites of the territories <u>Round 2:</u> n= 10,678 in 10 provinces *new* Question Topics: 1) Vaccine intentions 2) Vaccine perceptions 3) Vaccine hesitancy Survey tools available? Yes Formative research conducted? Yes Survey pre-tested? Yes	• Intention to vaccinate was lowest among those aged 18-49 (7% unlikely to vaccinate) followed by 5% among those 50-49, and 3% among those 60+. • Men, those with less education, and those with smaller household incomes were less likely to intend to vaccinate. • The most common reasons for not getting a vaccine yet was not being in an age priority category (47%), not being able to get an appointment yet (13%), and not wanting to be vaccinated at this time (8%). • Among those not wanting to be vaccinated, the top reasons were lacking trust in the safety in the vaccine (45%) or effectiveness (30%), and not believing they are at high risk for COVID-19 (26%). • The top trusted sources for vaccine information were PHAC (84%), health scientists and researchers (70%), and provincial, territorial, regional health authorities (68%). • Outcomes for immigrants found in Table 7. **Round 1** • The majority of respondents had already received one dose (80%) with 16% likely to get vaccinated and few unlikely to get vaccinated (4%). • Respondents were more likely to have received a vaccine or were likely to be vaccinated if they has a post-secondary degree or higher (85% vs 68% for having received a vaccine and 13% vs 23% for likely to get vaccinated respectively). • 10% of those unlikely to be vaccinated had household income of less than $60,000 compared to 2% among those with incomes between $60,000 to more than $120,000. • Most felt vaccines were safe (95%) and effective (97%) compared to the COVID-19 vaccine which garnered lower support for safety (86%) and efficacy (88%). • 94% of respondents felt confident that Canada's process only approved safe and effective vaccines (94%).

		• Top sources for COVID-19 vaccination information were Public Health Agency of Canada and Health Canada (89%) and provincial, territorial or regional health authorities (85%).
Centre for Addiction and Mental Health (2021) *unpublished* (77) Cross-sectional study Canada Mar 2021	An online survey of 1000 Canadians as part of Asking Canadians web panel was conducted to measure mental health and vaccine intentions. Question Topics: 1) Vaccine intentions Survey tools available? No Formative research conducted? No Survey pre-tested? No	• 66.4% of respondents who haven't received a vaccine yet definitely intend to get one, 21.8% will probably get a vaccine, and 11.8% definitely or probably will not get a vaccine.
Tang (2021) *preprint* (14) Cross-sectional study Canada Jan-Mar 2021	To assess vaccination hesitancy in population subgroups in Canada, an online survey of 14,621 panel members from the nationally representative Angus Reid Forum was conducted. Question Topics: 1) Vaccine intentions 2) Vaccine hesitancy Survey tools available? No Formative research conducted? No Survey pre-tested? No	• Overall, 9.3% do not intend on receiving a vaccine. This was highest in AB (16.4%), MB & SK (13.8%) and lowest in QC (8.3%), the Atlantic provinces (8%), ON (7.8%), and BC (7.2%). • Vaccine hesitancy was significantly associated with those aged 40-59 years (OR 0.87, 95% CI: 0.78-0.97), being a visible minority (OR 0.56, 95% CI: 0.37-0.84), lower education, and belonging to a household of five or more people (OR 0.82, 95% CI: 0.76-0.88).
Syan (2021) *preprint* (36) Cross-sectional study	Factors associated with intention to receive a COVID-19 vaccine was assessed in 1,367 adults (18+) living in Southern Ontario using an online survey.	• 82.8% were willing to receive a vaccine and 17.2% were unwilling. • The most common reasons for vaccine hesitancy were concern over long-term (65.5%) and immediate (60.5%) side effects, and a lack of trust in the vaccine (55.2%).

Canada Jan – Feb 2021	Question Topics: 1) Vaccine intentions 2) Vaccine hesitancy 3) Vaccine attitudes Survey tools available? No Formative research conducted? No Survey pre-tested? No	• Higher intention to vaccinate was significantly associated with male gender (P=0.002) and higher education levels (P<0.001). • The perception of COVID-19 vaccine safety was significantly lower (-10.7%) than vaccines in general. Females, older adults, and those with less education reported lower perceived COVID-19 vaccine safety.
Leger (2021) *unpublished* (47) Cross-sectional study Canada Jan 2021	An online survey of 800 participants from Manitoba (18+) was conducted to investigate vaccine perceptions and intentions to vaccinate. Question Topics: 1) Vaccine intentions 2) Vaccine perceptions 3) Vaccine rollout perceptions Survey tools available? No Formative research conducted? No Survey pre-tested? No	• 72% reported the intention to vaccinate when a vaccine is available. • Intention to vaccinate increases with age. 82% of those aged 55+ reported they would definitely or probably intend to vaccinate compared to 65% of those aged 18-51. • Higher education and higher incomes are associated with an increased intention to vaccinate. • Vaccine safety is still a concern as 57% don't want to be in the first wave of people getting vaccinated and want to wait until safety has been established. 49% have concerns about safety but have generally pro-vaccine opinions. • >66% agree that the vaccine should be mandatory for all healthcare workers. • 71% of respondents are comfortable with how the Manitoba government is determining priority groups for early vaccination.
Leger (2021) *unpublished* (48) Cross-sectional study Canada Jan 2021	1000 residents of Alberta (18+) were surveyed online regarding their perceptions of the vaccine rollout. Question Topics: 1) Vaccine rollout perceptions Survey tools available? No Formative research conducted? No	• Approval of the overall vaccine rollout in Alberta was split, 48% were satisfied and 43% were dissatisfied. • For the order of priority groups established by the government, 64% were satisfied and 28% were dissatisfied. • 44% were satisfied with the government's communication of the rollout plan and 48% were not. • More individuals were dissatisfied (56%) with the pace of the rollout compared to satisfied (35%).

	Survey pre-tested? No	• 53% believe they will have the opportunity to receive a vaccine after September.
Insights West (2021) *unpublished* (78) Cross-sectional study Canada Jan 2021	Intention to vaccinate was analyzed using an online survey of 824 residents of British Columbia. Question Topics: 1) Vaccine intentions 2) Vaccine rollout perceptions Survey tools available? Yes Formative research conducted? No Survey pre-tested? No	• 58% of respondents were definitely willing to be vaccinated, 22% were probably willing, 5% probably will not get vaccinated, and 7% definitely will not. • 67% of older respondents (55+) were more likely to get vaccinated compared to those in younger age groups (52% among 18-34 year olds). • 69% felt that those with underlying conditions were should have been put ahead of others on the list. • When asked about the vaccine rollout plan, 5% rated the rollout as excellent, 30% good, 51% fair, 14% poor, and 7% very poor. Similar trends were seen for perceptions on clarity of the rollout and prioritization levels.
Afifi (2021) (79) Cross-sectional study Canada Nov-Dec 2020	Using survey respondents from the longitudinal Well-Being and Experiences study (2017-2020) vaccine intentions were recorded for Winnipeg adolescents aged 16-21 and their caregivers/parents using an online survey. Question Topics: 1) Vaccine intentions 2) Vaccine hesitancy Survey tools available? No Formative research conducted? No Survey pre-tested? No	• 65.4% of respondents intend to receive a vaccine, 26.1% were not sure, and 8.5% were not willing. • Parents with trade school, community college or less, with incomes of less than $49,999, experienced quite a bit COVID-19 financial strain, self-reported low knowledge of COVID-19 were associated with lower intentions to get a vaccine. • Having a self-reported health condition was associated with higher intentions to accept a vaccine. • After adjusting for sex, age and household income, children who had no experience with spanking (aRR 0.33, 95% CI: 0.17–0.62), no peer victimization (aRR 0.49, 95% CI: 0.25–0.96), no household substance abuse (aRR 0.41, 95% CI: 0.20–0.83), no contact with foster care/child protective office (aRR 0.34, 95% CI: 0.16–0.72), and no risk of their household running out of money (aRR 0.45 95% CI: 0.21–0.97) were more willing to get vaccinated. • Reporting no to any household challenge adverse childhood experience (ACE) was associated with willingness to vaccinate (aRR 0.45, 95% CI: 0.20–0.99).

		• The top concerns for being unwilling to accept a vaccine were for vaccine safety (64.5%), not knowing enough about the vaccine (60.6%), and not thinking the vaccine would be effective (23.4%).
Province of Manitoba (2020) *unpublished* (80) Cross-sectional study Canada Nov 2020	An online survey of 9872 adults in Manitoba was conducted to assess COVID-19 vaccine perceptions and intention to vaccinate. Question Topics: 1) Vaccine intentions 2) Vaccine perceptions Survey tools available? Yes Formative research conducted? No Survey pre-tested? No	• 55% and 19% of participants reported they definitely or probably will receive the COVID-19 vaccine when available, respectively. The other participants stated they were undecided (8%), probably would not (7%) or definitely would not (12%) take the vaccine. • 61% of participants agreed with the statement "Vaccines are safe and I have no doubts about vaccinating myself or my family, as recommended by my doctor".
Independent Polling System of Society (IPSOS)/Radio Canada (2020) *unpublished* (81) Cross-sectional study Canada Nov 2020	Intention to vaccinate and perceptions on the vaccine were analyzed using an online survey of 3001 adults (18+). Question Topics: 1) Vaccine intentions 2) Vaccine perceptions Survey tools available? No Formative research conducted? No Survey pre-tested? No	• 64% of participants would probably or certainly get vaccinated, 16% definitely would not, and 21% were unsure. • Of those who would be vaccinated, 36% would get vaccinated as soon as possible, 38% would wait one or two months to see what happens, 15% would wait several months, and 11% were undecided. • The majority of respondents were worried about possible side-effects and risks associated with the vaccine.
Independent Polling System of Society (2020) *unpublished* (38)	An online survey of 1001 adults (18+) analyzed intention to vaccinate and perceptions on the vaccine. Question Topics: 1) Vaccine intentions	• 52% of respondents would take a COVID-19 vaccine as possible without hesitation. However, when other options, 36% would take the vaccine waiting to see if there were adverse side-effects and 28% would after waiting to see if it's effective. • 13% of participants would refuse vaccination under any circumstance.

Cross-sectional study Canada Nov 2020	2) Vaccine perceptions 3) Vaccine hesitancy Survey tools available? No Formative research conducted? No Survey pre-tested? No	• 71% of participants say that taking a vaccine that was created and approved so quickly makes them nervous and 69% are concerned about long-term effects. • 59% of participants support mandatory COVID-19 vaccination, a drop from 61% in Sept, and 72% in July. • Some participants stated that a recommendation by a family doctor (21%), or seeing friends and family receive the vaccine (10%) would make them willing to take a vaccine. • Most agree that frontline healthcare workers (62%) and first-responders (52%) should be first in line to receive the vaccine. However, outside of these target groups, Canadians are divided on who should be a priority. • Three in ten (30%) believe that we can beat COVID-19 without a vaccine, down from 40% in Oct.
Racey (2021) (37) *new* Cross-sectional study Canada Aug-Nov 2020	5,076 public school teachers in British Columbia participated in an online survey regarding the likelihood of accepting a vaccine. Question Topics: 1) Vaccine intentions 2) Vaccine hesitancy Survey tools available? Yes Formative research conducted? Yes Survey pre-tested? Yes	• 89.7% of respondents were either likely or very likely to accept a COVID-19 vaccine, 4.6% were neutral, and 5.7% were either unlikely or very unlikely to accept a vaccine. • Indigenous status was not significantly associated with increased or decreased intentions. • Intention to vaccinate was positively associated with having a science/engineering educational background (aOR 1.36, 95% CI: 1.04-1.79), male gender (aOR 1.41, 95% CI: 1.07-1.88), viewing public health, school boards/teachers union, and healthcare providers as a reliable source of information (aOR 1.43, 95% CI: 1.12-1.83, aOR 1.51, 95% CI: 1.22-1.87, and aOR 1.51, 95% CI: 1.22-1.87 respectively), viewing healthcare providers as reliable sources of information (aOR 1.51, 95% CI: 1.22-1.87), higher vaccine knowledge (aOR 1.58 95% CI: 1.38-1.80), and viewing COVID-19 as a serious illness (aOR 5.79, 95% CI: 4.09-8.19). . • Intention to vaccinate was negatively associated with prior delay or refusal of vaccination (aOR 0.19,

		95% CI: 0.15-0.24), lack of confidence in vaccines and (aOR 0.5, 95% CI: 0.44-0.58) and perceived risk of vaccination (aOR 0.36, 95% CI: 0.31-0.42). • LGBTQ+ outcomes located in Table 5.
Independent Polling System of Society (2020) *unpublished* (82) Cross-sectional study Canada Oct 2020	An online survey of 1000 adults analyzed intention to vaccinate and perceptions on the vaccine. Of these, 1000 participants were Canadian. Question Topics: 1) Vaccine intentions 2) Vaccine perceptions 3) Vaccine hesitancy Survey tools available? No Formative research conducted? No Survey pre-tested? No	• 54% of Canadians would be willing to take a vaccine as soon as it is available. Atlantic Canada have the highest intentions (75%), followed by SK/MB (65%), QC (63%), BC (60%), AB (58%), and ON (57%). • 61% of participants support mandatory COVID-19 vaccination, a drop from 72% in July. • 82% indicate that they would wait for reports about the effectiveness or any side-effects of a COVID-19 vaccine before taking it. • The majority (88%) of participants agree that seniors and other vulnerable communities should be the first priority to receive the vaccine. • Four in ten (40%) believe that we can beat COVID-19 without a vaccine.
Toronto Public Health (2020) *unpublished* (83) Cross-sectional study Canada Oct 2020	Intention to receive a COVID-19 vaccine was evaluated using an online survey of 1201 residents of Toronto, Ontario. Question Topics: 1) Vaccine intentions Survey tools available? No Formative research conducted? No Survey pre-tested? No	• 73% of participants report that when a COVID-19 vaccine is available they will "definitely" or "probably" get it. 20% will "definitely" or "probably" not receive it and 11% are undecided.
Statistic Canada (2020) *unpublished* (20) Cross-sectional study	A telephone survey of 120,000 (18+) was conducted to assess intention to vaccinate. Question Topics: 1) Vaccine intentions	• When comparing all visible minorities against Whites race, vaccine intentions were nearly identical (77.3% vs 77.0%). • Within visible minority groups intention to vaccinate from lowest to highest was Black (57.0%), Latin American (58.5%), Filipino (64.2%),

Canada Sept-Oct 2020	Survey tools available? Yes Formative research conducted? Yes Survey pre-tested? Yes	South East Asian (75.8%), other visible minorities (77.6%), Chinese (85.5%), and Arab (88.3%). • 69.3% reporting an Aboriginal identity were accepting of a vaccine compared to 77.6% not reporting an Aboriginal identity. • Higher levels of education and having an underlying medical condition were associated with higher acceptance. • Outcomes on intention to vaccinate in LGBTQ+ and immigrants can be found in Tables 5&7.
Ogilvie (2021) (22) Cross-sectional study Canada Aug-Sep 2020	Intention to vaccinate was assessed in 4058 adults and healthcare workers from British Columbia (25-69 years old). Question Topics: 1) Vaccine intentions 2) Vaccine perceptions 3) Vaccine hesitancy Survey tools available? Yes Formative research conducted? Yes Survey pre-tested? Yes	• 79.8% of respondents were somewhat or very likely if available to them and was recommended for them. • Households with two adults (OR 1.2, 95% CI: 1.00-1.43) were more likely to vaccinate but there were no significant changes in intention with number of children. • Multivariate analysis demonstrated that younger respondents (30-40 years old aOR 0.64, 95% CI: 0.49-0.83, 40-50 years old aOR 0.78, 95% CI: 0.62-0.97, 50-60 years old aOR 0.67, 95% CI: 0.55-0.82), females (aOR 0.7, 95% CI: 0.55-0.89), lower education level (aOR 0.62, 95% CI: 0.51-0.77), South Asian (aOR 0.65, 95% CI: 0.39-1.07), non-White (aOR 0.76, 95% CI: 0.61-0.95), identified as Indigenous (aOR 0.58, 95% CI 0.38-0.87), other essential non-health care workers (aOR 0.72, 95% CI: 0.6-0.87), and those who suspected they had COVID-19 (aOR 0.76, 95% CI: 0.61-0.96) had significantly lower odds of intending to receive a vaccine. • Lack of confidence in vaccines (aOR 0.66, 95% CI: 0.57-0.75) and belief in vaccine risks (aOR 0.72, 95% CI: 0.66-0.80) were associated with decreased intention to vaccinate. • Intention to vaccinate was positively associated with higher attitudinal scores towards the vaccine (aOR 1.06, 95% CI: 1.04-1.08), influenced by direct social norms (aOR 1.06, 95% CI: 1.03-1.08), indirect

		social family doctor/primary care physician opinions (aOR 1.04, 95% CI: 1.00-1.08), indirect norms from the provincial health officer (aOR 1.04, 95% CI: 1.01-1.08), and indirect family norms (aOR 1.09, 95% CI: 1.06-1.13). • Outcomes on intention to vaccinate in HCWs and LGBTQ+ can be found in Tables 2 & 5.
Lang (2021) (30) Cross-sectional study Canada Aug 2020	An online survey of 60 adults (18+) in Alberta was conducted to assess their intention to vaccinate. Question Topics: 1) Vaccine intentions Survey tools available? Yes Formative research conducted? No Survey pre-tested? No	• 68% of respondents would accept a vaccine if it were available, 20% would not, and 12% were unsure. • White respondents were less likely to accept a vaccine (63%) compared to other ethnicities (100%). • Those with higher education (college or university) were less likely to accept a vaccine (63%) compared to those who had attended post-secondary technical school (100%) or had a high school diploma (70%). • Intention to vaccinate was positively associated with concerns about getting COVID-19 (P <0.001) and spreading the virus (P = 0.006), and complying with public health measures such as staying home when sick (P = 0.033), masking in public (P < 0.001) and physical distancing (P = 0.005). • Respondents who received their COVID-19 health information from the Chief Medical Officer of Health media briefings (P = 0.030) and Alberta Health or Alberta Health Services websites (P = 0.040) were significantly more likely to accept a COVID-19 vaccine. • Intention to vaccinate was lower in other urban centers (29%) and rural Alberta (50%) compared to Calgary (75%) and Edmonton (80%), (*P* = 0.030).
Carleton University (2020) *unpublished* (84)	An online opinion survey regarding vaccine intentions and perceptions was conducted online in 2000 individuals.	• 62% will definitely get the vaccine, 24% will probably get the vaccine, 5% will not likely get the vaccine, and 9% will definitely not get the vaccine.

Cross-sectional study Canada Jul 2020	Question Topics: 1) Vaccine intentions 2) Vaccine hesitancy 3) Vaccine perceptions Survey tools available? No Formative research conducted? No Survey pre-tested? No	• Resistance to a vaccine is highest in MB and SK where only 37% will definitely get vaccinated across both provinces. • In terms of views on mandatory vaccination, 36% strongly agree, 26% somewhat agree, 14% strongly disagree, and 7% somewhat disagree. • The most common reason (40%) for hesitancy was potential for harmful side-effects. • The 9% of respondents who expressed strong anti-vaccine views, suspicion about the influence of the pharmaceutical industry over public health care (41%) and concern about vaccine safety and the potential for harmful side-effects (29%) were the most common reasons for refusal.
Frank (2020) *unpublished* (85) Cross-sectional study Canada Jun 2020	Factors associated with willingness to vaccinate was investigated using an online survey of ~4000 adults. Question Topics: 1) Vaccine intentions 2) Vaccine hesitancy Survey tools available? No Formative research conducted? Yes Survey pre-tested? No	• 57.5% and 19% of respondents indicated they are very likely or somewhat likely to get a COVID-19 vaccine when it becomes available, respectively. • Older Canadians (65+) reported they were more likely to vaccinate (70.3%) compared to those aged 15-64 (52-58%). • Those that were born in Canada were more likely to vaccinate compared to immigrants (59.4% vs 52.0%). • Residents in the Atlantic Provinces are more likely to vaccinate (67.7%) followed by Ontario (58.8%), Prairies region (56.2%), BC (55.5%), and QC (54.3%). • Other factors associated with a higher intention to vaccinate include higher education and not having children under the age of 18. • The top two reasons for not intending to vaccinate were a lack of confidence in the safety of the vaccine (54.2%) and concerns about its risks and side-effects (51.7%).
Frank (2020) *unpublished* (86)	An online survey of ~36,000 adults was conducted to investigate factors associated with willingness to vaccinate.	• 68.2% and 15.2% of participants reported that they were very likely or somewhat likely to accept a COVID-19 vaccine, respectively. 12% were unlikely or very unlikely to vaccinate.

Cross-sectional study Canada May-Jun 2020	Question Topics: 1) Vaccine intentions Survey tools available? No Formative research conducted? Yes Survey pre-tested? No	• Those who had a high level of trust in the federal government were more likely to be willing to vaccinate compared to those with a low level of trust (77.3% vs 53.8%). • Similar trends were also seen with trust in others, and trust in federal public health authorities.
Taylor (2021) (87) Cross-sectional study Canada & USA Jun-Jul 2020	An online survey of 2078 adults (18+) was used to explore the potential relationship between attitudes on wearing a face mask and COVID-19 vaccination. The sample consisted of 1036 participants from the USA and 1042 from Canada. Question Topics: 1) Vaccine attitudes Survey tools available? No Formative research conducted? Yes Survey pre-tested? No	• The network of anti-masks attitudes is linked to other variables such as disregard for social distancing and anti-vaccination attitudes.
Waite (2021) (35) Cross-sectional study Canada May 2020	An online survey of 1001 Canadians aged 50–64 years and 3,500 aged 65+ was conducted to evaluate intention to vaccinate against COVID-19. Question Topics: 1) Vaccine intentions 2) Vaccine attitudes Survey tools available? No Formative research conducted? Yes Survey pre-tested? No	• Among those aged 50-64 years, 69.1% intend to vaccinate when available, 11.3% would not vaccinate, and 19.6% were unsure. • 79.5% of those 65+ intend to receive a vaccine when available, 5.6% would not vaccinate, and 14.9% were unsure. • In both age groups, those who would accept a vaccine were significantly more likely to be male and more likely to have at least one chronic condition (P< 0.05). • The preferred location to receive a vaccine in both groups was family physician office, followed by pharmacy, workplace (for those 50–64 years), and public health clinics.
Taylor (2020) (18)	Intentions to vaccinate and attitudes towards vaccines were	• Significantly more Americans (25%) than Canadians (20%) responded that they would not

Cross-sectional study Canada & USA May 2020	measured using an online survey of 3674 adults (Canada = 1902, USA = 1772). Question Topics: 1) Vaccine intentions 2) Vaccine hesitancy 3) Vaccine attitudes Survey tools available? No Formative research conducted? Yes Survey pre-tested? No	get vaccinated if a vaccine was available, χ^2 (*df* = 1) = 12.41, $p < 0.001$. • Negative attitudes toward a COVID-19 vaccination, and vaccinations in general, were significantly correlated ($p < 0.001$) with the intention not to vaccinate. Mistrust of the benefit of a COVID-19 vaccine was the largest factor with respect to attitude on the decision not to get the vaccine. • Vaccination refusal was significantly associated with female gender, age, completed full or partial college education (vs. did not complete), being unemployed, and minority status (vs. Caucasian). • Of those who indicated they would not get vaccinated (n=812), 38% would vaccinate if they were convinced the vaccine had been rigorously tested and 36% would vaccinate if they saw that enough people were vaccinated without any serious side-effects. • Compared to White ethnicity, minority status (Asian, African American/Black, Latino/Hispanic, or other) was significantly associated with vaccine refusal (r = −0.04, P < 0.05).
Carleton University (2020) *unpublished* (26) Cross-sectional study Canada May 2020	An online opinion survey regarding vaccine intentions and perceptions was conducted online in 2000 individuals. Question Topics: 1) Vaccine intentions 2) Vaccine perceptions Survey tools available? No Formative research conducted? No Survey pre-tested? No	• 49% and 24% of the participants would "definitely" or "probably" get the vaccine when available, respectively. • 17% expressed uncertainty and 10% were unwilling. • 65% believe that the vaccine should be mandatory. • Age and political affiliation were significantly associated with intention to vaccinate. Older individuals were more willing to vaccinate than younger. Those who voted Liberal or NDP in the 2019 election were more likely to vaccinate compared to those who voted for other parties. • Respondents living in Atlantic Canada showed the strongest levels of intention to vaccinate compared to those in other provinces.

		• Those who believed one of the four health myths or conspiracy theories regarding COVID-19, were less likely to intend to vaccinate than those who did not believe the scientifically inaccurate claims about COVID-19.
Parsons Leigh (2020) (88) Cross-sectional study Canada Apr-May 2020	COVID-19 perceptions, knowledge, attitudes, and behaviors were analyzed using an online survey of 1996 participants (18+). Question Topics: 1) Vaccine intentions 2) Vaccine knowledge Survey tools available? Yes Formative research conducted? Yes Survey pre-tested? Yes	• 75.8% (n = 1,436) of respondents reported that they would get vaccinated when a vaccine became available. • Participants responded they "strongly agree" or "agree" that they will get vaccinated in BC (72.1%), AB (69.9%), MB/SK (69.9%), ON (66.1%), Atlantic (63.1%), and QC (41.9%). • Participants responded they "strongly agree" or "agree" that they will not get vaccinated in AB (12.4%), QC (12.1%), ON (8.1%), Atlantic (6.6%), MB/SK (6%), and BC (4.8%). • Information about vaccines and treatments were most frequently (n = 933, 48.9%, 95% CI: 46.7-51.2%) cited as topics of misinformation, however only half (n = 937, 47.4%, 95% CI: 45.2%-49.6%) of respondents felt moderately or extremely confident that they could identify incorrect or misleading information about COVID-19.
Underschultz (2021) (89) Cross-sectional study Canada Apr 2020	COVID-19 knowledge, attitudes, and practices were analyzed using an online survey of 1593 participants (16+). The survey was primarily targeted to residents of Alberta and Ontario. Question Topics: 1) Vaccine perceptions Survey tools available? No Formative research conducted? Yes Survey pre-tested? No	• 93% of respondents believe that a vaccine is needed in Canada and 81% endorsed a wide-spread vaccination strategy (having everyone vaccinated). • Vaccine acceptance was significantly associated with higher knowledge scores ($p<0.001$), being worried about COVID-19 (OR 20.4; 95% CI: 8.4-49.5, $p<0.001$), optimism in controlling the pandemic (OR 8.1; 95% CI: 3.4-19.7, $p<0.001$), and feeling informed about COVID-19 (OR 3.9; 95% CI: 1.7-9.3, $p=0.0049$).

Research Co (2020) *unpublished* (25) Cross-sectional study Canada Apr 2020	Intention to vaccinate was assessed using an online survey. Question Topics: 1) Vaccine intentions Survey tools available? No Formative research conducted? No Survey pre-tested? No	• If a vaccine becomes available, 42% and 31% would "definitely" or "probably" get the vaccine, respectively. • Men were more likely to vaccinate than women (78% vs 68%). • The Atlantic (79%) and Alberta (78%) had the highest intentions to vaccinate and Saskatchewan/Manitoba (65%) had the lowest. • Intention to vaccinate was highest in those who voted liberal (79%) in the 2019 election, followed by NDP (76%), and conservative (69%).
Qualitative studies (n=1)		
Benham (2021) (90) Qualitative study Canada Aug-Sep 2020	Nine focus groups were conducted with 50 adults (18+) from Alberta to evaluate attitudes towards public health measures including vaccination. Question Topics: 1) Vaccine intentions 2) Vaccine perceptions	• Intention to vaccinate responses were mixed. Some stated they would vaccinate right away, while others would not vaccinate as they believed COVID-19 would not impact their health or the health of their family members. • Some participants reported that they would be willing to take a vaccine but not right away. This was more prominent in the older age groups. • Participants who regularly received the annual flu vaccine were more likely to state they would take a COVID-19 vaccine when available. However, a few experienced side effects with the annual flu shot (e.g., getting sick) which would make them less likely to get a COVID-19 vaccine. • Barriers for vaccine uptake included a lack confidence that a vaccine will work, and that it may do harm.
Quasi-experimental studies (n=1)		
Poder (2021) *unpublished* (91) Quasi-experimental study	An online survey of vaccine intentions of 1,695 Quebec adults was conducted which included an assessment of preferences through a series 12 binary choice scenarios (20,350 choice responses in total).	• At least 7.2% always chose not to be vaccinated in any given scenario. • Depending on the scenario, 69-93% of participants would opt for the vaccine when available. • 24% of participants would make the choice to refuse the vaccine if certain conditions were not

Canada Oct-Nov 2020	Question Topics: 1) Vaccine intentions Survey tools available? Yes Formative research conducted? Yes Survey pre-tested? No	met which were determined to be in order of priority: 1) vaccine efficacy 2) possible side effects of the vaccine 3) duration of effectiveness (minimum of 9 months for acceptability) 4) the organization recommending the vaccine (Public health organizations of Québec, WHO) 5) geographic origin of vaccine (European Union or United States) 6) waiting period to be vaccinated once the vaccine is available in Quebec (4 months maximum) 7) high priority populations (no preferences)
Expert Stakeholders		
Cross-sectional studies (n=2)		
MacDonald (2020) (92) Cross-sectional study Canada Aug-Oct 2020	Eighteen teleconference interviews with 25 public health leaders from 10 of 13 provinces and territories were conducted to evaluate perspectives on priority groups for early vaccination. Participants were asked to rank, in order of importance, their top five priority groups for vaccination. Question Topics: 1) Vaccine strategy perceptions Survey tools available? No Formative research conducted? No Survey pre-tested? No	• All ten province and territories ranked long-term residents and health-care workers in their top five priority groups to receive vaccination. • Those with chronic medical conditions and seniors were also ranked in the top five priority groups by nine and eight provinces and territories, respectively. • To a lesser extent, those with Indigenous ancestry (n=4), with socioeconomic disadvantage (n=3), with infants or children (n=2), living in remote communities (n=2), and new immigrants and refugees (n=1) were ranked in the top five priority groups.
Zhao (2020) *preprint* (93)	Among 74 expert stakeholders, an online survey was conducted to establish perspective on the relative importance of pandemic	• For all pandemic scenarios, stakeholders generally ranked the strategies in the following order from most to least important:

Cross-sectional study Canada Jul-Aug 2020	immunization strategies for different COVID-19 pandemic scenarios at the time of initial COVID-19 vaccine availability. Questions asked the respondent to rank, in order of importance, four pre-defined COVID-19 pandemic immunization strategies. Question Topics: 1) Vaccine strategy perceptions Survey tools available? No Formative research conducted? No Survey pre-tested? No	○ Protect those who are most vulnerable to severe illness and death from COVID-19 ○ Protect healthcare capacity ○ Minimize transmission of COVID-19 • Protect critical infrastructure

aOR = adjusted odds ratio, CI = confidence interval, HCWs = healthcare workers, NR = not reported, RR = risk ratio

HEALTHCARE WORKERS

Table 3. Evidence of vaccine attitudes of healthcare workers (n=7)

STUDY	METHODS & SURVEY TOOLS	KEY KAB OUTCOMES
Lunsky (2021) (50) Cross-sectional study Canada Jan-Feb 2021	To evaluate vaccination intent and predictors of intent, an online survey of 3371 social service employees supporting individuals with intellectual disabilities in Ontario was conducted. Question Topics: 1) Vaccine intentions 2) Vaccine hesitancy Survey tools available? No Formative research conducted? Yes	• 62% and 20% reported that they were very likely, or somewhat likely to accept a vaccine, and 7% and 11% somewhat unlikely or very unlikely to get the vaccine, respectively. • Compared to individuals aged 50 +, younger individuals aged 18-29 (aOR 2.74, 95% CI: 1.70–4.43) and 30-39 (aOR 1.75, 95% CI: 1.16–2.64) were more likely to refuse a vaccine when available. • Women were more likely to refuse a vaccine compared to men (aOR 1.58, 95% CI: 0.97-2.59). • Compared to European respondents, Asian (aOR 0.88, 95% CI: 0.33-2.36), African and Caribbean (aOR 0.81, 95% CI: 0.35-1.86), and unknown ethnicities (aOR 0.88, 95% CI: 0.36-2.17) were less

	Survey pre-tested? No	likely to refuse a vaccine and Indigenous, First Nations, and Metis (aOR 1.73, 95% CI: 0.67- 4.43), Latin (aOR 1.22, 95% CI: 0.21-7.24), and mixed ethnicities (aOR 1.11, 95% CI: 0.27-4.55) were more likely to refuse. • Reasons to refuse a vaccine included lack of trust in the vaccine (OR 5.72, 95% CI: 3.84–8.53), fear of vaccine side effects (OR 2.30, 95% CI: 1.56–3.39), and belief that there was no need for the vaccine due to good health (OR 4.22, 95% CI: 2.66–6.68). • Individuals who would refuse a vaccine were less likely to believe that vaccination would protect clients (OR 0.36, 95% CI: 0.24-0.54) or family (OR 0.19, 95% CI: 0.13-0.28),be concerned about clients (OR 0.57, 95% CI: 0.34-0.97) or themselves (OR 0.51, 95% CI: 0.34-0.76) becoming ill with COVID-19, get the flu shot in a normal year (OR 0.61, 95% CI: 0.43-0.88), and get the vaccine if their co-workers did (OR 0.16, 95% CI: 0.08-0.29).
Desveaux 2021 *preprint* (49) Cross-sectional study Canada Jan 2021	Factors associated with intention to vaccinate was evaluated in 8634 non-physician HCWs (18+) in Ontario using an online survey. Question Topics: 1) Vaccine intentions 2) Vaccine hesitancy Survey tools available? No Formative research conducted? No Survey pre-tested? No	• 80.4% of participants reported that they intend to get a COVID-19 vaccine. • Compared to their counterparts, those who were younger (<40 years old) and who had less education (less than a high school diploma) were more likely to be unwilling to intend to vaccinate (P<0.001). • HCWs who identified as Filipino (OR 1.07, 95% CI: 0.41-2.76, P<0.001), Caribbean (OR 3.20, 95% CI: 1.52-6.75, P<0.001), or Other (OR 1.44, 95% CI: 0.93-2.22, P<0.001) ethnicity were more likely to be unwilling to vaccinate compared those who identified as European. • Vaccine hesitancy was strongly associated with mistrust about how fast the vaccines were developed and vaccine safety concerns. It was also associated with various beliefs such as not requiring a vaccine due to one's own good health, low confidence that the vaccine would protect

		their family and patients, and that getting vaccinated was not a professional responsibility. • HCWs were more likely to intend to vaccinate if direct financial supports such as paid sick days were provided (74% vs 25%, P<0.001).
SafeCare BC (2021) *unpublished* (19) Cross-sectional study Canada Dec 2020	An online survey of 1,500 continuing care workers in British Columbia was conducted to evaluate attitudes on COVID-19 vaccination. Question Topics: 1) Vaccine intentions 2) Vaccine hesitancy Survey tools available? No Formative research conducted? No Survey pre-tested? No	• 57% of respondents intend to get a vaccination, 28% were not sure, and 15% did not intend to get vaccinated. • Male (72% vs 56%), higher age (65+) and flu shot acceptance were predictors of intention to vaccinate. • Managers and senior leaders had the highest intentions to vaccinate (71%). Healthcare assistants were the most unsure (30%), and nurses were most likely to say no to a vaccine (20%). • Reason for hesitancy were side effects (84.6%), the newness of the vaccine (64.6%), mistrust of authorities (23.5%), belief that the vaccine will not work (16%), preferred natural remedies (10.5%), and personal or religious beliefs (8%). • Intention to vaccinate was highest in East (61%) and South Asian (70%). Latino and Black respondents were the most likely to refuse a vaccine (30%) and Indigenous respondents were most likely to be unsure about their decision to vaccinate (40%). • East/South Asian respondents were more concerned about side effects (93%) whereas White or Indigenous respondents were more concerned about newness (72% and 62%, respectively). • 33% said more support for vaccinations is needed e.g. more information to understand the development process, efficacy, and transparency of reporting adverse events. • The biggest perceived barrier to administering the vaccine was storage and handling constraints (66%). • Indigenous respondents had the least amount of trust in all sources of information including healthcare providers.

INSPQ (2020) & INSPQ (2021) *unpublished* (32, 40) Longitudinal study Canada Apr-Dec 2020	Analysis of the acceptability of vaccination against COVID-19 was evaluated using an online survey of adults and healthcare workers in Quebec. Number of participants was not clearly stated (~3300 each collection period). There were multiple collection periods, one in Apr-May and one in Sep and Dec. Article in French. Question Topics: 1) Vaccine intentions 2) Vaccine hesitancy Survey tools available? No Formative research conducted? No Survey pre-tested? No	• In May, 73% of HCWs responded with the intention to vaccinate. In Dec this decreased to 65% and increased to 71% in Dec. • Intention to vaccinate did not differ between the general public and healthcare workers and factors associated with intention to vaccinate were not differentiated between the two groups. • Those that were older (70+) were more likely to vaccinate compared to those 25-44 years old (83% vs 57%). • Men, those with a university education, and those with one or more chronic diseases are more likely to intend to vaccinate. • The most common reasons to not intend to vaccinate include fears related to taking a new vaccine, and concern regarding the effectiveness and side-effects.
Verger (2021) (51) Cross-sectional study Belgium, France & Canada Oct-Nov 2020	Intention to vaccinate and intention to recommend vaccination to patients was evaluated using an online and telephone survey in general practitioners (GPs) in France (n=1209) and French-speaking parts of Belgium (n=414) , and nurses in Quebec, Canada (n=1055). Belgium and France results can be found in the Europe section. Question Topics: 1) Vaccine intentions 2) Vaccine hesitancy Survey tools available? Yes Formative research conducted? No Survey pre-tested? Yes	• In Canada, 79.6% of nurses would definitely or probably recommend their patients vaccinate, 3.1% would not, and 17.2% were unsure. For themselves, 70.4% would definitely or probably be willing to receive the vaccine, 11.8% would refuse, and 17.8% were unsure. • 40.9% of participants reported that the safety of vaccines developed in an emergency during an epidemic cannot be guaranteed. • Opinion about the safety of vaccines developed in an emergency and distrust in the ministry of health to ensure vaccine safety were the two most important factors independently associated with vaccine hesitancy and reluctance. • Intention to vaccinate was positively associated with a history of personal vaccination against the flu.

Ogilvie (2021) (22) Cross-sectional study Canada Aug-Sep 2020	Intention to vaccinate was assessed in 4058 adults and healthcare workers from British Columbia (25-69 years old). Unclear how many healthcare workers in the survey. Question Topics: 1) Vaccine intentions 2) Vaccine perceptions 3) Vaccine hesitancy Survey tools available? Yes Formative research conducted? Yes Survey pre-tested? Yes	• 81.8% of healthcare workers report that they intend to receive a vaccine. • Other results found in general population. • Multivariate analysis demonstrated that South Asian (aOR 0.65, 95% CI: 0.39-1.07), non-White (aOR 0.76, 95% CI: 0.61-0.95), and those who identified as Indigenous (aOR 0.58, 95% CI 0.38-0.87) had significantly lower odds of intending to receive a vaccine.
The Canadian PSW Network (2020) *unpublished* (52) Cross-sectional study Canada NR 2020	Intention to vaccinate in 562 personal support workers (PSWs), nurses, and healthcare workers using an online survey. 84% of the sample were PSWs. Question Topics: 1) Vaccine intentions 2) Vaccine perceptions Survey tools available? No Formative research conducted? No Survey pre-tested? No	• 64.2% of respondents intend to vaccinate when it is available, 16.2% refuse to vaccinate, 10.7% are unsure, and 8.9% will only take the vaccine if it's mandatory. • 71.7% do not believe there is enough clear education on the vaccine.

aOR = adjusted odds ratio, CI = confidence interval, HCWs = healthcare workers, PSW = personal support worker

HIGH-RISK POPULATIONS

Table 4. Evidence of vaccine attitudes of high-risk populations (n=1)

STUDY	METHODS & SURVEY TOOLS	KEY KAB OUTCOMES
OLDER ADULTS		

Waite (2021) (35) Cross-sectional study Canada May 2020	An online survey of 1001 Canadians aged 50–64 years and 3,500 aged 65+ was conducted to evaluate intention to vaccinate against COVID-19. Question Topics: 1) Vaccine intentions 2) Vaccine attitudes Survey tools available? No Formative research conducted? Yes Survey pre-tested? No	• Among those aged 50-64 years, 69.1% intend to vaccinate when available, 11.3% would not vaccinate, and 19.6% were unsure. • 79.5% of those 65+ intend to receive a vaccine when available, 5.6% would not vaccinate, and 14.9% were unsure. • In both age groups, those who would accept a vaccine were significantly more likely to be male and more likely to have at least one chronic condition (P< 0.05). • The preferred location to receive a vaccine in both groups was family physician office, followed by pharmacy, workplace (for those 50–64 years), and public health clinics.

LGBTQ+

Table 5. Evidence of vaccine attitudes of LGBTQ+ (n=4)

STUDY	METHODS & SURVEY TOOLS	KEY KAB OUTCOMES
LGBTQ+		
Racey (2021) (37) *new* Cross-sectional study Canada Aug-Nov 2020	5,076 public school teachers in British Columbia participated in an online survey regarding the likelihood of accepting a vaccine. Question Topics: 1) Vaccine intentions Survey tools available? Yes Formative research conducted? Yes Survey pre-tested? Yes	• Those identifying as female gender or non-Binary/genderqueer/S2/other were less likely to intend to vaccinate compared to those who identified as male. • 22.6% of non-Binary/genderqueer/S2/other (n=31) do not intended to vaccinate and 77.4% do. • General population outcomes found in Table 1.
Statistic Canada (2020) *unpublished* (20)	A telephone survey of 120,000 (18+) was conducted to assess intention to vaccinate. Question Topics: 1) Vaccine intentions	• 87.6% of LGBTQ2+ were willing to accept a vaccine compared to 76.4% non-LGBTQ2+.

Cross-sectional study Canada Sept-Oct 2020	Survey tools available? Yes Formative research conducted? Yes Survey pre-tested? Yes	
Ogilvie (2021) (22) Cross-sectional study Canada Aug-Sep 2020	Intention to vaccinate was assessed in 4058 adults and healthcare workers from British Columbia (25-69 years old). Question Topics: 1) Vaccine intentions Survey tools available? Yes Formative research conducted? Yes Survey pre-tested? Yes	• Non-binary, gender queer, agender, two-spirit or other were more likely to be receive a vaccine compared to heterosexual woemn (OR 3.04, 95% CI: 1.08-8.55, P<0.04).
Statistics Canada (2020) & Statistics Canada (2021) *unpublished* (53, 72) Longitudinal study Canada Sep-Dec 2020	An online survey conducted by Statistics Canada as part of the Canadian Community Health Survey (CCHS) assessed Canadians behaviors to safeguard their own health as well as the health of others. In the September survey, a question about vaccine intentions was added. The most recent report captures 20,000 responses from individuals aged 12+. Question Topics: 1) Vaccine intentions Survey tools available? Yes Formative research conducted? Yes	• Over the sampling period 77% were willing to receive a vaccine. This represents an increase from Sept (75.5%) to Oct (74.8%), and Nov/Dec (80.3%). • LGBTQ2+ were more likely to get a vaccine (83.3%).

	Survey pre-tested? Yes	

PARENTS

Table 6. Evidence of vaccine attitudes of parents (n=7)

STUDY	METHODS & SURVEY TOOLS	KEY KAB OUTCOMES
PARENTS		
INSPQ (2020), INSPQ (2021), INSPQ (2021), INSPQ (2021), INSPQ (2021), INSPQ (2021), INSPQ (2021), INSPQ (2021), INSPQ (2021) *unpublished* (1, 9, 29, 32-34, 40, 43, 71) Longitudinal study Canada Apr 2020 – Jun 2021	Analysis of the acceptability of vaccination against COVID-19 was evaluated using an online survey of adults and healthcare workers in Quebec. Number of participants was not clearly stated (~3300 each collection period). There were multiple collection periods, one in Apr-May 2020, Sep and Dec 2020, Apr-Jul 2021 *new*. Articles in French. Question Topics: 1) Vaccine intentions Survey tools available? No Formative research conducted? No Survey pre-tested? No	**July** • 87% of parents intend to vaccinate their children (up 1% from June), 11% have no intention (up from 8%), and 3% were unsure (down from 6%). • General population outcomes found in Table 1.
Government of Manitoba (2021) *unpublished* (42) Longitudinal study Canada	An online research panel of 600 Manitobans were surveyed to understand attitudes towards vaccination and possible incentives to increase uptake. Question Topics: 1) Vaccine intentions 2) Vaccine perceptions	• In a group of 70 parents or guardians of children aged 12-17, 15% were not sure if they will vaccinate their children, and 13% will not vaccinate their children. • Those who did not intend to vaccinate their children were in households making less than $40,000, would not get the vaccine themselves, and didn't believe adults should get all the regular vaccines.

May 2021	Survey tools available? No Formative research conducted? No Survey pre-tested? No	
McKinnon (2021) *preprint* (56) Cross-sectional study Canada Jan – Apr 2021	Willingness to vaccinate children according to level of education, neighbourhood, and visible minority status was evaluated using an online survey in 380 parents with children aged 2-17 in Montreal. Question Topics: 1) Vaccine intentions 2) Vaccine hesitancy Survey tools available? No Formative research conducted? No Survey pre-tested? No	• Parents were 61% very likely, 25% somewhat likely, 9.2% somewhat unlikely, and 4.5% very unlikely to have their child vaccinated. • Concern over the lack of information about the vaccine's safety and possible side effects was the most common reason for hesitancy (48%). • Comparing visible minority to non-visible minority parents, 30.3% vs. 66.6% were very likely to vaccinate their children, 36.8% vs. 23.9% were somewhat likely, and 32.9% vs. 9.5% were unlikely to vaccinate, respectively.
Vallis (2021) (55) Cross-sectional study Canada Jun-Oct 2020	Attitudes and concerns towards COVID-19 vaccination in individuals living with overweight and obesity were evaluated using an online survey. Two samples were used: 1) representative sample of 1089 individuals living with overweight and obesity and 2) convenience sample of 980 individuals recruited from obesity clinical services or patient organizations. Question Topics: 1) Vaccine intentions 2) Vaccine hesitancy Survey tools available? No	• 64.6% of those living with obesity were comfortable receiving a vaccine and 35.4% were hesitant. • Individuals were less comfortable with their children receiving the vaccine (58.5% comfortable, 41.6% hesitant, P<0.001).

	Formative research conducted? Yes Survey pre-tested? No	
Drouin (2021) *preprint* (54) Cross-sectional study Canada Aug 2020	Parental intention to have their child with asthma vaccinated against COVID-19 was assessed using an online survey in 305 parents. Question Topics: 1) Vaccine intentions 2) Vaccine hesitancy Survey tools available? No Formative research conducted? No Survey pre-tested? No	• 63% of parents were likely to have their child vaccinated, 19.1% were unlikely, and 17% were unsure. For themselves, 64% were likely to get vaccinated, 21% were unlikely, and 15.1% were unsure. There was a strong relationship between a parents' intention to vaccinate their children and person intention to vaccinate. • Factors significantly associated with a parents' decision to vaccinate their child included higher level of education, being employed, sex of the child (female), presence of other chronic diseases, prior influenza vaccination, parental anxiety, and consultation with a health professional.
Lackner (2021) (58) Cross-sectional study Canada May-Jun 2020	The demographic, experiential, and psychological factors associated with the anticipated likelihood and speed of having children receive a COVID-19 vaccine was investigated in 455 families (857 children). Question Topics: 1) Vaccine intentions Survey tools available? No Formative research conducted? Yes Survey pre-tested? No	• Factors associated with a higher likelihood of having their children vaccinated include older parental age, living in the Prairies (relative to Central Canada), more complete child and parental vaccination history, positive attitudes towards vaccines in general, higher psychological avoidance of the pandemic, and a greater tendency to prioritize the risks of the disease relative to the risks of side-effects. • In some models, perceived COVID-19 risk and higher levels of state anxiety were associated with increased likelihood of having children vaccinated. • The above factors were also predictors of faster speed of intended vaccination. However, higher SES was a trend-level predictor.
Hetherington (2021) (57) Cross-sectional study Canada	Participants from the longitudinal cohort study All Our Families (n=1321) in Alberta were invited to participate in an online COVID-19 impact survey to understand factors associated with COVID-19	• 60.4% of parents intended to vaccinate their children, 8.6% said they did not intend to vaccinate, and 31% were unsure. • Participants with less education were more likely to not want to vaccinate (OR 2.80, 95% CI: 1.78-4.40) or be unsure (OR 1.98, 95% CI: 1.47-2.71). A similar pattern was seen for income.

May-Jun 2020	vaccine intentions among parents of 9-12 year old children. Question Topics: 1) Vaccine intentions 2) Vaccine hesitancy Survey tools available? No Formative research conducted? No Survey pre-tested? No	• History of partial or non-vaccination was associated with intent to not vaccinate (OR 2.81, 95% CI: 1.78-4.40). There was no association between vaccination history and uncertainty regarding a COVID-19 vaccine (OR 1.29, 95% CI: 0.92-1.80). • Concerns over vaccine safety and efficacy, long-term effects, and a rushed vaccination process were reported.

IMMIGRANTS

Table 7. Evidence of vaccine attitudes of immigrants (n=6)

STUDY	METHODS & SURVEY TOOLS	KEY KAB OUTCOMES
Innovative Research Group (2021) *new* *unpublished* (5) Cross-sectional study Canada May-Jun 2021	An online poll of 2,838 adults with a specific over sampling of Black Canadians (n=502) was conducted to evaluate COVID-19 vaccine intentions and hesitancy. Question Topics: 1) Vaccine hesitancy Survey tools available? No Formative research conducted? No Survey pre-tested? No	• Vaccine hesitancy was higher amongst Black Canadians and Non-Black Canadians born in Canada than those born outside of Canada. • General population outcomes located in Table 1.
INSPQ (2020), INSPQ (2021), INSPQ (2021), INSPQ (2021), INSPQ (2021) *unpublished* (29, 32-34, 40)	Analysis of the acceptability of vaccination against COVID-19 was evaluated using an online survey of adults and healthcare workers in Quebec. Number of participants was not clearly stated (~3300 each collection period). There were multiple collection periods, one in Apr-May 2020, Sep and Dec 2020,	• Immigrants were more hesitant and more unsure about receiving a vaccine compared to non-immigrants.

Longitudinal study Canada Apr 2020 – May 2021	Apr and May 2021. Articles in French. Question Topics: 1) Vaccine intentions 2) Vaccine hesitancy Survey tools available? No Formative research conducted? No Survey pre-tested? No	
Statistics Canada (2021) *unpublished* (3, 76) Cross-sectional study Canada Mar-May 2021	Vaccine intentions and perceptions were analyzed in the second round COVID-19 Vaccination Coverage Survey (CVCS) involving Canadian adults (18+) in the provinces using mail invites and computer assisted telephone interviews for non-responses. Round 1: n= 1,025 capital cites of the territories Round 2: n= 10,678 in 10 provinces *new* Question Topics: 1) Vaccine intentions 2) Vaccine perceptions 3) Vaccine hesitancy Survey tools available? Yes Formative research conducted? Yes Survey pre-tested? Yes	**Round 2** • 11%* of non-permanent residents were unlikely to vaccinate compared to 5% of non-immigrants, 4% among immigrants in Canada for more than 10 years, and 3% among immigrants living in Canada for less than 10 years. • General population outcomes located in Table 1
Muhajarine (2021) *preprint* (4) *new*	9,252 responses collected from 7,265 Saskatchewan adults (18+) were enrolled from landlines and online to complete an online survey	• Those who were born outside of Canada and living in Canada less than 20 years were more vaccine hesitant compared to those born in Canada (RRR 3.14, 95% CI: 1.56-6.34).

Cross-sectional study Canada Apr-May 2021	regarding vaccine acceptance and hesitancy. Question Topics: 1) Vaccine intentions 2) Vaccine hesitancy Survey tools available? No Formative research conducted? No Survey pre-tested? No	• General population outcomes found in Table 1.
Statistics Canada (2020) & Statistics Canada (2021) *unpublished* (53, 72) Longitudinal study Canada Sep-Dec 2020	An online survey conducted by Statistics Canada as part of the Canadian Community Health Survey (CCHS) assessed Canadians behaviors to safeguard their own health as well as the health of others. In the September survey, a question about vaccine intentions was added. The most recent report captures 20,000 responses from individuals aged 12+. Question Topics: 1) Vaccine intentions Survey tools available? Yes Formative research conducted? Yes Survey pre-tested? Yes	• Immigrants were slightly less likely to vaccinate (74.6%) but this varied greatly between older and younger immigrants (73.2% for 12-64 and 81.1% for those 65+).
Statistic Canada (2020) *unpublished* (20) Cross-sectional study	A telephone survey of 120,000 (18+) was conducted to assess intention to vaccinate. Question Topics: 1) Vaccine intentions	• Immigrants living in Canada for less than 10 years (80.3%) and more than 10 years (70.7%) had comparable intentions to vaccinate compared to non-immigrants (75.9%). • Women who were non-immigrants or who immigrated less than 10 years ago had lower intentions than men (74.7% vs 77.2% for non immigrants and 78.1% vs 82.9% for less than 10 years).

Canada Sept-Oct 2020	Survey tools available? Yes Formative research conducted? Yes Survey pre-tested? Yes	

INDIVIDUALS WITH COMORBIDITIES OR DISABILITIES

Table 8. Evidence of vaccine attitudes of individuals with comorbidities (n=1)

STUDY	METHODS & SURVEY TOOLS	KEY KAB OUTCOMES
CANADA		
Vallis (2021) (55) Cross-sectional study Canada Jun-Oct 2020	Attitudes and concerns towards COVID-19 vaccination in individuals living with overweight and obesity were evaluated using an online survey. Two samples were used: 1) representative sample of 1089 individuals living with overweight and obesity and 2) convenience sample of 980 individuals recruited from obesity clinical services or patient organizations throughout Canada. Question Topics: 1) Vaccine intentions 2) Vaccine hesitancy Survey tools available? No Formative research conducted? Yes Survey pre-tested? No	• 64.6% of those living with obesity were comfortable receiving a vaccine and 35.4% were hesitant. • Individuals were less comfortable with their children receiving the vaccine (58.5% comfortable, 41.6% hesitant, P<0.001). • The mean score on the confidence subscale of the vaccine hesitancy scale was significantly lower than any other measure (mean = 2.26). • Fear of COVID-19 was a predictor of vaccine attitudes for all dependent measures. • Comfort levels in receiving the vaccine were positively associated with male gender, having more comorbidities, having lower depression scores, not practicing social distancing, and past acceptance of influenza vaccinations.

CANADA COMPARED TO GLOBAL POPULATION

Table 9. Evidence of vaccine attitudes of the global population (n=6)

STUDY	METHODS & SURVEY TOOLS	KEY KAB OUTCOMES
Quasi-experimental studies (n=1)		

Duch (2021) *preprint* (94) Quasi-experimental study 13 countries (Australia, Brazil, Canada, Chile, China, Colombia, France, India, Italy, Spain, Uganda, UK, USA) Nov-Dec 2020	To understand public opinions on key aspects of vaccine allocation, an online experiment of 15,536 adults (18+) across 13 countries was conducted. Participants were require to make eight binary choices about hypothetical vaccine recipients that randomly varied on five attributes including occupation, age, transmission status, risk of death from COVID-19, and income. Question Topics: 1) Vaccine perceptions Survey tools available? Yes Formative research conducted? Yes Survey pre-tested? No	• Overall there was global consensus on which population segments should have priority for a COVID-19 vaccine. • In almost all countries and across participants of different education levels, incomes, and political ideologies, results show that the public favors prioritizing the vaccine to healthcare workers, those at high risk, those in lower income brackets, and older populations. • At least two thirds of participants in each of the countries (80% in Canada) believed that the government should assume the lead role in the distribution of COVID-19 vaccines. However, there is evidence that a large proportion of individuals would be willing to pay for a vaccine if it were available privately. This ranged from 18% of participants in France to 79% in India and Uganda. 35% of Canadians would be willing to pay for a vaccine. • There was no consensus on support for mandatory vaccination either globally or within national borders. In the global sample, 24% were strongly opposed and 38% were strongly in favor. In France 60% of participants opposed mandatory vaccination whereas in China, India, and Uganda very few people were strongly opposed.
Cross-sectional studies (n=5)		
Crespo (2021) *preprint* (59) Cross-sectional studies 15 countries: Australia, Canada, Denmark, Finland, France, Germany, Italy,	Change in intention to vaccinate over time was assessed using two online surveys, one in Nov 2020 and the other in Jan 2021 across fifteen countries. It is unclear if and how many individuals completed both surveys. Question Topics: 1) Vaccine intentions	• In Canada, intention to vaccinate increased from 44.2% in Nov to 55.2% in Jan. • In the Jan survey, the countries with the highest intentions to vaccinate included the UK (77.5%), Denmark (67%), and the Netherlands (63.1%). The countries with the lowest intentions included South Korea (43.7%), France (39.2%), and Singapore (34.8%). • Increase in intention to vaccinate between Nov and Jan was seen in Spain (24.1%), UK (23.2%), Sweden (22.7%), Finland (20.4%), Netherlands (18.5%), Italy (15.4%), Norway (14.6%), France

Japan, Netherlands, Norway, Singapore, South Korea, Spain, Sweden, UK Nov-Jan 2021	Survey tools available? No Formative research conducted? No Survey pre-tested? No	(14.2%), Denmark (13.3%), Germany (13.0%), Canada (11%), and Japan (0.8%). • Countries with a decrease in intentions between Nov and Jan included Australia (-6.6%), South Korea (-5.0%), and Singapore (-1.3%). • In 11/15 countries there was a significant decrease in the proportion of individuals who reported concern about the side-effects of a vaccine. In Canada, this concern decreased from 53.3% in Nov to 47.9% in Jan.
Clarke (2021) (95) Cross-sectional study Australia, Canada, France, Italy, Spain, UK and USA Nov-Dec 2020	An international online survey of 8209 adults from high income countries was conducted with the goal of evaluating perceptions of prioritization of global vaccine allocation on a scale 0 ('very much disagree') to 100 ('very much agree'). Question topics: 1) Vaccine perceptions Survey tools available? No Formative research conducted? No Survey pre-tested? No	• All countries favoured in order of most support: allocating based on need, by affordability, and by which country developed the vaccine. • The UK had the largest percentage of respondents who do not favor donating purchased vaccines to other countries (26%) and Italy and Spain had the lowest (15%). • Between 48% and 56% of respondents would donate their country's vaccines at some level. The highest was Canada (56%) and lowest France (48%).
World Economic Forum (2020) *unpublished* (96) Cross-sectional study 15 countries (Australia, Brazil, Canada, China, France, Germany, India,	An online survey of 18526 individuals globally analyzed intention to vaccinate and perceptions on the vaccine. Of these, 1000 participants were Canadian. Question Topics: 1) Vaccine intentions 2) Vaccine perceptions 3) Vaccine hesitancy	• 73% stated they would get a vaccine for COVID-19 if it were available. Compared to three months earlier (Aug), this is a 4% drop. • Intention has declined between Aug and Oct in 10/15 countries, most of all China, Australia, Spain, and Brazil. • Countries with the highest intent include India (87%), China (85%), South Korea (83%), and Brazil (81%). • France has the lowest intention to vaccinate (54%), followed by the USA (64%), and Spain (64%).

Italy, Japan, Mexico, South Africa, South Korea, Spain, UK, and USA) Oct 2020	Survey tools available? Yes Formative research conducted? Yes Survey pre-tested? Yes	• 52% indicated that they would become vaccinated within three months after vaccine becomes available to all. • 55% believe that a vaccine will not be available on the market until the third quarter of 2021. • Globally, the most common reasons for hesitancy include concerns about side-effects (34%), and concerns that clinical trials are moving too quickly (33%).
Mannan (2021) *preprint* (97) Cross-sectional study 60 countries: (Afghanistan, Algeria, Argentina, Australia, Bangladesh, Belgium, Bolivia, Botswana, Brazil, Canada, Chile, China, Columbia, Cuba, Dominican Republic, Ecuador, Egypt, El Salvador, England, Fiji, France, Germany, Guatemala, India. Italy, Jamaica, Japan, Kenya, Kiribati, Libya, Mali, Malaysia,	Sixty national representative online and telephone surveys were conducted capturing 26,852 responses from adults (19+) regarding vaccine acceptance and attitudes. Question Topics: 1) Vaccine intentions 2) Vaccine hesitancy 3) Vaccine attitudes Survey tools available? Yes Formative research conducted? Yes Survey pre-tested? No	• 62.6% of Canadians strongly accepted a COVID-19 vaccine which was the lowest acceptance recorded among countries in North America. • 65.5% strongly agreed that it was important to get a vaccine to protect others, 57.6% agreed that pharmaceutical companies will develop a safe vaccine, and 31.7% believed that vaccines were safer if they made in America or Europe rather than other countries. • Hesitancy was demonstrated with 48.7% worried about side effects, 44.7% worried about unforeseen impacts, 43.7% had concerns over commercial profiteering, 42.6% had general mistrust of vaccine benefits, and 34.6% had a preference for natural immunity. • Vaccine acceptance for each country: **Africa** Algeria (66.3%), Egypt (43.6%), Botswana (71.2%), Kenya (61.3%), Libya (49.6%), Mali (62.4%), Mauritius (82.8%), Morocco (48.4%), Nigeria (61.5%), South Africa (79.3%) **Asia** Afghanistan (47.2%), Bangladesh (49.8%), China (87.4%), India (73.9%), Japan (71.4%), Malaysia (52.7%), Saudi Arabia (51.1%), Singapore (66.8%), South Korea (76.2%), Turkey (59.2%) **Oceania** Australia (89.9%), Fiji (87.2%), New Zealand (88.4%), Kiribati (89.8%), Nauru (88.3%), Palau (89.2%), Papua New Guinea (91.9%), Solomon Islands (92.6%), Tonga (92.9%), Tuvalu (90.5%)

Mauritius, Mexico, Morocco, Nauru, New Zealand, Nicaragua, Nigeria, Palau, Panama, Papua New Guinea, Paraguay, Peru, Poland, Russia, South Africa, Saudi Arabia, Singapore, Solomon Islands, Spain, South Korea, Sweden, Switzerland, Turkey, Tonga, Tuvalu, United States of America, Uruguay, Venezuela) Jun-Sep 2020		**North America** Canada (62.6%), Cuba (77.9%), Dominican Republic (79.5%), El Salvador (71.8%), Guatemala (75.0%), Jamaica (71.0%), Mexico (73.3%), Nicaragua (81.2%), Panama (87.4%), United States (74.8%) **South America** Argentina (81.3%), Brazil (86.2%), Bolivia (82.8%), Chile (79.2%), Columbia (81.8%), Ecuador (70.2%), Paraguay (67.7%), Peru (77.8%), Uruguay (75.6%), Venezuela (74.8%) **Europe** England (69.3%), Belgium (60.4%), Germany (65.2%), Italy (68.4%), France (51.9%), Poland (52.3%), Spain (72.5%), Sweden (62.7%), Switzerland (60.2%), Russia (51.3%)
Lazarus (2020) (98) Lazarus (2021) (99) Cross-sectional study 19 countries: (Brazil, Canada, China, Ecuador, France, Germany, India, Italy, Mexico,	Vaccine acceptance rates and factors influencing acceptance of a COVID-19 vaccine was analyzed using an online survey of 13,426 adults. The data from this survey was analyzed differently in two publications. Question Topics: 1) Vaccine intentions Survey tools available? Yes	• 71.5% of participants reported that they would be "very likely" or "somewhat likely" to take a COVID-19 vaccine • 48.1% reported that they would accept their employer's recommendation to take the vaccine. • China (88.6%), Brazil (85.4%), and South Africa (81.6%) had the highest acceptance rates and Nigeria (58.9%), Poland (56.3%), and Russia (54.9%) had the lowest. • The acceptance rate in Canada was 68.7%. • Individuals aged 25+ were more likely to accept the vaccine than those aged 18-24. The strongest difference was seen (OR 1.73, 95% CI: 1.48-2.02)

Nigeria, Poland, Russia, Singapore, South Africa, South Korea, Sweden, UK, USA) Jun 2020	Formative research conducted? Yes Survey pre-tested? Yes	when responses from the oldest age cohort (65+) were compared to the youngest cohort (18-24). • People with higher education, women, those who earned more income, those who reported COVID-19 illness in the family, and those who trusted their government were more likely to accept the vaccine. • Having a high/very high education may be linked to lower vaccine acceptance in Canada, Spain, and the UK.

Emerging Evidence on COVID-19

Rapid Review on Protective Immunity

Introduction

Do antibodies to SARS-CoV-2 confer immunity against reinfection with SARS-CoV-2, is there long-term protective immunity (greater than 6 months post-infection) and does past infection with the original wild-type SARS-CoV-2 protect against the current variants of concern?

Understanding the extent and limits of protective immunity has important implications for the COVID-19 pandemic. Immunity arising from coronaviruses in general varies tremendously, from a few months for the seasonal coronaviruses associated with the common cold, to 2-3 years for the emerging coronaviruses such as SARS-CoV-1 and MERS (1). For SARS-CoV-2, it is known that most people develop immune responses after infection, however, for how long and to what extent this protects people from reinfection is not yet clear.

Reinfection with SARS-CoV-2 appears to be uncommon but there are challenges to studying this. RT-PCR testing is excellent for identifying the presence of virus in making the initial diagnosis, but it will also be positive in the presence of non-infectious virus particles (RNA fragments) so, on its own, it cannot confirm reinfection. To address this, several definitions of reinfection have been proposed both in the literature and by public health organizations (e.g., ECDC, PAHO). For the purposes of this review, confirmed reinfection is at least one documented negative RT-PCR test between episodes and genomic sequence data from both episodes to distinguish two different genetic clades or viral lineages (2). Suspected cases of reinfection are defined in this review as those with clinically or lab confirmed initial infection with a positive RT-PCR test >90 days from first episode or episodes occurring less than 90 days apart but with epidemiological evidence of re-exposure to SARS-CoV-2 (2, 3). There are also challenges in assessing long-term immunity from COVID-19. This arises from the fact that not all people who have positive antibodies for SARS-CoV-2 are immune and not everyone who has been diagnosed with COVID-19 develops antibodies after infection. Some people who are diagnosed with COVID-19 do not have detectable antibody levels but still recover, even when they have severe disease. This is likely influenced by strong cell-mediated immune responses, specifically from CD4+ and CD8+ T-cells that may contribute to long-term immunity against reinfection. Evidence suggests neutralizing antibodies and immune cell activity specific to SARS-CoV-2 are good indicators of protective immunity. A number of techniques and tests have been developed to measure immune responses. The variation and interplay of antibodies, B and T cell response to infection, and the variety of detection techniques available not only complicate the assessment of long-term immunity, it also complicates the question of whether immunity to the original wild-type SARS-CoV-2 protects against the current variants of concern.

This rapid review summarizes the evidence from the most recent studies on reinfection, persistence of antibodies and other immune markers for more than 6 months following initial SARS-CoV-2 infection and preliminary evidence on immunity against variants of concern published before February 11, 2021. Animal models of disease were not included.

Key Points

- Forty-nine studies were identified including fifteen recent cohort studies on risk of reinfection, twenty-one studies on the kinetics and durability of antibodies and other immunity markers at >6 months from initial SARS-CoV-2 infection, ten studies on antibody response or immunity and the new variants of concern and three relevant systematic reviews.
- Overall we found that the risk of reinfection was low, most people had markers of immunity at 6 months and in preliminary studies the B.1.351 variant was not as readily neutralized by convalescent sera.

Risk of reinfection:

- The best evidence to date on protective immunity comes from reinfection data reported in fifteen recently published cohort studies with both prospective and retrospective designs. More preliminary evidence from twenty-one case reports/series on risk of confirmed reinfection in 30 cases are reported in Appendix 1.
- The included studies report that previous infection resulting in antibodies seems to be associated with protection from reinfection for up to seven months.
- Cohorts that used only confirmed cases of reinfection in their risk estimates reported higher levels of protection (96-99%) (4-6) than those that included suspected cases of reinfection (83-94%) (7-11). This trend was echoed by the adjusted risk of reinfection estimates. In a cohort of confirmed reinfections from Qatar, the risk of reinfection was 0.01% (95%CI: 0.01-0.02%, n=133266). In cohorts of suspected reinfections from the UK and Mexico, the risk of reinfection was 0.7% (95%CI: 0.6-0.8, n=36,509) (12) and 0.26% (n=100,432) (13), respectively.
- The median time between initial infection and reinfection in the case reports (Appendix 1) was 81 days (range 13-250), in the confirmed reinfection cohorts it was 52-65 days (range 15-212) (5, 6), and in the suspected reinfection cohorts is was 56-172 days (range 40-227) (8, 13). The latter may have data points that are misclassified and instead represent re-positive results or recurrence, both of which have been reported in the literature.
- Based on both confirmed and suspected reinfection cohorts, individuals with evidence of previous infection had much lower attack rates of infection at follow-up up to 9 months compared to those who were seronegative or RT-PCR negative at baseline (0%-3.4% vs. 1.29%-28.7%) (4, 7, 9-11, 14-17). Several studies indicate that those who did not seroconvert may not have the same degree of protection from reinfection as those with high titers of antibodies (4, 14, 18). However, after reinfection the majority of cases showed an IgG response (14).
- Higher and prolonged IgG response was correlated with a lower risk of reinfection. Older age, duration of symptoms, and number of symptoms were correlated with higher IgG responses after primary infection (18).

Immune response markers >6 months post infection:

- Twenty-two recently published studies with follow-up of > 30 observations beyond 6 months post infection (up to 9 months) provide evidence to support immunity based on circulating antibody levels, B-cells and T-cells against SARS-CoV-2 (Table 2). The relationship between these correlates of immunity and protection against SARS-CoV-2 infection or reinfection by either wild type SARS-CoV-2 or emerging variants of concern are not fully understood.
- Eight studies report cellular immune response linked to memory B cells (i.e., immune cells that produce virus targeting antibodies) and T cells (i.e., immune cells that guide cell mediated adaptive immune responses) following a natural infection likely confer some long-term immunity to subsequent reinfections (1, 19, 20).
    - Memory B-cell and T-cell activity were elevated and expanded beyond 6 months post infection, which may be better measures of protective immunity compared to circulating antibodies that wane overtime after recovering from SARS-CoV-2 infection (21-24).
    - In 80% of individuals that had mild to moderate COVID-19, a high frequency of total memory B cells specific to the Receptor Binding Domain (RBD) of SARS-CoV-2 virus were identified (25).
    - CD8+ T cell activity was variable, and not directly comparable primarily due to differences in peptide sequences used in cell simulation. One study reported SARS-CoV-2 CD8+ T-cells to be detectable in 50% of cases between 6-8 months, while another study reported CD8+ T-cells memory responses to be significantly increased between 6-9 months post infection (21, 25). Whereas memory CD4+ T-cell activity continued to be detected in 92% of individuals between 6-8 months (25).
    - A single study reports a correlation between IgG and IgM seropositivity and CD8+ T-cell activity among those that had severe COVID-19 (23).
- Long-term trends in antibodies were described in twenty studies:
    - Eleven studies report the majority (>86%) of individuals remained positive for circulating SARS-CoV-2 specific neutralizing antibodies (NAb), S protein and/or RBD IgG antibodies ≥6 months from infection (18, 19, 24-27, 27, 28, 28-30).
    - NAb levels were higher and S protein IgG levels were lower than among severe COVID-19 cases when compared to those who experienced mild to moderate COVID-19 (18, 19, 24-27, 27, 28, 28-30).
    - Only 25-50% of participants remained positive for N protein antibodies (class variable or not specified) beyond 6 months (17, 17, 27, 29-31), which was comparatively less time than other virus targeting antibodies. (17, 27, 29, 30)

Immunity and new variants of concern:

- Preliminary experiments (n=10) on neutralization of the variants of concern have shown *in vitro* evidence that B.1.1.7 can be neutralized while B.1.351 is less likely to be neutralized by antibodies from wild-type SARS-CoV-2.

Reviews:

- Relevant rapid and systematic reviews include COVID-19 research up to June–September, 2020, on correlates of immunity from studies early in the pandemic. These are included as resources for research on time points earlier than 6 months.

Overview of the Evidence

Reinfection studies included prospective cohorts, some of which were large, multi-center studies that were at low risk of bias and have high generalizability. Multivariable analyses to account for potential confounding were not always conducted and this may bias the results. Retrospective cohorts of medical record data or routinely collected surveillance data on COVID-19 were also captured. Some of these studies appeared to have good generalizability as they represented large or national databases. Others were more focused on healthcare workers at a single center or specific patient groups. However, retrospective cohorts are at higher risk of bias due to the retrospective nature of the study, missing data, and confounding. The case reports/series included in the appendix are at high risk of bias due to selection bias and lack of a comparator group. However, they offer additional data on the case attributes and timing of reinfection.

The long-term immunity studies mainly included longitudinal evidence from observational studies, particularly of, prospective cohort, case series and cross-sectional design, which are at moderate to high risk of selection biases and confounding. For example, most studies reported clinical infection severity among study participants, but many do not appear to have considered differences in baseline immune status influenced by co-morbid conditions (e.g., cancer, heart conditions, kidney disease, diabetes, etc.) within study samples. Immune responses ≥ 6 months after a SARS-CoV-2 infection were highly variable across studies. Differences in study participant demographics, baseline immune status, clinical severity of infections, investigated immune outcomes, follow-up time and measurement methods likely contributed to observed heterogeneity. Variability may also come from the application of different antibody and immune cell detection methods with different test sensitivity and specificity parameters. All of these factors make it difficult to compare results across studies and introduce detection bias (29).

Preliminary evidence from *in vitro* studies using convalescent or vaccinated sera have examined the neutralization of variants of concern, mainly B.1.1.7 and B.1.351. These studies give us an early indication of potentially how well the circulating antibodies will recognise the variants, but they do not tell us how cross-reactive immune memory may be affected and their generalizability is limited. Additional research and monitoring of the convalescent and vaccinated populations will add further insight in the near future.

Knowledge gaps:

- Lack of high quality studies on the duration and efficacy of protection by neutralizing antibodies.
- Lack of understanding of how the immunological measures (e.g., neutralizing antibody titers) correlate to protection. Clinical effectiveness data is also needed to provide a definitive assessment of vaccine mediated protection.
- The role of specific antibodies, B cells and T cells in the elimination of infection have not been definitively identified in humans.
- Additional evidence is needed on variants of concern and the role of cross-reactive immune memory on reinfection from these variants.

CONTENTS

RISK OF REINFECTION

The European CDC has created a flowchart for assessing reinfection (2) and further definitions to differentiate confirmed reinfection from relapse/reactivation and recurrence have been proposed (3). The definitions used in this review are based on these published guidelines.

Confirmed reinfection requires: Confirmed initial infection by RT-PCR AND confirmed second infection by RT-PCR AND negative RT-PCR result(s) collected between first and second infection AND genomic sequence data from both episodes to distinguish two different viral isolates

Suspected reinfection requires: Positive RT-PCR test >90 days from first episode (either clinically or lab confirmed) OR <90 days between episodes but epidemiological evidence of re-exposure to SARS-CoV-2.

The best evidence to date on protective immunity comes from the few recently published cohort studies on risk of reinfection. Small case reports/series detailing suspected reinfections have been excluded, however, cases of confirmed reinfection have been summarized in Appendix 1. Studies of prolonged and recurrent infections are also excluded but have previously been summarized in an Infectious Period rapid review, available through the emerging science secretariat.

Results of reinfection cohort studies (n=15):

- Previous infection resulting in antibodies seems to be associated with protection from reinfection for up to seven months, however there has been a small proportion of people that have become reinfected. Reasons for reinfection or lack of protective immunity are not well understood.
- Only three studies calculated risk of reinfection estimates from confirmed reinfection cases. These studies reported a high estimate of protection against reinfection in cohorts from the UK (>96%) and Qatar (>99%) (4-6).
- Prospective cohorts of suspected reinfections from the UK and France suggest past SARS-CoV-2 infection provides protective immunity for up to 6 months in 83-90% of individuals (7-9). Retrospective cohorts from the USA and UK indicated 90-94% of previously infected individuals had protection for up to 6 months (10, 11).
- Risk of reinfection was low across studies based on large general population retrospective cohorts. In Qatar, the adjusted risk for confirmed reinfection was 0.01% (95%CI: 0.01-0.02%, n=133266) (5). Risk estimates were slightly higher in cohorts that included suspected reinfection: In the UK the risk was 0.7% (95%CI: 0.6-0.8, n=36,509) (12) and in Mexico the risk was 0.26% (n=100,432) (13).
- Time to reinfection was a median of 52-65 days (range 15-212) in the confirmed reinfection cohorts (5, 6) vs. 56-172 (range 40-227) in the suspected reinfection cohorts (8, 13). The latter may have data points that are misclassified and instead represent re-positive results or recurrence, both of which has been reported in the literature.
- Individuals with evidence of previous infection had much lower attack rates of infection at follow-up times of up to 9 months compared to those who were seronegative or PCR negative at baseline (0%-3.4% vs. 1.29%-28.7%) (4, 7, 9-11, 14-17). Several studies indicate that those who did not seroconvert may not have the same degree of protection from reinfection as those with high titers of antibodies (4, 14, 18). However, after reinfection the majority of cases showed IgG responses (14).
    - Healthcare workers with positive SARS-CoV-2 anti-spike IgG responses had lower rates of PCR-positive tests after 31 weeks of follow-up compared to healthcare workers with no IgG responses at the start of the study (0.13 vs. 1.09 per 10,000 days at risk) (7).
- Higher and prolonged IgG response was correlated with a lower risk of reinfection. Older age, duration of symptoms, and number of symptoms are correlated with higher IgG responses after primary infection (18).
- A surveillance study conducted in the UK, reporting a rate of suspected reinfection of 0.7%, found that reinfection was more positively correlated with the overall regional increase in cases rather than the regional increase in the B.1.1.7 percentage, indicating that the immunity built up from initial infection likely also provides protection against the B.1.1.7 variant (12).
- The symptomology reported during reinfection has been highly variable:

- One study found that patients with serious primary disease were more likely to develop severe symptoms during reinfection (13). However, as no mass screening was in effect, second-time asymptomatic cases of SARS-COV-2 infection are not likely to be identified. Many reports of reinfection may be biased toward identification of more severe cases.
- Another study found that 88.5% of cases had more symptoms upon reinfection than initial infection, however overall severity of symptoms was not reported (14).
- Two studies reported that reinfection was less severe than primary infections (5, 6).

Table 1: Cohort studies evaluating the risk of reinfection with SARS-CoV-2 (N=15)

STUDY	METHOD	KEY OUTCOMES
Confirmed reinfection (n=3)		
Jeffery-Smith (2021) (4) Outbreak investigation and longitudinal study UK Apr-Oct 2020	Two long-term care homes that had experienced an outbreak in the first wave of COVID-19 experienced a second outbreak. Outbreak investigations and SARS-CoV-2 serology were conducted to assess the role of prior antibodies in the protection against SARS-CoV-2 reinfection.	Nasal swabs -1.1% (1/88) of individuals that had confirmed previous SARS-CoV-2 exposure (either seropositive or PCR positive) from the first outbreaks (5 months earlier) became PCR-positive during the second outbreaks compared with 24.7% (18/73) of those with seronegative status after the first outbreaks. -Prior exposure had a protective effectiveness of 96.2% (95% CI: 72.7%–99.5%) against infections during the second outbreaks for an estimated risk ratio of 0.038 (95% CI: 0.005–0.273; p < 0.0001). -Whole genome sequencing found that the second COVID-19 outbreaks were caused by SARS-CoV-2 strains that were genetically different from their respective first outbreaks.
Abu-Raddad (2021) (6) *Preprint* Retrospective cohort study Qatar Apr-Dec 2020	SARS-CoV-2 antibody-positive persons with a PCR-positive swab ≥14 days after the first-positive antibody test were followed for a median of 17 weeks (range: 0-45) for evidence of reinfection (n=43,044). Seronegative individuals (n=149,923) were also followed for incidence of infection. Viral	Nasopharyngeal and oropharyngeal swabs -314 seropositive individuals had a PCR-positive swab ≥14 days after the first-positive antibody test. - 32/314 suspected cases had good evidence for reinfection (Ct ≤30 for reinfection swab), 97 cases with some evidence (Ct >30 for reinfection swab), while evidence was weak for the remaining 185 cases. -For cases with good evidence for reinfection (32/314, 10.2%), the median time between the first-positive antibody test and the reinfection swab was 52 days (range: 15-212 days). Reinfections were less severe than primary infections. -Genome sequencing demonstrated that 5/16 cases, for which paired specimens were available, were confirmed reinfection for a confirmation rate of 31.6%.

	genome sequencing was conducted for paired viral specimens (n=16) to confirm reinfection.	-The reinfection risk among antibody-confirmed cases was 0.10% (95% CI: 0.08-0.11%) and the reinfection incidence rate was 0.66 per 10,000 person-weeks (95% CI: 0.56-0.78). -The infection risk for seronegative individuals was estimated at 2.15% (95% CI: 2.08-2.22%), with an infection incidence of 13.69 per 10,0000 person weeks (95% CI: 13.22-14.14) -A decreasing trend in the incidence rate of reinfection with each additional month of follow-up demonstrated that protective immunity did not wane over the seven months. -Efficacy of natural infection against reinfection was estimated to be 95.2% (95% CI: 94.1-96.0%).
Abu-Raddad (2020) (5) *Preprint* Retrospective cohort study Qatar Feb-Aug 2020	All SARS-CoV-2 laboratory-confirmed cases with at least one RT-PCR positive swab that was ≥45 days after a first-positive swab were individually investigated for evidence of reinfection (n= 133,266 cases). Viral genome sequencing of the paired first-positive and reinfection viral specimens was conducted to confirm reinfection in a small subset of cases (n=12).	Nasopharyngeal and oropharyngeal swabs -243 persons (0.18%) had a subsequent positive swab ≥45 days after the first-positive swab. Of these, 54 cases (22.2%) had strong or good evidence for reinfection (PCR positivity was associated with contextual evidence supporting the status of reinfection). -Median time between first and reinfection swab was 64.5 days (45-129, range). -Only one person was hospitalized at time of reinfection, this case only had mild infection. -Only four cases of reinfection were confirmed by viral genome sequencing. -Risk of reinfection was estimated at 0.01% (95% CI: 0.01-0.02%) and incidence rate of reinfection was estimated at 0.36 (95% CI: 0.28-0.47) per 10,000 person-weeks. -The authors conclude that reinfection is a rare phenomenon and immunity against reinfection likely lasts at least a few months after first infection.
Suspected reinfection (n=12)		
Lumley (2020) (7) Prospective cohort study UK Apr-Nov 2020	Followed asymptomatic and symptomatic staff (n=12,541) at Oxford University Hospitals for up to 31 weeks to estimate the relative incidence of PCR-positive test results and new symptomatic infection according to antibody status.	Nasal and oropharyngeal swab -Health care workers with positive SARS-CoV-2 anti spike IgG assays at baseline have lowers rates of PCR-positive tests at follow up than workers with negative baselines results (0.13 vs 1.09 per 10,000 days at risk). -The incidence of positive PCR tests was inversely associated with anti-spike antibody titers, suggesting previous infection resulting in antibodies to SARS-CoV-2 is associated with protection from reinfection for at least 6 months. -Of the three seropositive health care workers that had subsequent PCR-positive tests for SARS-CoV-2 infection, only one had previously tested positive for SARS-CoV-2, 190 days

		prior. This case was asymptomatic upon possible reinfection, with negative RT-PCR tests 2 and 4 days later and no subsequent rise in antibody titers -Reinfection results could be consistent with a re-exposure to SARS-CoV-2 that did not lead to symptoms but could also plausibly have been a false positive. Caution should be used when interpreting the results of this study.
Hall (2021) (8) *Preprint* Prospective cohort study UK Jun-Nov 2020	Asymptomatic and symptomatic staff (n=20,787) working at hospital sites participating in the SARS-CoV-2 Immunity and Reinfection Evaluation (SIREN) Study were followed for 5 months to estimate the relative incidence of PCR-positive test results according to baseline antibody and/or PCR results.	Swab type not specified -6,614 (32%) participants had evidence of prior infection and were assigned to the positive cohort, 14,173 (68%) participants that had no evidence of prior infection were assigned to the negative cohort. -On follow-up, 409 new infections in the negative cohort and 44 reinfections were identified. Of these, 22% of new infections and 66% of reinfections were asymptomatic. -The incidence density was 3.3 and 17.0 for new RT-PCR positive infections per 100000 days follow-up. -The cumulative incidence for probable, possible, and all reinfections was 0.3, 2.3 and 6.7 per 1,000 participants, respectively, whereas all new infections were 22.4 per 1000 participants. -Previous infection was found to have a significant protective effect. Considering only probable reinfections, the participants in the positive cohort had a very low odds of reinfection (adjusted OR: 0.01, 95% CI 0.00-0.03). The adjusted OR considering both probable and possible reinfections was 0.17 (95% CI 0.13-0.24). -The median interval between the historic PCR positive date or date of primary infection and the reinfection PCR positive date was 162 days (95-223) or 172 days (90-227), respectively.
Dimeglio (2021) (9) *LTE* Prospective cohort study France Jun-Dec 2020	Healthcare workers (n=8758) were screened for serum SARS-CoV-2 anti-spike antibodies and neutralizing antibody titers after the first wave of epidemic (June/July). Serology was investigated over time and new infections were identified during follow-up in Nov/Dec.	Swab type not reported -The median follow-up was 167 days (IQR:156-172). -Among the seropositive group, 1.8% (5/276) were positive at follow-up compared to 12.1% (1028/8482) of the seronegative group ($p<0.01$). -The five individuals who tested seropositive at baseline and then experienced infection during follow-up included two with low/undetectable neutralizing antibody titers after the first infection, and three with above-median titers. -The data indicate that previous infection provided protective immunity for at least 167 days.
Clarke (2021) (17)	Longitudinally screened patients	Nasopharyngeal swab

Preprint Prospective cohort study UK Feb 2020-Jan 2021	receiving in-centre haemodialysis (n=356) for SARS-CoV-2 seropositivity (anti-NP or anti-RBD antibodies) and RT-PCR positivity. Recorded positive PCR test results at >60 days following a positive serological test at baseline, to prevent capture of persistent viral detection rather than reinfection.	-Patients with initial seropositive results were significantly less likely to test positive by PCR at follow up compared to patients that were initially seronegative: 3.4% (5/129) vs. 13.2% (30/227), p<0.005. -Immune responses to natural SARS-CoV-2 infection in haemodialysis patients lasted for up to 6 months, even in patients who had mild or asymptomatic infection.
Dobaño (2021) (18) *Preprint* Prospective cohort study Spain Mar-Nov 2020	Evaluates the seroprevalence and levels of antibodies 149-270 days after the onset of symptoms in a cohort of 173 primary health care workers with confirmed infection (via RT-PCR) at the first peak of the pandemic (March-April 2020). Three venous blood collection time points between September and November 2020 were used in assessing immunity and possible reinfection among these healthcare workers as part of a 1.5 year long cohort study.	-The percentage of seropositivity at follow-up combining RBD and S antigens was 60.69% for IgM, 76.30% for IgA, and 90.17% for IgG. -2.3% reinfections (4/173). Two symptomatic cases were seronegative prior to reinfection, one asymptomatic case was seropositive, and one had unknown serostatus. Reinfections occurred between 3-8 months post initial infection. -Having been admitted to hospital, presenting with fever, anosmia and/or hypogeusia, and previous allergies were associated with higher levels of antibodies during follow-up (5-9 months later). -Older age, duration of symptoms, and number of symptoms correlated with higher IgGs.
Graham (2021) (12) *Preprint*	General population longitudinal data that was prospectively collected using the	Swab type not reported -304 individuals reported two positive tests separated by more than 90 days, 249 of which had a symptom free period between

Longitudinal surveillance study UK Sept-Dec 2020	COVID Symptom Study app was combined with surveillance data from the Covid-19 UK Genetics Consortium to study rate of reinfection, as well as other COVID-19 disease characteristics. Reinfection was defined as two RT-PCR positive tests separated by more than 90 days with an asymptomatic period for more than seven days between PCR tests. Assessed risk of reinfection for the new variant B.1.1.7 by calculating the correlations between number of possible reinfections and the proportion of new variant cases over time.	the two tests, for a rate of reinfection estimate of 0.7% (95%CI: 0.6-0.8) (249/36,509). -Reinfection rate did not vary across regions or time. -Reinfection was more positively correlated with the overall regional increase in cases rather than the region increase in the B.1.1.7 percentage, indicating that the immunity built up from the initial infection may also provide protection against the B.1.1.7. variant.
Ali (2020) (14) *Preprint* Retrospective Cohort Iraq May-Oct 2020	To investigate the impact of the immunoglobulin (IgG) level on reinfection in recovered COVID-19 patients (n=829 patients admitted between May and Oct to a single center), IgG levels against SARS-CoV-2 were measured just following recovery (a negative RT-PCR result defined as a Ct-value >36.7) and patients were	Pharyngeal swabs -Of the 87 patients that tested negative for IgG following initial recovery, 25 (28.7%) were considered reinfected, confirmed by positive RT-PCR result. This was higher than in the group of 742 patients that tested positive for IgG following initial recovery (1/742, 0.13%). This suggests that patients with low IgG levels following initial infection may be more susceptible to reinfection. -The occurrence of reinfection in the group ranged from 26 to 138 days after recovery from the initial infection. -88.5% of cases had more symptoms upon reinfection than initial infection, however overall severity of symptoms was not reported. -95% of cases were positive for IgG following reinfection. -Result are preliminary and methods were poorly described in this study. It is unclear if patients were enrolled and prospectively followed or whether reinfection status is based on

	presumably followed to assess reinfection.	medical records. Caution should be used when interpreting the results of this study.
Harvey (2020) (10) Retrospective cohort study USA Jan-Aug 2020	Analysis of a national sample from a de-identified dataset based on commercial laboratory tests and medical claims and records (n= 3 257 478). Patients were identified at baseline as either SARS-CoV-2 antibody-positive or antibody-negative then assessed in 30 day intervals (up to >90) for nucleic acid amplification test (NAAT) positivity.	Swab type not specified -Seronegative patients (n=2,876,773) were followed for a median of 47 days (IQR: 8-88) and seropositive patients (n=378,606) were followed for a median of 54 days (IQR: 17-92). - 18.4% of patients converted from seropositive at baseline to seronegative during follow-up of 90 or more days after first antibody test. -Patients who were seropositive and had a NATT test during follow-up (n=41587) were at a decreased risk of SARS-CoV-2. NAAT positive: 2.7% from 31 to 60 days, 1.1% from 61 to 90 days, and 0.3% at more than 90 days. Whereas approximately 3% of individuals who were seronegative had a NAAT positive test during each follow-up period. -This corresponds to a ratio of positive NAAT results among patients who had a positive antibody test at index vs those with a negative antibody test at index: 0.67 (95% CI: 0.6-0.74) at 31 to 60 days; to 0.29 (95% CI: 0.24-0.35) at 60 to 90 days; and to 0.10 (95% CI: 0.05-0.19) at more than 90 days.
Breathnach (2021) (11) *LTE* Retrospective cohort study UK Feb-Dec 2020	Analyzed laboratory data to compare risk of having a positive SARS-CoV-2 PCR assay in the second wave of the pandemic between patients who had evidence of COVID-19 (PCR positivity or seropositivity) in the first wave of infections (n=10,727) vs. patients who had a previous negative PCR or antibody test (n=55,274). Cases where the second positive result occurred ≤ 90 days from the first wave were excluded.	Swab type not reported -Only eight patients with evidence of past COVID-19 had a positive PCR result during the second wave (0.07%, 8/10,727). PCR positivity was higher during the second wave for patients with no evidence of COVID-19 in the first wave (1.29%, 713/55,274). -This implies a protective effect and relative risk of 0.06 (95% CI: 0.03-0.12) for those with evidence of infection in the first wave.
Hanrath (2020) (16)	Analysis of healthcare worker testing data	Nasopharyngeal and oropharyngeal swabs

Preprint Retrospective cohort study UK Mar-Nov 2020	during an initial (Mar 10-July 6, 2020) and following second wave (July 7-Nov 20, 2020) of the pandemic, to address the question of whether previous SARS-CoV-2 infection was associated with protection. The primary endpoint for analysis was symptomatic SARS-CoV-2 infection confirmed by RT-PCR during the second wave. Asymptomatic PCR screening was also conducted on a pilot basis.	-1038 HCWs with evidence of previous infection (positive PCR and/or Ab) and 10,137 without (negative Ab, without positive PCR) were identified during the first wave. -During the second wave, 2243 healthcare workers underwent PCR testing for symptoms. 128 of which had previous confirmed infection and 2115 did not. -No reinfections were identified in those with previous infection (test positivity 0%) during second wave follow-up median 173 (IQR: 162–229) days, while test positivity for those without previous infection was 13.7% (290/2115, 95% CI: 12.3–15.2). -Considering the population as a whole, test positivity was 0/1038 (0% [95% CI: 0–0.4) for those with previous infection, compared to 290/10,137 (2.9% [95% CI: 2.6–3.2) for those without (P<0.0001). -Similar results were found in the asymptomatic pilot test: no positive results in the group with previous infection 0/106 (0%, 95% CI: 0–3.5), compared to 22/375 (5.9%, 95% CI: 3.9–8.7, P = 0.011) positive PCR results in the group without previous infection.
Murillo-Zamora (2020) (13) *Preprint* Retrospective cohort Mexico Mar-Jul 2020	RT-PCR was performed on samples from 100,432 patients. Reinfection was defined by the reappearance of COVID-19 symptoms at 28+ days from the first positive COVID-19 test. Clinical and epidemiological data of interest were obtained from medical files and death certificates. Linear regression models were used to evaluate factors associated with the risk of severe symptomatic SARS-CoV-2 reinfection.	Nasopharyngeal or deep nasal swabs -258 laboratory-confirmed cases of 'reinfection' were identified (0.26%). -Time between first and second time episodes was 56 days (IQR: 40-81). No significant differences were observed between patients with non-severe and severe primary disease. -When severe and non-severe second-time infections were compared, patients with more serious primary disease were more likely to develop severe symptoms (39.5% vs. 5.5%, p <0.001), as well as those aged 50 years old or above (52.6% vs. 12.3%, p < 0.001). -In multiple analyses, factors associated with more severe symptomatic reinfection were increasing age, personal history of obesity, asthma, type 2 diabetes mellitus and chronic kidney disease. -Subjects with previous severe COVID-19 had a 20% increased risk of also presenting severe symptoms during secondary disease.
Xu (2020) (15)	COVID-19 patients (n=185) who had	Pharyngeal and anal swabs

Retrospective cohort study China Jan-Apr, 2020	undergone antibody testing were followed up every two weeks to assess immune responses (IgG and IgM) and reinfection over time. The mean follow-up time was 45.7 days.	-No reinfection or evidence of transmission occurred in any patient after discharge. -Of the 35 IgM positive cases, 12 cases turned IgM negative during the follow up. -There were 154 (82.4%) patients with positive IgG results and 33 (17.6%) patients with negative IgG results at 53 days from disease onset. Compared with the IgG negative group, the IgG positive group patients were older, had a longer hospital stay, higher proportion of antibiotic use, higher proportion of severe cases, and higher proportion of CT abnormalities.

LTE= letter to editor, RBD= receptor binding protein

LONG-TERM (>6 MONTHS) IMMUNE RESPONSE MARKERS

This section summarizes twenty-one studies that report immune responses measured ≥ 6 months (up to 9 months) following SARS-CoV-2 infection in studies with >30 observations. Twenty studies reported on circulating antibody levels and eight studies reported on long-term immune responses linked to B-cells and/or T-cells. The majority of included studies (n=19) were prospective cohorts or case series that followed the serology of RT-PCR confirmed COVID-19 cases over time, while the remaining studies were cross-sectional (n=3).

Overall, there was a lot of variability across studies due to differences in study participants, COVID-19 infection severity, frequency and duration of follow-up, investigated immune outcomes and measurement methods, which limit the synthesis of results across studies. Furthermore, the association between detectable immune response markers and protection against re-infection from both the wild-type and emerging VOC is largely unknown.

Key outcomes from B-cell and T-cell immune responses at ≥6 months post infection (n=8):

- Memory B cells (i.e., immune cells that produce virus targeting antibodies) and memory T cells (i.e., immune cells that guide cell mediated adaptive immune responses) following a natural infection likely confer some long-term immunity to reinfection (1, 19, 20). The viral antigen targets, activity, and counts of these memory cells were most frequently measured by flow cytometry cell analysis techniques and various assays. The variability of molecular biology techniques and the viral antigen markers used across studies limit the comparability of study results (17, 21-23, 23-25, 30, 32).
- B-cells are immune cells responsible for the production of antibodies targeting SARS-CoV-2 antigens (1, 19, 20). B-cells can be broadly classified into antibody secreting cells (plasma cells) and memory cells (20). Activated plasma cells produce and secrete circulating antibodies targeting SARS-CoV-2 antigens, while the latter do not actively secrete antibodies but retain the memory to protect against subsequent infections and establish long-term immunity (20).

- Four studies measure and report on B-cell activity alongside circulating antibodies beyond 6 months of infection (23-25, 30). Flow cytometry was the most frequently applied method for detecting B-cell specificity and activity.
    - Memory B-cells specific for S and N proteins, and RBD, viral antigens, were detected in participants at post-infection follow-up beyond 6 months and findings were that the cell counts remained stable or increased in abundance and B-cell clones expanded and matured (23-25, 30).
    - 80% (n=29/36) of mild to moderate COVID-19 cases had high frequencies of total memory B-cells specific to RBD antibodies (IgG+, IgM+, or IgA+) (25) beyond 180 days post infection.
    - In a cohort of previously hospitalized COVID-19 cases B-cell percentages were reported to be highest among IgG and IgM antibody negative participants (range 16.1 ± 6.4 to 16.7 ± 5.5) compared to IgG and IgM positive individuals (range 7.2 ± 3.1 to 7.5 ± 3.8) (23).
    - A single study notes the reduction of S protein antibody secreting B-cells and an increase in memory B-cells targeting SARS-CoV-2 viral antigens, in both severe and mild COVID-19 cases (30). This study also reported SARS-CoV-2 RBD B-cells were minimally cross-reactive with other human coronavirus antigens (30).
- T-cells are immune cells classified by surface receptors CD4+ or CD8+. The primary role of T-cells can be separated into the production of antibodies via B-cell activation (CD4+ T-cells) or the destruction of infected cells presenting certain antigens (CD8+ T-cells) (20, 33). Most of the included studies measured T-cell activity based on simulation by SARS-CoV-2 peptide sequences. The variability and/or the lack of detail on peptide sequences used in simulation studies limit the comparability of study results.
- Six studies report on T-cell outcomes in previously infected cases beyond 6 months post infection (17, 21-23, 25, 32). These studies isolated peripheral blood mononuclear cells from serum samples and analyzed T-cell activity by flow cytometry and/or the simulation of isolated cells with pools of SARS-CoV-2 peptide sequences (i.e., amino acids that make up viral proteins).
    - T-cell responses were highly variable. Generally, the breadth and magnitude of memory T-cell responses increased as time from symptom onset increased and circulating IgG and IgM antibodies waned (21-24).
    - CD8+ T-cells were found to be less robust than CD4+ T-cell responses beyond 6 months from infection in some studies (21, 25, 32). CD8+ T-cell activity was detected in 50% of mild to moderate cases at 6-8 months post infection, while memory CD4+ T-cell activity continued to be detected in 92% of individuals in the same sample (25). Another study found memory CD8+ T-cells to have increased between 6-9 months post infection (21).
    - One study found CD8+ T-cell activity to be correlated with IgG and IgM seropositivity throughout the course of COVID-19 infection in a sample of severe COVID-19 infections (23).

Key outcomes from circulating antibodies immune responses at ≥6 months post infection (n=20):

- Humoral immunity, also called antibody mediated immunity, generally refer to circulating antibodies that are directed at viral antigens (1, 19, 20). Among included studies, circulating antibodies in serum samples were measured by antibody affinity assays, pseudovirus neutralization assays, flow cytometry, and other molecular biology based techniques. The range of reported antibody outcomes included total antibodies, neutralizing antibodies (NAb), antibody class (i.e., IgG, IgM, IgA) which were frequently further described by subclass (i.e., IgG1, IgG3) and/or binding affinity to SARS-CoV-2 viral antigens. Many studies often specified the viral antigen targets of the measured Ig antibodies, which include viral structural proteins: spike (S) protein, S1 or S2 subunit of the S protein, nucleocapsid (N), envelope (E), membrane (M) proteins, receptor binding domain (RBD) proteins, and accessory proteins (i.e., open reading frame (ORF) proteins).
- Studies found SARS-CoV-2 specific antibodies to be detectable in the majority of previously infected individuals beyond 6 months from infection, but seroprevalence of different antibody types was variable. Longitudinal trends in antibody ≥ 6 months post infection across include studies are outlined below, by viral antigen specificity and clinical severity.
- Neutralizing antibodies (NAb) target the SARS-CoV-2 S protein and/or the RBD to neutralize the binding of the virus to ACE2 receptors of potential host cells (27, 28, 34, 35). NAb were detected in ~ 91% of mild cases at 6 months post infection (25, 29); levels remained elevated among individuals with severe COVID-19, in comparison to individuals with less severe disease (24, 26).
- S protein IgG levels were consistently high and detectable across studies, and stable or elevated in 86%-99% of those with less severe infections (18, 19, 25, 27, 27, 28, 28-30). The long-term maintenance of S protein IgG in serum beyond 6 months of infection appears to be reduced among those with severe infection (26, 36).
- RBD IgG antibodies and S protein IgG antibodies were detected in 88-90% of mild to moderate COVID-19 cases, as well as among hemodialysis patients (17, 18, 25). A study quantifying the decrease in antibody levels between baseline and 6 months post infection in mild to moderate cases reported the following reductions, 15% RBD IgA, 33% RBD IgG, and 53% RBD IgM (24).
- Multiple studies confirm the correlation between RBD Ig antibodies (all Ig classes), and the neutralization activity targeting SARS-CoV-2 (27, 28). This association was consistent among those with mild to moderate and severe infections.
- Generally, N protein antibodies (class variable or not specified) appeared to reduce and wane relatively more rapidly than NAb, S protein, RBD antibodies (17, 27, 29, 30). Less than 25-50% of participants remained positive for N protein antibodies (class variable or not specified) beyond 6 months after infection, and reductions do not appear to be linked to infection severity (17, 17, 27, 29-

31). The half life of N protein IgG antibodies was estimated to range from 59-68 days (95% CI 55-90 days), much shorter than the estimated half lives of other antibodies (25, 26).

  - A single study reports the persistence of high N protein Ig levels at approximately 5 months post infection to may be associated with long term effects of COVID-19, such as fatigue, anosmia and ageusia (22).

- One study compared circulating antibodies between infected children and adults (37). Children had lower levels of antibodies against S and N proteins (Ig class of measured antibodies could not be identified) and the proportion of global antibodies against accessory proteins were greater and more stable among children than adults (37).

Table 2: Immune responses more than 6 months after SARS-CoV-2 infection (n=21)

STUDY	METHOD	KEY OUTCOMES
Circulating Antibody, B-cell and T-cell Immune Responses		
Dan (2021) (25) Cross-sectional USA Mar – Nov 2020	Assessed protective immune responses, based on memory CD4+ T-cell, CD8+ T-cell, B-cells, and antibody levels, among RT-PCR confirmed COVID-19 convalescent cases (n=188); 93% of participants were not hospitalized. Some serum samples (n=43/188) were collected between 6 to 8 months after infection. ELISA, pseudovirus neutralizing antibody assays, flow cytometry were applied to detect antibodies and immune cell frequencies and activities. SARS-CoV-2 memory CD8+ T-cells were measured using a series of peptide pools covering the entirety of the SARS-CoV-2 open reading frames (ORFs), most common were S protein, M protein, N protein and ORF3a.	Immune outcomes at 6-8 months post infection identified in the study: Antibody dynamics - S protein IgA was detectable in the majority of participants. - S protein IgG, RBD IgG titers demonstrated modest declines but were relatively stable. - The proportion of participants positive for S protein IgG decreased from 98% (54/55) to 90% (36/40), from one month to 6-8 months post infection. - 88% (35/40) of participants were positive for RBD IgG. - 90% (36/40) of participants were positive for NAb. SARS-CoV-2 specific memory B-cell activity - Memory B-cells specific for the S protein, N protein, RBD, viral antigens were detected in almost all participants, and were more abundant at post-infection follow-up. - 80% (n=29/36) had higher frequencies of total (IgG+, IgM+, or IgA+) RBD memory B cells (25) were present at beyond 180 days post infection. SARS-CoV-2 specific memory T-cell activity - 70% (40/57) of participants had CD8+ T-cells at 1 months post infection, while 50% (18/36) of

		participants were positive for these cells at more than 6 months post infection. - 93% (53/57) of participants had memory CD4+ T-cells at 1 month post infection, while 92% of (33/36) of participants were positive for these cells at more than 6 months post infection. In summary, while there was heterogeneity of immune responses associated with circulating SARS-CoV-2 antibody levels, cellular immunity through stable memory B-cell and T-cells was established beyond 6 months post infection.
Shen (2021) (23) Case series China Jul- Aug 2020	Serum samples were collected at multiple time points post admission to rehab (i.e., 0, 2 and 4 weeks) from a group of previously infected participants (n=110) whose hospital discharge from acute SARS-CoV-2 was a minimum of 6 months prior. Infections were confirmed by RT-PCR. Serum IgM and IgG antibodies, IL6, CD3+, CD8+, CD4+ T-cells , NK cell and B cell levels were measured by assay and flow cytometry. Notable differences in the percentage of serum CD3+ , CD8+ and CD4+ T-cells , NK cells and B cells (no additional details provided), by IgM and IgG antibody positivity were confirmed by correlation analysis.	- Overall, 29.1% (32/110) participants were positive for IgM and IgG antibodies, 34.5% (38/110) were only IgG positive, 36.4% (n=40) were negative for both IgM and IgG antibodies. - No significant differences in demographics, clinical presentation or co-morbid conditions could be identified between the antibody positive and negative groups. T-cell dynamics, 6+ months post hospitalization, by antibody positivity: - CD8+ T-cell decreased slightly over the sampling period. - CD8+ T-cell percentage was greatest (range from 48.6 ± 7.3 to 43.7 ± 9.7) among IgG and IgM antibody positive participants at all follow-up time points. - CD8+ T-cell percentage was lowest (range from 25.5 ± 9.3 to 25.9 ± 10.1) among IgG and IgM antibody negative participants. - NK-cells increased slightly over the sampling period. - Increase in NK cells percentage was highest among IgG and IgM antibody negative participants at all follow-up points (range 25.7 ± 6.3 to 27.1 ± 8.3), and lowest among IgG and IgM positive participants (range 13.7 ± 7.4 to 15.0 ± 9.6). B-cell dynamics, 6+ months post hospitalization, based on antibody positivity:

		- B-cell levels remained stable among antibody positive and antibody negative participants, but significantly increased among IgM negative and IgG positive participants during follow-up time points. - B-cell percentages were highest among IgG and IgM antibody negative participants (range 16.1 ± 6.4 to 16.7 ± 5.5) compared to IgG and IgM positive individuals (range 7.2 ± 3.1 to 7.5 ± 3.8). - The authors conclude loss of IgM antibodies in serum led to gradual improvements in cellular immunity linked to NK and B-cells. The authors suggest serum lymphocyte percentages (CD3+, CD8+ and CD4+ T-cells , NK cells and B lymphocytes) to be correlated with changes in serum IgM and IgG antibody levels, but not related to inflammatory cytokines or the severity of infection (i.e. Hs-CRP or IL6), among previously hospitalized and recovered patients.

Gaebler (2020) (24)
 	
Case series
 	
USA
Apr-Oct 2020
	Serum samples from seroconverted SARS-CoV-2 cases (n=87) were collected at 1.3 and 6.2 months (range 165-223 days) post infection. Infection and seroconversions were confirmed by RT-PCR, and 10% of the sample was hospitalized for infection. RBD IgG, IgM, IgA antibody, NAb levels were measured by ELISA and pseudovirus neutralization assay. B-cell levels and activity was measured by flow cytometry.	RBD antibody levels were significantly reduced at 6 months post infection. Overall, antibody reductions were inversely proportional and directly correlated with initial antibody levels (i.e., individuals with the highest antibody levels during early infection experienced the greatest decrease).
		- Antibody dynamics at 6 months post infection identified in the study:
		  - RBD IgM reduced by 53%
		  - RBD IgG reduced by 33%
		  - RBD IgA reduced by 15%
		  - NAb activity demonstrated a 5 fold reduction
		The number of RBD-specific memory B-cells in the majority of individuals remained unchanged. However, these cells did display maturation, varied clonal expansion and turnover between 1.3 to 6.2 months post infection.
		The authors conclude the observed changed among memory B-cells to be suggestive of long-term immunity, as well as the ability to mount

		rapid and effective immune responses to reinfection.
Sokal (2020) (30) Case series France Mar 2020	Serum samples from infected individuals (n=39) were collected at three time points, in the first month following symptom onset, at 3 months and 6 months post symptom onset. Approximately 53% (n=21) of the sample experienced severe infection. N protein, S protein, RBD IgG antibody levels were measured by ELISA. Virus antigen specific memory B-cell responses were measured by ELISA B-cell receptor sequencing and flow cytometry.	Immune outcomes up to 6 months post symptom onset identified in the study: Antibody dynamics: - N protein IgG antibodies underwent a rapid decrease in both mild and severe cases. This reduction was more pronounced among mild cases, and N protein IgG titers were undetectable in 50% on the mildly symptomatic participants by 6 months. - S protein IgG antibodies were stable overtime, only 9% of mild cases had undetectable antibody levels at 6 months follow up. The antibody levels were significantly higher at 3-6 months post infection follow-up among participants with severe infections. B-cell activity: - S protein and RBD specific B-cell clones, as well as cross-reactive B-cell clones from previous beta-corona virus exposures underwent somatic maturation and significant expansion. - S protein antibody secreting cells were marginally detectable at 6 months, at which time point S protein B-cells mostly resided in the CD21+CD27+CD38-CD71int/- resting memory B-cell compartment in both severe and mild. - Active B-cells remained detectable up to 6 months post infection. These B-cell clones are assumed to contribute to long-term immunity in convalescent patients.
Bilich (2020) (22) *Preprint* Case series Germany *Spring 2020	Convalescents with mild to moderate infection (n=51) were longitudinally followed up at approximately 1 month (median 40 days; range 35-56 days) and 5 months (median 159 days; range 141-183 days) post positive RT-PCR results. T-cell activity was measured by IFN-g ELISPOT assays and single epitope	Antibody dynamics at approximately 5 months post RT-PCR results identified in the study: - A greater than two fold decrease in S protein IgG and IgA antibodies was noted among 31-44% of participants, between the two follow-up time points. - A less than 2 fold reduction in N protein antibody levels were noted in 13% of participants up to second follow-up.

	mapping. IgG and IgA antibody levels were measured by immunoassay.	- High N protein antibody titers, at 5 months post infection, were associated with higher prevalence of post-infection symptoms, such as fatigue, anosmia and ageusia. T-cell immune responses at 5 months post infection: - The percentage of participants with detectable T-cells specific to viral antigens increased from 93% to 100% by the second follow up time point. A sub-group of T-cells targeting specific viral ORF derived epitopes (HLA-DR epitopes; HLA class 1 epitopes), associated with long-term post infection immunity against SARS-CoV-2, persisted among participants up to at 6 months post infection.
Clarke (2021) (17) *Preprint* Prospective cohort UK Feb 2020 - Jan 2021	Hemodialysis patients with end stage kidney disease were screened for SARS-CoV-2 antibodies and the results in this paper are for antibodies at time 0 (n=356) and 6 months (n=301). Infection was confirmed by PCR. N protein and RBD IgG antibodies were measured by CIMA and ELISA assay. T-cell activity was measured by ELISPOT assay in participants who had seroreverted at 6 months (n=11). Clinical severity of infection among participants followed-up at 6 months was not provided.	190 were negative for N protein antibodies and 129 were positive for N protein antibodies at time 0. At 6 months samples were available for 111/129 N protein antibody positive group to examine long-term immunity: - N protein IgG antibodies could not be detected in 36% (n=40) of the initially positive participants. - RBD IgG antibodies were more persistent than N protein IgG antibodies, 87% (n=97) of the initially seropositive sample remained positive for RBD IgG antibodies (including 70% (n=28) of individuals who were negative for N protein IgG). - 64% (n=71) of participants continued to be seropositive for N protein antibodies, but levels were significantly lower in comparison to initial screening point ($p<0.0001$). - 10% (n=12) of the initially seropositive participants were seronegative for RBD and N protein antibodies, but 80% of these individuals demonstrated SARS-CoV-2 antigen specific T-cell activity.
T-cell Immune Responses		
Breton 2020 (32)	Paired serum samples were collected from SARS-CoV-2 positive participants (n=41),	Compared to uninfected participants, significant shifts in circulating CD4+ and CD8+ T-cell

Prospective cohort USA Mar-Oct 2020	who had mainly mild disease, up to 6 month post infection. Infections were confirmed by RT-PCR. Serum samples from infected participants were compared to uninfected individuals (n=20). T-cell phenotypes and SARS-CoV-2 antigen specificity were measured by flow cytometry, ELISPOT and other assays.	compartments which persisted for 6 months after SARS-CoV-2 infection, was noted. SARS-CoV-2 T-cell activity up to 6 months after infection: - Both CD8+ and CD4+ T-cell proportions returned to near physiologic levels by 6.1 months - Antigen specific CD4+ T-cells that expressed memory markers as well as IL-2, IFN-g, TNF-a, CD154 and polyfunctional cytokine responses were markedly increased in convalescent sera, compared to uninfected participants; the relative frequency of the cells had decreased (22-32%) at 6.1 month follow-up. - CD8+ T-cells that produced Mip-1b, CD107a, IL-2, INF-g and TNF-a persisted at 6.1 month follow up, although at lower levels than previously measures. - 95-97% of previously infected participant serum provided evidence of antigen specific CD4+ and CD8+ T-cells activity at both 1.3 and 6.1 months post infection. When compared to CD4+ T-cell activity at 6.1 months, CD8+ T-cell responses were far more variable and generally less robust.
Li (2020) (21) *Preprint* Cross-sectional China Apr-Sep 2020	Convalescent COVID-19 individuals (n=31) and unexposed controls (n=11) were included in the study; exposure status confirmed by RT-PCR. The median period between disease onset and serum collection was 169 days (range: 83 to 274 days). Analysis examined differences between T-cell responses in first 6 months and 6-9 months post infection. 56.6% (17/31) of the infected cases were hospitalized, 19% (6/31) were asymptomatic. T-cell activity was measured by flow	- A proportion of T-cells weakly responded to viral proteins in uninfected individuals, but with a much lower magnitude than that observed among previously infected individuals. - At the time of final follow-up, 45% of previously infected individuals remained IgG positive, and 29% remained IgG and IgM positive. CD4+ T-cell responses were observed to be more robust among individuals who had become negative for IgG antibodies. - Loss of memory CD4+ and CD8+ T-cell responses were observed in 16.13% and 25.81% of previously infected individuals. Loss of memory CD4 T-cells was more frequent in asymptomatic individuals. - CD4+ and CD8+ T-cell responses were highly variable. Generally, the breadth and magnitude

	cytometry, and viral S protein, N protein, M protein sequences was used for cell simulation.	of the cell responses increased as time from symptom onset increased. T-cell dynamics, in the first 6 months post symptom onset, in comparison to 6-9 months post symptom onset: - Over the first 6 months post disease onset reductions in the magnitude of cytokine producing CD4+ T-cells against S protein, N protein, and M protein were noted. Then CD4+ T-cells then increased during the 6-9 months post infection period. - No change was observed in cytokine producing CD8+ T-cell. - There was a significant increase in the number of reactive memory CD8+ T-cell pools (i.e. the breath and magnitude of responses) between 6-9 months post symptom.
Circulating Antibody Immune Responses		
Levi (2021) (38) *Preprint* Prospective cohort Italy Apr- Aug 2020	Measured changes in serum antibody levels over a 5 month period in a sample of healthcare workers from multiple health care facilities (n=4534). S protein (S1 and S2) specific IgG levels were measured by assays (IgG ≥ 12 AU/mL set as a threshold). Of the HCWs with IgG levels above threshold, 14% (n=91/613) were asymptomatic. Factors associated with antibody dynamics were identified through logistic regression analysis.	- IgG levels were found to be higher among HCWs that had symptomatic COVID-19, when compared to asymptomatic and paucisymptomatic HCWs. - The symptoms reported to be associated with sustained and increased IgG levels at 5 months included fever, cough, muscle pain, asthenia, tachycardia and anosmia/dysgeusia. - Regression analysis only found those presenting with anosmia/dysgeusia (OR 2.75, 95% CI 1.753 – 4.301) to be significantly associated with IgG maintenance. Note: Study results may be biased as increases in HCW antibody levels were noted in regions most impacted by SARS-CoV-2, and reduced in regions least impacted (i.e., antibody levels could be increasing because of re-infections).
Dobaño (2021) (18) *Preprint* Prospective cohort Spain	Evaluated antibody levels and seropositivity in a sample of primary health care workers (n=173), 149-270 days after symptom onset; serum samples were collected at three time points. Infections were confirmed by PCR.	Antibody dynamics approximately 5-9 months after symptom onset, identified in the study: - 92.49% of participants were positive for at least one immunoglobulin isotype, indicative of highly stable and persistent immunity. - 60% of participants were positive for RBD and S protein IgM, 76.30% for RBD and S protein

Mar-Dec 2020	The majority of the sample was mild to moderate cases, and 14% were hospitalized. Levels of S protein and RBD IgM, IgA and IgG antibodies were measured by assay (not specified). Factors associated with higher levels of antibodies were identified by stepwise multivariable regression analyses.	IgA, and 90.17% for RBD and S protein IgG antibodies. - Factors associated with higher levels of antibodies at follow-up were hospital admission, fever, anosmia and/or hypogeusia, and previous allergies.
Wagner (2020) (28) *Preprint* Prospective cohort Austria Apr – Oct 2020	A large seroprevelance study (n=1655) identified individuals with positive S protein IgG and/or IgA antibodies (n=168). Only 42% of participants reported experiencing symptoms compatible with infection in the 3 months prior to recruitment. Serum samples of seropositive individuals were collected at 3 and 6 months post initial test results (n=1292/1655). S1 subunit of S protein, N protein, RBD antibodies, and NAb antibodies were detected through serological assays.	Antibody dynamics at 6 months post initial seropositive test results, identified in the study: - S1 IgG levels, which suggest exposure rather than protective immunity persisted in 90% of (9/10) the seropositive cases. - N protein IgG was no longer detectable in 55.5% of the sample. - RBD IgM had decreased at 3 months (from initial seropositive results) in 53.3% of the sample, but remained stable from 3 to 6 months. - 50% of the initially RBD IgM as well as N protein IgG seropositive at baseline were seronegative at 6 months. - S1 protein IgA was decreased at 6 months compared to baseline. - RBD total antibodies correlated best with NAb (a surrogate marker for protection from the virus) and both were maintained at 6 months. - RBD antibody levels were found to be independent of infection attributed symptoms and severity. - The authors concluded RBD antibody specific assays can reliably detect SARS-CoV-2 specific antibodies for at least six months following infection.
Zhou (2020) (36) Prospective cohort	S protein IgM and IgG antibody levels were tested in convalescent serum samples of convalescent COVID-19 participants (n=165). All participants had been	Antibody dynamics up to 7 months post initial hospitalization event, identified in the study: - S protein IgM decreased after peaking around 22-28 days of; 79% of individuals were

China Spring 2020*	hospitalized and infections confirmed by RT-PCR. ELISA was used to measure antibody levels in serum samples. All samples were collected between day 1 through 7 months from symptom onset, 28 serum samples informed the 7 month post infection data point.	negative for these antibodies at 7 months post infection. - S protein IgG levels increased from day 1 to 28 with peak levels being maintained up to 4 months post symptom onset, but dropped sharply at 7 months.
Vanshylla (2021) (39) *Preprint* Prospective cohort Germany Apr- Dec 2020	Antibody levels in a sample of recovered individuals (n=131/963), detected in serum samples collected up to 10 months post symptom onset or confirmatory diagnosis; 41.8% of the convalescent COVID-19 individuals had been hospitalized and infection confirmed by RT-PCR. NAb and S protein IgG levels were measured by multiple assays, and inform linear regression mixed effects modeling estimates antibody half-lives.	Antibody dynamics 4-10 months post symptom onset or confirmatory diagnosis, identified in the study: - S protein IgG levels decreased between 1-4 months post infection, then were constant for the remaining months of follow-up. - 73% of individuals were positive for S1 IgG at 9-10 months post infection, a 13% reduction from 1 month post infection. - Half-life of S protein IgG estimated to be 8.7 months. NAb levels and activity were found to decrease rapidly over the initial two months post infection, but neutralizing functions of purified IgG antibodies, including against the S protein, were maintained up to seven months post infection. These results suggest a more stable and long-term memory IgG B cell repertoire and stable levels of IgG in the majority of individuals recovered from infection.
Whitcombe (2020) (27) *Preprint* Case series New Zealand Spring 2020*	Serum samples from RT-PCR confirmed convalescent COVID-19 individuals who had mild/moderate disease (n=112) was collected, 80/189 serum samples from 50 participants had multiple samples and informed the 4-8 months post-infection onset time points. Samples were assayed to identify IgG, IgM and IgA antibodies and	Antibody dynamics 4-8 months post infection onset compared to baseline levels, identified: - 99% (79/80) of participants had anti-RBD IgG and 96% (77/80) had anti-S protein IgG. - RBD 64% (51/80), S protein IgG1 antibodies 59% (47/80) and IgG3 S protein antibodies 60% (48/80) persisted. - <30% of participants remained positive for N protein antibodies, which waned quickly.

	subclasses (IgG1, 2, 3 and 4) specific to N protein, S protein, and RBD, as well as neutralizing antibodies (NAbs) by an in-house Triplex assay.	- 90% (72/80) NAbs were detectable. Across the study these were relatively stable and correlated with RBD IgA (Pearson's r ≥ 0.87). Using paired serum samples (n=50 participants) the rate of decay for Nabs to halve was estimated to be 146 days (95% CI: 100-199), which is considerably shorter than the exponential decay (625 days) or growth-decay (425 days) models predicted.
Han (2021) (40) *Preprint* Prospective Cohort China Dec 2019 – Mar 2020	Acute and convalescent plasma of RT-PCR confirmed severe COVID-19 individuals was tested for RBD, S protein and N protein IgG (n-=104). Follow up was approximately 6-7 months (median 195 days; range 188-201 day) post infection. Serum samples from 31 healthy controls with no follow-up also included. Ab levels measured by ELISA and micro neutralization assay. Correlations between convalescent antibody levels and virus neutralization activity estimated by ANOVA.	Antibody dynamics approximately 6-7 months after symptom onset: - All measured viral antigen specific antibodies were significantly higher among infected cases at both acute and convalescent time points, when compared to healthy controls. - Viral antigen specific antibodies were not significantly different based on participant age or gender. - RBD and N protein IgG levels were significantly lower from the acute to convalescent time points ($p<0.000$); no significant reductions in S protein IgG levels. - Median reductions between acute and convalescent serum estimated at 15.90% (IQR, 7.83 to 30.91%) for S protein IgG, 51.63% (IQR, 31.25 to 66.30%) N protein IgG, and 58.98% (IQR, 48.15 to 68.25%) RBD IgG, - Significant ($p<0.0001$) and strong correlations between virus neutralization activity and NAb levels with RBD IgG levels; significant ($p<0.0001$) and moderate correlations between RBD and N protein IgG levels were noted in convalescent sera.
Choe (2021) (29) Cross-sectional South Korea Feb – Oct 2020	Serum samples from RT-PCR confirmed COVID-19 individuals (n=58), 7 asymptomatic and 51 mildly symptomatic participants were collected 8 months post infection. Antibody levels were investigated using multiple immunoassays.	Antibody dynamics 8 months post infection: - 91.4% of participants remained positive for N protein Ig antibodies - 25.9% of participants positive for N protein IgG - 86% participants positive for S protein IgG antibodies, and 69% participants positive for S1 protein IgG antibodies - 53.4% of participant sera demonstrated positive NAb activity

		The detection of antibodies was confirmed to vary by applied immunoassay methods.
Zhang (2020) (31) Case series China Jan – July 2020	Serum samples from convalescent COVID-19 participants were (n=54/112) collected between 158-194 days post symptom onset, and compared to antibody levels during the acute infection phase. Infections among all participants were confirmed by RT-PCR, 77.7% were mild cases and 22.3% were severe. N protein and RBD IgG and IgM antibody levels were measured by ELISA.	Antibody dynamics approximately 5-6 months post symptom onset : - All participants were positive for N protein antibodies (Ig class not specified), antibody levels had decreased when compared to their acute infection titers. Both mild (median 46.31% (IQR 5.37%–68.96%) and severe (median 46.02% (IQR 11.01%–65.75%) infection groups experienced similar reductions in N protein antibody titres.
Kwada (2020) (41) *Preprint* Case series Japan Apr – Nov 2020	Serum samples from seropositive HCWs from a hospital outbreak, 42/45 were RT-PCR confirmed and severity not reported, were followed-up on a monthly basis up to seven months post diagnosis (n=45). Total Ig N protein and S protein antibody levels were measured up to 7 months post infection (n=45).	Antibody dynamics approximately 7 months post infection diagnosis: - 33% (n=15) N protein Ig levels significantly increased and was maintained, 33% (n=16) these antibodies initially increased and declined, 31% (n=14) antibodies increased modestly and persisted. - Individuals with high and maintained Ig N protein antibodies also had higher levels of S protein antibody at 7 months post diagnosis. Levels of N protein antibodies showed no apparent correlation with either COVID-19 contact or symptoms. - Authors suggest N protein pan Ig levels may not be related to disease recovery.
Dehgani-Mobaraki (2020) (42) *Preprint* Prospective cohort Italy Mar – Nov 2020	Serum samples were collected from RT-PCR confirmed COVID-19 participants (n=30/114) 1 month to 8 months after diagnosis up to 5 time points. Blood samples collected at multiple time points were assayed to measure antibody. Target viral antigens are not specified. Individuals with mild (n=17) and moderate to severe	IgG antibody persistency was demonstrated in 76.7 % of the subjects (n=23/30) at 8 months post diagnosis. Generally, IgG antibody levels were more elevated from baseline levels among moderate to severe cases, when compared to mild cases. Antibody dynamics up to 8 months post infection identified in the study: In mild cases at 1 vs. 8 months post diagnosis:

	infection (n=13) were equally represented in the study sample.	- IgM levels significantly (p-value <0.001) decreased from 0.50 (0.46-0.52) to 0.21 (0.18-0.35). - IgG levels increased from 1.84 (0.68-3.54) to 3.13 (1.05-3.66). In moderate-severe cases at 1 vs. 8 months post diagnosis: - IgM levels significantly reduced from 0.64 (0.64-1.07) to 0.54 (0.25-0.81). - IgG levels 2.37 (1.14-20.7) remained persistent 1.89 (0.83-8.53).
Pradenas (2020) (26) Prospective Cohort Spain Apr – Oct 2020	Serum samples were collected at time of diagnosis, 3 and 6 month from 210 COVID-19 RT-PCR confirmed cases (106 mild, 104 hospitalized). Only 28/210 participants contribute to the longitudinal data. RBD, S protein S2, N protein IgG antibody, as well as NAb levels, were measured by ELISA and pseudovirus assay.	Antibody dynamics, up to 6 months post symptom onset/diagnosis identified in the study: - Beyond 30 days since infection onset, the half-life for RBD IgG 86 days, S protein S2 IgG 108 days, N protein IgG 59 days were estimated. - NAb antibody levels in participants that had a mild or asymptomatic infection developed a 10 fold lower maximal neutralization titer than severe cases, but remained steady with insignificant decay up to 6 months. - Compared to the mild or asymptomatic, hospitalized participants had higher NAb titers though to end of follow-up. These antibody levels underwent an initial rapid decline that slowed and stabilized after 80 days. - The authors, based on assumed NAb activity threshold of 1:250 to prevent reinfection, suggest hospitalized participants have a higher capacity for long-term neutralization and preventing infection.
Hachim (2021) (37) *Preprint* Prospective cohort Hong Kong Apr – Nov 2020	Serum samples from infected children (n=122) and adults (n=36) were compared to samples from never infected participants (n=33); infections were confirmed by RT-PCR. 36% of the samples and 25% of adult samples were from asymptomatic COVID-19. Children serum samples ranged from 0-206 days post symptom onset (mean+/-	- The model of specific antibodies in pediatric samples (n=58/122) up to 6 months indicates antibodies to both structural proteins (S1, S2, S2', M, E and N) and non-structural proteins (NSP1, ORF3a, ORF3b and ORF7a ORF6, ORF8 and ORF10) are stable or increased. - Antibodies specific to accessory protein ORF7b antibody were significantly reduced.

	stdev: 39±47 days) and the adult samples ranged from 24-123 days post symptom onset (mean±stdev: 54±20 days). Long-term follow-up included 58/122 up to 206 days post symptom onset and only 16/122 had data points between 4 to 6 months post symptom onset and informed a linear mixed effect model. Serum samples underwent LIPS and ELISA assay targeting S protein, S1, S2 subunits, N protein, E protein, M protein, as well as antibodies specific to non-structural and accessory proteins, NSP1 and ORF proteins were measured.	

ELISA = enzyme linked immunoassay, E protein = envelope, Ig= Immunoglobulin antibodies, LTE= letter, LIPS = luciferase immunoprecipiation system assay, M protein = membrane, NAb = neutralizing antibodies, N protein = nucleocapsid, ORF = open reading frame, S = spike protein, RBD= receptor binding domain

VARIANTS OF CONCERN AND IMMUNITY

Variants of SARS-CoV-2 have acquired mutations, which occurs frequently and often does not change the characteristics of the virus. However, at times mutations are acquired that change the epidemiology and/or virulence of the virus (e.g. changes in transmission, severity or mortality or disease, immune evasion or affects diagnostic testing). Recently several variants of concern have been identified, as of February 2021 those include: B.1.1.7 (43), B.1.351 (44) and P.1 or P.2 (45):

- B.1.1.7 aka VOC 202012/01 aka 201/501Y.V1 aka Kent variant first reported in the UK has been reported to have increased transmissibility and maybe severity. Reported in many countries.
- B.1.351 aka 501Y.V2 aka 20H7501Y.V2 first reported in South Africa has been reported to cause higher transmission, viral loads and immune escape. The combination of E484K, K417N and N501Y mutations results in higher binding affinity. This variant has been reported in many countries, but has not spread to the same extent as B.1.1.7 as of February 2021.

- P.1 aka B.1.1.28.1 and P.2 aka B.1.1.28.2 (and maybe B.1.1.33) aka 20J/501Y.V3 have been primarily circulated in Brazil. The key mutations are similar to B.1.351: K417T, E484K, N501Y. This variant has been reported in several counties including Canada and its epidemiology is currently unclear. No relevant studies were identified on this variant.

Studies on immunity against variants of concern were included in this section of the review, due to the preliminary nature of this research, no restrictions on study design or number of observations were placed on included studies. Ten preliminary *in vitro* experiments that looked at whether neutralizing antibodies from convalescent COVID-19 individuals or individuals who received one or two doses of a COVID-19 vaccine were effective against B.1.1.7 or B.1.351 were identified.

- Across studies, B.1.1.7 was reported to be neutralized with similar or slightly reduced efficacy compared to wild-type SARS-CoV-2 by both convalescent and vaccinated sera, with stronger neutralization following the second dose of vaccine (46-48). Weaker neutralizing of B.1.1.7 response was seen for those who one had one dose of vaccine compared to two doses (49).
- For B.1.351, studies note this variant evaded neutralization in a high proportion of samples from both convalescent and vaccinated sera (50-52). A single study also shows that vaccination of convalescent individuals resulted in an increase in neutralizing antibodies, however neutralization of B.1.351 was still lower than the wild-type SARS-CoV-2 (53). Thus, there is some evidence from neutralization experiments that immunity from wild-type SARS-CoV-2 may not be effective against B.1.351. The impact of B.1.351 immune evasion has yet to be established.

Table 3: Data on convalescent or vaccine immunity against variants of concern (N=10)

STUDY	METHOD	KEY OUTCOMES
B.1.351		
Wibmer (2020) (52) *In vitro* experiment NA Jan 2021*	Neutralization and binding of non-neutralizing antibodies against B.1.351 were evaluated using convalescent serum (n=44) from both severe (n=14) and mild/moderate (n=30) cases. The study also explores the evasion of B.1.351 from specific antibodies in neutralization assays.	- Convalescent plasma was used to evaluate neutralizing activity of B.1.351. - Individuals reporting more severe SARS-CoV-2 had higher neutralizing antibody titres s average ID50 titre 4212 (n=14) vs. average ID50 titre 488 (n=30) mild/moderate cases against wild-type SARS-CoV-2. - The same samples assessed against B.1.351 showed no detectable neutralization activity in 48% (21/44), with only three samples (7%) retaining titres of ID50 >400. - They also show against B.1.351 non-neutralizing antibodies were able to bind to the RBD with a small proportion, 32% (14/44), experiencing a 5-fold reduction. - The mutation E484K has been shown to reduce neutralization sensitivity. This has implications

		for rates of reinfections and vaccine effectiveness.
Stamatatos (2021) (53) preprint *In vitro* experiment USA* Jan 2021*	We collected blood and isolated serum and PBMC from persons with previously confirmed SARS-CoV-2 infection (n=10) who later received a single dose of either the Pfizer/BioNTech or Moderna mRNA vaccine.	- Before immunization 9/10 convalescent serum neutralized wild-type and 5/10 for B.1.351. - After immunization there was a 50-fold increase in binding signal, but binding was significantly lower from B.1.351. - Neutralizing potency of several specific antibodies were also evaluated with varying results across antibodies. B.1.351 virus was more resistant to neutralizing antibodies.
Cele (2021) (54) Preprint *In vitro* experiment South Africa* Jan 2021*	Using 6 convalescent plasma samples collected in the first wave (up to August). A focus forming microneutralization assay was used to quantify neutralization.	- Using convalescent plasma from the first wave of COVID-19 the decrease in neutralization ranged from 6-200 fold.
B.1.351 and B.1.1.7 or combinations of their mutations		
Collier (2021) (51) preprint *In vitro* experiment UK* Jan 2021*	Neutralising antibody responses following a single immunization of BNT162b2 vaccine was evaluated. Serum and peripheral blood mononuclear cells samples were collected 3 weeks post vaccination from 24 participants median age 82. Pseudoviruses expressing the wild-type Spike protein, the 8 mutations found in the B.1.1.7 Spike protein or with the addition of E484K mutation were used for these experiments.	- Antibody response was heterogeneous with almost 100-fold variation in IgG titres to S and Spike RBD across the 24 vaccinated participants. - Pseudovirus bearing S protein with the full set of mutations present in the B.1.1.7 variant (i.e., H69/V70, 144, N501Y, A570D, P681H, T716I, S982A, D1118H) did result in small reduction in neutralisation by sera from vaccinated participants. - Adding in the E484K mutation (found in B.1.351 variant) resulted in a significant loss of neutralising activity compared with wild type and B.1.1.7; mean fold change for the E484K B.1.1.7 Spike was 9.6 compared to 2.4 for B.1.1.7 alone ($p<0.05$)
Wang (2021) (50)	Antibody and memory B cell responses in a cohort of 20 volunteers who received either the Moderna (mRNA-1273) or Pfizer-	- 8 weeks after the second vaccine injection volunteers showed high levels of IgM, and IgG anti-SARS-CoV-2 spike protein (S) and receptor binding domain (RBD) binding titers.

In vitro experiment USA* Jan 2021*	BioNTech (BNT162b2) vaccines is investigated. Vaccine sera neutralizing activity against variants with E484K or N501Y or the K417N:E484K:N501Y mutations were investigated. As well as the individual neutralizing activity against 17 of the most potent antibodies.	- The plasma neutralizing activity, and the relative numbers of RBD-specific memory B cells in vaccinated individuals were equivalent to individuals who recovered from natural infection. - The activity against SARS-CoV-2 variants encoding E484K or N501Y or the K417N:E484K:N501Y combination was reduced by a small but significant margin. - Neutralization by 14 of 17 of the most potent antibodies tested was either reduced or abolished by the variants.
Wang (2021) (55) Preprint *In vitro* experiment USA* Feb 2021*	20 convalescent sera from more than one month post SARS-CoV-2 infection were collected in Spring 2020. 10 had severe COVID-19, 10 were not severe. 12 vaccinated sera (Moderna, 2 doses with sera collected at day 42.) 10 vaccinated sera (Pfizer, 2 doses with sera collected on day 28) Pseudoviruses were developed to represent the wild type SARS-CoV-2, B.1.1.7 and B.1.351	- Compared to the wild type neutralization was lower. - No substantial loss in convalescent sera, Moderna and Pfizer against B.1.1.7. - 9.4 fold lower in convalescent sera, 12.4 fold lower for Moderna and 10.5 fold lower for Pfizer against B.1.351. - Loss of potency was 16/20 for B.1.351 and activity was maintained for B.1.1.7 pseudoviruses.
B.1.1.7		
Muik (2021) (47) *In vitro* experiment UK* Jan 2021*	Using sera immune sera from 40 people 23-73 years old 7-21 days post 2nd dose of vaccine BNT162b2, the authors evaluated whether the B.1.1.7 spike interferes with antibody binding using neutralization assays. Based studies of antibody correlates of disease protection for influenza virus vaccines, a 20% reduced titer does not indicate a biologically significant change in neutralization activity.	- The immune sera had slightly reduced but overall largely preserved neutralizing titers against the B.1.1.7 lineage pseudovirus. These data indicate that the B.1.1.7 lineage will not escape BNT162b2-mediated protection.
Edara (2021) (48) Preprint	Blood samples collected from 20 COVID-19 cases (8-24 days post symptom onset), convalescent COVID-19 individuals (30-90 days	- Neutralization titers correlated between the EHC-83E and B.1.1.7 variants across acutely infected COVID-19 patients (R2 =0.7971; p<0.0001), convalescent COVID-19 individuals

In vitro experiment USA* Jan 2021*	PSO) and 14 vaccinated (2 doses of mRNA-1273 vaccine) were tested for neutralizing antibody response against a panel of SARS-CoV-2 variants including D614G and B.1.1.7.	(R2= 0.8092; p<0.0001), and mRNA1273 vaccinated individuals (R2= 0.7639; p= 0.0027). - The neutralizing antibodies from COVID-19 cases and vaccinated individuals were effective against B.1.1.7.
Shen (2021) (49) Preprint *In vitro* experiment USA* Jan 2021*	Sera (n=40) of those vaccinated mRNA-1273, Moderna collected at day 29 post first dose and 28 days post second dose. Sera (n=28) from Novavax trial were collected at random times >2 weeks post second dose. Convalescent sera (n=15) were from an observational study that collected samples between 1-8 weeks post resolution of symptoms or 2-10 post last positive test and were preselected to represent high, medium and low neutralization titres. Pseudotyped viruses were developed for several SARS-CoV-2 isolates including B.1.1.7 and evaluated using neutralization assays.	- The B.1.1.7 variant was neutralized by all vaccine sera, although with modestly diminished susceptibility compared to the D614G variant. - The same was seen for convalescent sera, however the decrease was less than for vaccine sera. - Sera with weaker neutralizing activity exhibited a reduction in activity against B.1.1.7. Most of the weak neutralizing activity against B.1.1.7 was post first dose of vaccine and the decreased activity against B.1.1.7 was less after the second dose of vaccine. - B.1.1.7 exhibited partial and modest escape from specific antibodies; COVA1-18, COVA2-15, S309 and B38; and DH1042 and H4, respectively.
Rees-Spear (2021) (46) preprint *In vitro* experiment UK* Jan 2021*	Neutralization of a series of mutated spike pseudotypes including B.1.1.7 were evaluated with a panel of antibodies and 36 convalescent COVID-19 serum samples.	- Most convalescent samples neutralized B.1.1.7, however potency was reduced in 3/36 samples by 5-10 fold. - Serum samples form those who had severe COVID-19 showed more resilience compared to those with mild COVID-19, 56% of whom showed a 3-fold drop in potency against at least one mutant. - Neutralization activity of some spike-specific monoclonal antibodies was dramatically reduced by B.1.1.7 and other Spike mutations.

REVIEW LITERATURE

The systematic review identified offer summaries of what was known in June and September 2020. As such the studies included in these review include early research on relevant immune outcomes <6 months from initial COVID-19.

Table 4: Systematic reviews and rapid reviews relevant to immunity (n=3)

STUDY	METHOD	KEY OUTCOMES
Poland (2020) (1) Review NA Oct 2020*	This review discusses what was known about human humoral and cellular immune responses to SARS-CoV-2 as of the search date Sept 24, 2020.	- The article reviews humoral and cellular immunity and presents some data on kinetics and durability of antibody response and correlation with T-cell response. Many inconsistencies were noted in the initial research. - Knowledge gaps include high-quality studies on duration of protection by neutralizing antibodies and a good understanding of how the immunological measures being used correlate to protection.
Post (2020) (19) Systematic review NA Jun 2020	A systematic review on antibody response to SARS-CoV-2 with a search date of June 26, 2020. 150 papers were included. Inclusion criteria included follow-up of greater than 28 days and measured antibody titres. High variability across includes studies and study designs was reported by the author. See appendix 2 for a figure on antibody kinetics over time.	- Inconsistency in antibody correlates were seen across the literature. - IgM (seroconversion 4-14d, peak 2-5 weeks and declining to undetectable levels around 6 weeks) was consistently detected before IgG. - IgG (seroconversion 12-15 d, peak 3-7 weeks, plateaued until at least 8 weeks with longest follow-up of 12 weeks still detecting antibodies). - IgA infrequently studied showed seroconversion between 4-11 days, with outliers reporting 24 days. - Neutralizing antibodies detected 7-15 days after symptom onset, peaking 14-22 days and then declining over 6 weeks. AT 39 days one study had 79% of participants with low neutralizing antibody titres, 3% with high titres. Mild cases had lower neutralizing antibodies. - Animal studies show promising initial results for protective immunity; however studies were small and short in duration. There are studies that have demonstrated correlations with disease severity. An inverse relationship with viral load has been inconsistently reported and no association with re-detection was reported. Studies cannot speak to lasting immunity.
Shrotri (2021) (33) Systematic Review NA Jun 2020	A systematic review that critically evaluates and synthesises published and pre-print literature from Jan 2020-Jun 26 2020 on T-cell mediated	- Symptomatic adult cases consistently show a reduction in peripheral T cell counts in the acute infection phase, which positively correlates with increased disease severity, duration of RNA positivity, and non-survival. The observed relative reductions in CD4+ and CD8+ T cell were variable. - Asymptomatic and paediatric cases display preserved T-cell counts.

	immunity post SARS-CoV-2 infection. 61 publications included in the review.	- Severe or critical COVID-19 cases developed more robust, virus-specific T-cell responses. Elevated levels of pro-inflammatory cytokines, interleukin-6 (IL-6), to lesser degree, interleukin-10 (IL-10), and tumour necrosis factor alpha (TNF-α) were identified in severe cases. - Longitudinal follow-up (14-44 days post infection) suggested recovery of T-cell subset counts alongside clinical recovery and viral clearance. - T-cell memory and effector function in early convalescents (up to approximately 3 months post onset) was demonstrated against viral antigens S, M and N proteins. T cell response breath and magnitude were generally enhanced among individuals recovering from sever infections. Cytokine producing activity of CD 8+ T cells specific to M and N proteins displayed wider functionality than those targeting S proteins among individuals with mild disease. CD3+ T cells were reduced in severe infections. - Cross-reactive T-cells among unexposed or individuals previously exposed to other coronaviruses (e.g., pre-pandemic seasonal corona virus strains, SARS-CoV-1) were often identified and appear long-term; in some cases maintained up to 17 years post infection. Cross-reactive T-cells targeting viral S protein and N proteins were the identified cross-reactive immune cells. The impact of cross-reactivity on SARS-CoV-2 infections remains largely unclear, but assumed to be low due to variability in coronavirus epitopes.

Methods:

A daily scan of the literature (published and pre-published) is conducted by the Emerging Science Group, PHAC. The scan has compiled COVID-19 literature since the beginning of the outbreak and is updated daily. Searches to retrieve relevant COVID-19 literature are conducted in Pubmed, Scopus, BioRxiv, MedRxiv, ArXiv, SSRN, Research Square and cross-referenced with the COVID-19 information centers run by Lancet, BMJ, Elsevier, Nature and Wiley. The daily summary and full scan results are maintained in a refworks database and an excel list that can be searched. Targeted keyword searching was conducted within these databases to identify relevant citations on COVID-19 and SARS-COV-2. Three separate searches were conducted to identify citations relevant to reinfection, immunity and variants and immunity. Search terms used included:
REINFECTION TERMS (reinfect* or re-infect* or recurren* or re-positive).
IMMUNITY TERMS (antibod* or CD+ or CD4 or CD8) across studies with the Immunology tag

VARIANT TERMs (B1.1.7 or 501Y.V1 or 202012/01 or B.1.351 or 501Y.V2 or P1 or P2 or B.1.1.28 or B.1.1.33 or 501Y.V3) AND (neutralization antibodies)
This review contains research published up to Feb 11, 2021.
Each potentially relevant reference was examined to confirm it had relevant data and relevant data was extracted into the review.

APPENDIX 1:

Reinfections, case reports/series (n=21)

- Thirty cases of confirmed reinfection were identified. The median time between initial infection and infection was 81 days (range 13-250).
- Confirmed cases of reinfection have been reported in China (56-59), South Korea (60), Brazil (61, 62), the United States (63-65), Belgium (66, 67), Spain (68), France (69, 70) the United Kingdom (71), the Netherlands (72), Ecuador (73), India (74, 75), and Iran (76).

- Onward transmission via reinfection cases was suspected in two reports (67, 68). In many studies, contact tracing/follow-up was not conducted. Infectivity and onward transmission during reinfection has not been sufficiently studied and remains a substantial knowledge gap.
- Symptomology among primary and re-infections has been heterogeneous in the literature. Seventeen cases experienced both asymptomatic/mild primary infections and reinfections (56, 57, 60, 62, 66, 67, 69, 74, 75). Three cases reported severe symptoms during primary infection and mild symptoms during reinfection (56, 65). Ten cases experienced mild/moderate symptoms during primary infection and more severe symptoms during reinfection (61, 63, 64, 68, 70-73, 76).
- A confirmed case of reinfection due to the Variant of Concern-202012/01 of lineage B.1.1.7 was reported in the United States (65). Immunological findings suggest that poorly developed or waned antibodies formed after the primary infection in March were not protective against reinfection with the new mutated variant acquired in July (65). Cases of reinfection with the E484K spike mutation in Brazil (61) and South African SARS-CoV-2 variant 501Y.V2 in France (70) have also been reported.
- Immunology findings indicate that the waning of humoral immunity may have predisposed patients to reinfection with a different strain of SARS-CoV-2. Those who do not seroconvert may not have the same degree of protection from reinfection as those with high titers of antibodies. The greater magnitude of antibody responses or T cell responses generated during severe COVID-19 may confer more robust and/or long-lasting protection. Alternatively, subsequent infections may be more severe due to acquisition of a more pathogenic strain (i.e. with viral escape mutations), or even a greater inoculum of infection as the second exposure (i.e. from household exposure) (63). Additional research is needed to understand the role of immunity in protection against SARS-CoV-2 post initial acute infection and how common reinfection is.

Appendix Table: Case reports of genetically confirmed reinfection with SARS-CoV-2 (N=21)

Reference	Method	Key Outcomes
Case series/reports of confirmed reinfection (n=21)		
Zhang (2020) (56) Case series China Jan-Apr 2020	Describes six cases of confirmed reinfection. Analysis supported by viral whole genome sequencing, phylogenomic analysis, serology, and epidemiological data.	Swab type not reported -Time between episodes ranged from 19 to 57 days. -There were five adults (33-84 years) and one 2-year-old child. Two were critical COVID-19 patients (P1, P6), and the other four had moderate primary infections (P2-P5). Three cases (P1-P3) developed symptoms again during the second episode, with P1 and P2 showing pulmonary inflammatory lesions, while the other cases were asymptomatic. - There was no difference in the infection duration and the viral loads between the first and second episodes.

		- P2 and P4 had low anti-RBD IgM/IgG (≤1:40) responses to the primary infection. In the other three patients (P1, P3 and P6), titers reached 1:80-1:320 for RBD-IgM and IgG. During the secondary infection, cases P1 and P2 displayed secondary immune responses with an increase in serum antibody titers. -All six paired-genomes were attributed to different lineages or descending lineages with 3-11 distinct SNPs between first and second episodes. Five of these six pairs were D614G mutants.
To, Hung, Chan, (2020); To, Hung, Ip, (2020); Chan (2020) (57-59) Case report China Mar-Aug 2020	These case reports describe a confirmed case of reinfection in a 33 year old male in Hong Kong with a travel history to Spain. Analysis supported by viral whole genome sequencing, phylogenomic analysis, serology, and epidemiological data.	Respiratory samples -Immunocompetent case tested re-positive for SARS-CoV-2 viral RNA 142 days after the first symptomatic episode. -First episode: mild symptoms, Ct 30.5 -Second episode: Asymptomatic, Ct 26-32 -Serum samples collected on days 10, 43, and 148 (day 3 of reinfection) did not detect antibodies against SARS-CoV-2. A strong IgG antibody response to N protein developed by day 5 of reinfection, suggesting that antibody against SARS-CoV-2 developed on reinfection. IgM was not detected. Reinfection coincided with a stronger interleukin-21 memory type response on day 148 than on days 10 and 43. -First and second viral genomes belonged to different clades/lineages, differing by 24 nucleotides. First genome clustered with viruses from Hong Kong, while second genome clustered with viruses from Spain. Epidemiological data, including a recent trip from Spain.
Lee (2020) (60) Case series South Korea Mar-May 2020	Describes six patients who recovered from COVID-19 and retested positive by RT-PCR after discharge. One confirmed case is reported in a 21 year old woman. Analysis supported by viral whole genome sequencing, phylogenomic analysis, and serology.	Nasopharyngeal, oropharyngeal, and sputum swabs -Time between episodes was 26 days. -First episode: mild, Ct ~22.5, seronegative -Second episode: mild, Ct ~31, seropositive, antibody levels increased 10 days after onset of the patient's reinfection episode, then decreased but remained positive within the following 3 weeks. - Phylogenetic analysis revealed that the virus strain from the second episode clustered in clade "V" with the strain from the first episode clustered in clade "G".
Vasques Nonaka (2021) (61)	Describes the first case of reinfection with the E484K spike mutation in Brazil in a 45 year old	Nasopharyngeal swab -Time between episodes was 147 days.

Case report Brazil May-Oct 2020	female. Analysis supported by whole genome sequencing and phylogenomic analysis.	-First episode: mild, Cts of N, E and RdRp targets were 25, 26, and 27, antibody testing not done -Second episode: moderate, Cts of N, E and RdRp targets were 21, 12 and 17, IgG test was performed 4 weeks after symptom onset and was positive. -The viral variant from the first episode was identified as B.1.1.33 lineage while the variant from the second episode was B.1.1.248 harboring the E484K mutation, located in a key residue of the receptor binding domain.
Fintelman-Rodrigues (2021) (62) *Preprint* Case series Brazil Mar-May 2020	Describes four patients who recovered from COVID-19 and retested positive. Two cases, a 57 year old woman and a 34 year old man were confirmed reinfection. Analysis supported by viral whole genome sequencing, phylogenomic analysis, and serology.	Nasopharyngeal swab Case 1 -Time between episodes was ~62 days. -First episode: mild symptoms, Ct 36 (~10^3 copies/ml), upregulation of markers of innate immune response (IL-6, IL-8 and TNF-α, IL-10, CXCL-10, IFN-y) but IgG anti-SARS-CoV-2 IgM, IgA or IgG antibodies were not detected. -Second episode: moderate symptoms, Ct 22 (~10^7 copies/ml), anti-SARS-CoV-2 immunoglobulins were detected along with low to non-neutralizing activity one week after onset. - Genome sequencing showed that the first and second episodes were associated with the emerging clades 19A and 20B, respectively. Case 2 -Time between episodes was ~53 days. -First episode: mild symptoms, Ct 36 (~10^3 copies/ml), upregulation of markers of innate immune response (IL-6, IL-8 and TNF-α, IL-10, CXCL-10, IFN-y) but IgG anti-SARS-CoV-2 IgM, IgA or IgG antibodies were not detected. -Second episode: moderate symptoms, Ct 17 (~109 copies/ml), anti-SARS-CoV-2 immunoglobulins not detected one week after onset, but were detectable 40 days after onset. - Genome sequencing of both episodes were associated with clade 20B, but they clustered apart on the phylogeny with significant statistical support with differing genetic markers between strains.
Larson (2020) (63) Case report	Describes a confirmed case of reinfection in a 42 year old healthy male military healthcare provider in Virginia. Analysis supported by viral	Respiratory swabs -Time between episodes was 51 days. -First episode: mild symptoms, no antibody test done.

United States Mar-Jun 2020	whole genome sequencing, phylogenomic analysis, and epidemiological data.	-Second episode: severe symptoms, IgG reactive on day 8 post symptom onset. -Viral culture was attempted but was unsuccessful. -Comparison of the sequence obtained from the initial and second episode identified several potential variations, including one high confidence variation. - The phylogenetic analysis placed the virus causing the second episode in lineage B.1.26, and the genome encoded the D614G variation in the spike protein. -Authors hypothesize that the second infection was more severe, potentially due to immune enhancement, acquisition of a more pathogenic strain, or perhaps a greater inoculum of infection as the second exposure was from within the household.
Tillett (2020) (64) *Preprint* Case report United States Apr-Jun 2020	Describes a confirmed case of reinfection in a 25 year old case in Nevada. Analysis supported by whole genome sequencing, phylogenomic analysis, and epidemiological data.	Nasopharyngeal swabs -Time between episodes was 48 days. -First episode: mild symptoms, Ct 35.2, no antibody test done. -Second episode: severe symptoms, requiring hospitalization and oxygen therapy, Ct 35.3, IgG/IgM reactive 7 days post symptom onset. - First and second viral genomes belonged to the same clade but differed by seven nucleotides. -The case may have been re-exposed to the virus by an infected parent.
Goldman (2020) (65) *Preprint* Case report United States Mar-Jul 2020	Describes a confirmed case of reinfection in a resident of a skilled nursing facility, aged between 60-69, with a history of severe emphysema and hypertension. Analysis supported by whole genome sequencing, phylogenomic analysis, and serology.	Nasopharyngeal swabs Time between episodes was 118 days. -First episode: severe symptoms, Ct 22.8, no antibody test done. -Second episode: mild symptoms, Ct 43.3, IgG antibodies against receptor binding domain (RBD), spike, and nucleocapsid were detected and showed a decreasing trend from day 14 to 42 after reinfection symptoms onset. -Immunological findings suggest that poorly developed or waned antibodies against the D614 virus formed after primary infection in March were not protective against reinfection with the D614G spike variant acquired in July. -Comparison of strain sequences from March and July revealed 10 high confidence intra-host single nucleotide variants of which 5 type the March sequence to clade 19B, and 5 type the July sequence to 20A.

Van Elslande (2020) (66) *LTE* Case report Belgium Mar-Jun 2020	Describes a confirmed case of reinfection in a 51 year old woman who took a daily dose of inhaled corticosteroids for asthma. Analysis supported by whole genome sequencing.	Nasopharyngeal swabs -Time between episodes was 93 days. -First episode: moderate symptoms, Ct 25.6, no antibody test done. -Second episode: mild symptoms, Ct 32.6, positive for anti-SARS-CoV-2 nucleocapsid antibodies one week post symptom onset. -First and second viral genomes belonged to different clades and differed by 11 nucleotides. Full length genome sequencing revealed the initial infection was caused by a lineage B.1.1 SARS-CoV-2 virus, while the relapsing infection was caused by a lineage A.
Selhorst (2020) (67) *Preprint* Case report Belgium Mar-Sep 2020	A case of reinfection was observed in a Belgian nosocomial outbreak involving 3 patients and 2 health care workers. Whole genome sequencing was performed on swabs of all individuals including the reinfection case's first episode. IgA, IgM, IgG, and neutralizing antibody responses were quantified in serum of all individuals, and viral infectiousness was measured in the swabs of the reinfection case.	Nasopharyngeal swabs -Case was positive for the first time in March 2020. The case worked at a facility were a nosocomial outbreak occurred and tested positive again in September 2020, 185 days after initial infection. -First episode: Mild symptoms, Ct 13, high IgG and neutralizing antibody levels after 3 months, IgA and IgM not detected at 3 months post diagnosis. -Second episode: Mild symptoms, Ct 19-25, replicating virus as indicated by RT-qPCR for negative strand RNA, yet culture was unsuccessful. Rapid rise in neutralizing antibodies within 14 days of symptom onset, with high IgG titers and low IgA and IgM titers. -Both initial and reinfections were mild. -Analysis of the sequences revealed a total of 18 nucleotide differences, with the strains belonging to different clades. This strain that cause reinfection matched that of three patients involved in the outbreak. -It was unclear whether the reinfection case played a role in transmission, however she provides the only link between some of the patients.
Lago (2020) (68) *Preprint* Case report Spain	Describes a confirmed case of reinfection in a 53-year old woman with asthma. Analysis supported by host genetics, viral whole genome sequencing, phylogenomic viral analysis, and epidemiological data obtained from interviews with the involved subjects.	Nasopharyngeal swabs -Time between episodes was 140 days. -First episode: mild, Ct 30, no antibody test done. -Second episode: severe, Ct 22-33, no antibodies detected on admission but titer of 7.04 detected 17 days after admission. -Case had contact with a confirmed COVID-19 case 12 days prior to second episode. Genomic analysis showed that the strain between the case and her

Apr-Aug 2020		close contact were identical. Further, reinfection was supported by phylogenetic analysis which revealed that the strain involved in the second episode was circulating in Madrid during the same time frame, but not during the range corresponding to the first episode. -The husband and daughter of the case tested positive for SARS-CoV-2 11 and 7 days, respectively, after the onset of the cases' second episode. The daughter's husband and four children also developed infection. Epidemiological and genomic data demonstrates that onward transmission occurred from the case to her husband and daughter during her second episode.
Zucman (2021) (70) Case report France Sep 2020-Jan 2021	Describes a case of reinfection caused by the South African variant 501Y.V2 in a 58 year old immunocompetent male. Analysis support by epidemiological data and whole genome sequencing.	Nasopharyngeal swab -Time between episodes was 129 days. -First episode: mild, no antibody testing done -Second episode: severe, IgG positive seven days after onset. -Genome sequencing identified D80A, E484K and N501Y mutations in the spike region, characterizing the 501Y.V2 lineage B.1.351 variant. -While the strain from the first episode was not available for sequencing, the occurrence of the primary infection one month before emergence of the 501Y.V2 strain in South Africa and three months before its first description in France rules out persistent viral shedding.
Colson (2020) (69) *LTE* Case report France Apr-Aug 2020	Describes a confirmed case of reinfection in a 70 year old immunocompetent man. Analysis supported by viral whole genome sequencing, phylogenomic viral analysis, and serology.	Nasopharyngeal swabs -Time between episodes was 105 days. -First episode: mild, Ct 27, IgG negative 2 weeks after onset but positive 4 weeks after onset (indicating seroconversion). -Second episode: asymptomatic, Ct 18, -Genomic analysis showed that the first and second viral strains differed by 34 nucleotides. The strain from the first episode was most closely related to strains from Nextrain clase 20A, circulating in the geographic area at that time during the first outbreak. The virus strain from the second episode was most closely related to the Marseille 4 lineage that emerged in the cases geographical area during the second outbreak.
Harrington (2021) (71)	Described a confirmed case of reinfection with caused by the 'new	Nose and throat swabs -Time between episodes was 250 days.

LTE Case report UK Apr-Dec 2020	variant' VOC-202012/01 of lineage B.1.1.7 in a 78 year old man with diabetes mellitus, diabetic nephropathy on haemodialysis, chronic obstructive pulmonary disease (COPD), mixed central and obstructive sleep apnoea, ischaemic heart disease. Analysis supported by viral whole genome sequencing, phylogenomic analysis, and serology.	-First episode: mild, Ct 26, SARS-CoV-2 IgM and IgG antibodies targeting viral nucleocapsid 'N' antigen were detectable on six occasions from two months after initial infection to 8 months after infection with no evidence of antibody waning. -Second episode: severe, Ct 28, no serology reported -Whole genome sequencing and phylogenetics showed that the virus strain in the first episode belonged to lineage B.2 while the virus strain in the second episode belonged to lineage B.1.1.7 and accumulated 18 amino-acid replacements across the genome.
Mulder (2020) (72) *LTE* Case report Netherlands Timeline not specified	Describes a confirmed case of reinfection in a 89 year old woman, suffering from cancer (Waldenström's macroglobulinemia), treated with B-cell-depleting therapy. Analysis supported by whole genome sequencing.	Nasopharyngeal swabs -Time between episodes was 54 days. -First episode: moderate symptoms, Ct 26.2, no antibody test done. -Second episode: severe symptoms resulting in death, Ct 25.2, WANTAI SARS-CoV-2 Ab and IgM ELISA were both negative. -The two strains differed at ten nucleotide positions and the sequences did not cluster in the phylogenetic tree.
Prado-Vivar (2020) (73) Case report Ecuador May-Jul 2020	Describes a confirmed case of reinfection in a 46 year old man. Analysis supported by viral whole genome sequencing and serology.	Oropharyngeal swabs -Time between episodes was 63 days. -First episode: mild symptoms, Ct 36.85, IgG negative & IgM positive six days after symptom onset. -Second episode: moderate symptoms, Ct 30.82, IgG and IgM positive 30 days post symptom onset. -First and second viral genomes belonged to different clades. For the first infection, the genome was assigned to the B1.p9 GISAID clade while the variant associated with the second episode was assigned to the A.1.1 GISAID clade.
Gupta (2020) (74) *LTE* Case report India May-Sep 2020	Describes confirmed cases of reinfection in two healthy healthcare workers (25 year old man and 28 year old woman) detected during routine surveillance. Analysis supported by whole genome sequencing.	Nasopharyngeal/oropharyngeal swabs Case 1 -Time between episodes was 108 days. -First episode: asymptomatic, Ct 36, no antibody test done. Second episode: asymptomatic, Ct 16.6, no antibody test done. -First and second viral genomes revealed 9 unique variant differences. Case 2 -Time between episodes was 111 days.

		-First episode: asymptomatic, Ct 28.16, no antibody test done. -Second episode: asymptomatic, Ct 16.92, no antibody test done. -First and second viral genomes revealed 10 unique variant differences. The genetic variation 22882T>G(S:N440K) was found within the receptor binding domain of the second episode viral genome. -The authors suggest that asymptomatic reinfection may be a potentially underreported entity.
Shastri (2020) (75) *Preprint* Case series India May-Jul 2020	Describes confirmed cases of reinfection in four frontline healthcare workers (27 year old male, 31 year old male, 27 year old male, 24 year old female). Analysis supported by whole genome sequencing, phylogenomic analysis, and serology.	Nasopharyngeal and oropharyngeal swabs -Time between episodes was 60, 59, 13, and 48 days. -First episode: two mild cases and two asymptomatic cases -Second episode: All cases were mild -Three cases were negative for anti-nucleocapsid antibodies after the second infection. -The authors hypothesize that those who do not seroconvert may not have the same degree of protection from reinfection as those with high titres of antibodies. -Comparative genomic and protein-based annotation analyses revealed differences in the presence and absence of specific mutations in the virus sequences from the first and second episode in all four paired samples.
Salehi-Vaziri 2021 (76) Preprint Case series Iran Mar-Apr 2020	Describes three confirmed COVID-19 cases that presented with possible re-infection some months after initial symptom resolution. Epidemiological data and whole genome sequencing supported the possibility of reinfection in two of the cases (32 year old male and a 42 year old male).	Nasopharyngeal and oropharyngeal swabs Case 1 -Time between episodes was 63 days. -First episode: mild, IgM positive -Second episode: moderate, IgG titration was assessed as 4.89 AU/ml which significantly increased after two months. - Genome sequencing revealed a D614G mutation of S gene from the second isolated sample. Case 2 -Time between episodes was 111 days. -First episode: mild, antibody testing not done -Second episode moderate, IgG titration was 17.5 IU/ml which decreased to 6.5 IU/ml after almost two weeks. - Genome sequencing revealed a D614G mutation of S gene from the second isolated sample.

LTE= letter to the editor

APPENDIX 2:

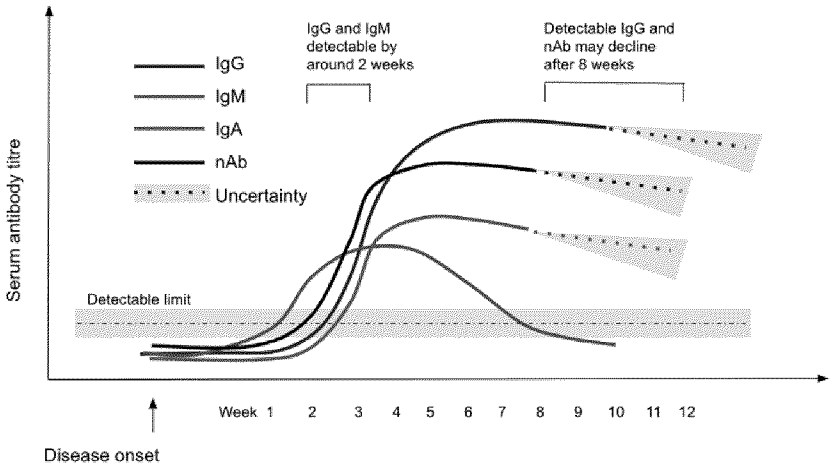

Figure 3 Post (2020) (19)

Nouveaux éléments de preuve sur la COVID-19

Revue rapide sur l'immunité protectrice, mise à jour 1

Introduction

Les anticorps contre le SRAS-CoV-2 confèrent-ils une immunité contre la réinfection par le SRAS-CoV-2? Offrent-ils une immunité protectrice à long terme (plus de six mois après l'infection) et l'infection antérieure par la souche sauvage originale du SRAS-CoV-2 protège-t-elle contre les variants préoccupants actuels?

Comprendre l'étendue et les limites de l'immunité protectrice aura d'importantes répercussions sur la pandémie de COVID-19 puisque l'immunité généralement associée aux coronavirus varie énormément et va de quelques mois pour les coronavirus saisonniers associés au rhume commun à deux ou à trois ans pour les coronavirus émergents comme le SRAS-CoV-1 et le SRMO (1). Dans le cas du SRAS-CoV-2, on sait que la plupart des gens développent une réponse immunitaire après l'infection ou après avoir été pleinement vaccinés, mais on ne sait pas encore pendant combien de temps et dans quelle mesure elle les protège contre la réinfection.

La réinfection au SRAS-CoV-2 semble peu fréquente, mais il n'est pas facile d'étudier cette question. Même si le test RT-PCR convient parfaitement pour déterminer la présence du virus dans le diagnostic initial, il continue de donner un résultat positif en présence de particules de virus non infectieux (fragments d'ARN), ce qui indique qu'il ne peut donc à lui seul être utilisé pour confirmer la réinfection. Plusieurs définitions de la réinfection ont été proposées tant dans la littérature disponible que par des organismes de santé publique (p. ex., CDC, CIRC) pour tenter de régler ce problème. Aux fins de la présente revue rapide, un cas confirmé de réinfection est défini comme une infection subséquente chez une personne qui a obtenu au moins un résultat négatif au test RT-PCR documenté entre les épisodes et pour lequel les données de séquence génomique des deux épisodes sont disponibles afin de permettre de distinguer deux clades génétiques ou lignées virales différentes (2). Parallèlement à cela, un cas présumé ou soupçonné de réinfection est défini comme tout cas dont l'infection initiale a été confirmée en clinique ou en laboratoire par un résultat positif à un test RT-PCR effectué plus de 90 jours après le premier épisode ou après un épisode qui se produit moins de 90 jours après le premier épisode, mais avec des preuves épidémiologiques de réexposition au SRAS-CoV-2 (2, 3).

Alors que le nombre de personnes partiellement et pleinement vaccinées commence à augmenter dans le monde, la recherche sur les infections ayant percé, soit les infections qui se produisent après la vaccination contre la COVID-19, commence à émerger. On voit une certaine hétérogénéité dans les études quant à la façon de définir les termes « pleinement vacciné » et « infection ayant percé ». La présente revue porte donc sur des articles rédigés à propos d'infections ayant percé. Ces infections, qui sont apparues plus de 14 jours après la fin de la première série de vaccins contre la COVID-19, sont déterminées par la découverte de l'ARN du SRAS-CoV-2 ou d'un antigène détecté sur un spécimen respiratoire recueilli conformément à la définition de cas établie par le CDC au titre de Breakthrough Infection Post-Vaccination ou Infections ayant percé (ou infections sporadiques) en français (4).

Il est également difficile d'évaluer l'immunité à long terme face à la COVID-19. Cela s'explique par le fait que les réponses immunitaires varient, que seules certaines personnes développent des anticorps spécifiques aux antigènes SARS-CoV-2 offrant une immunité protectrice suffisante et que seules certaines des personnes qui ont reçu un diagnostic de COVID-19 conservent des taux d'anticorps détectables après l'infection. Il ne faut

pas non plus oublier qu'une faible proportion des personnes infectées par le SRAS-CoV-2 ne semblent pas avoir de taux détectables d'anticorps neutralisants, mais se rétablissent tout de même, un état de fait qui n'est pas encore bien compris (5). Les données probantes indiquent que tant l'activité des anticorps neutralisants que celle des cellules immunitaires propres au SRAS-CoV-2 sont de bons indicateurs de l'immunité protectrice. Les variations dans les anticorps et l'interaction de ceux-ci, les réponses des lymphocytes B et T à l'infection, ainsi que la variété des techniques de détection compliquent l'évaluation de l'immunité à long terme.

Il ne faut pas oublier que les variants du SARS-CoV-2 ont acquis des mutations, ce qui est inévitable en raison des passages successifs du virus dans le corps de millions de personnes. La plupart des petites mutations ne modifient pas les caractéristiques du virus. Cependant, avec le temps, certaines mutations vont provoquer des changements dans la transmissibilité ou la gravité de la maladie, ou dans la létalité qui lui est associée, en plus de pouvoir modifier la précision des tests de diagnostic et d'entraîner une évasion immunitaire (6). En avril 2021, trois variants préoccupants (VP) ont été identifiés, soit B.1.1.7 (7), B.1.351 (8) et P.1 (9). De nombreux variants d'intérêt sont actuellement étudiés et surveillés afin de déterminer s'ils sont ou non préoccupants (6).

Des études *in vitro* sur la neutralisation des VP ont montré que la neutralisation des variants B.1.351 et P.1 était inférieure à celle des variants originaux, mais les résultats des expériences d'immunité cellulaire et des expériences effectuées sur des modèles animaux ont permis de conclure que l'activité immunitaire était toujours stimulée. Il n'est donc pas évident de savoir dans quelle mesure ces VP pourront entraîner un échappement immunitaire à la suite de l'infection naturelle ou de la vaccination (10-16). Les données sur la réinfection et les infections sporadiques après avoir reçu le vaccin porteront sur la mesure dans laquelle différents VP peuvent échapper à l'immunité naturelle ou générée par vaccin.

Cette revue rapide résume donc les données probantes tirées des études récentes sur la réinfection, les infections ayant percé, la persistance des anticorps et d'autres marqueurs immunitaires détectés pendant plus de six mois après l'infection initiale par le SRAS-CoV-2 ou la vaccination, y compris, le cas échéant, la preuve sur l'immunité contre les VP publiée avant le 9 avril 2021. En raison de l'abondance des données sur les humains, les modèles animaux et les études *in vitro* n'ont pas été inclus.

Points clés

- Soixante-douze études ont été recensées, dont trente sur le risque de réinfection, sept sur l'infection ayant percé, trente-six sur la cinétique et la durabilité des anticorps et d'autres marqueurs immunitaires plus de six mois après l'infection initiale par le SRAS-CoV-2 ou la vaccination et quatre revues rapides ou systématiques.
- Dans l'ensemble, nous avons constaté que le risque de réinfection était faible, que le risque d'infection sporadique par les variants originaux ou par le VP B.1.1.7 était plus élevé même après la vaccination, mais qu'il était malgré tout assez faible. Six mois après l'infection, la majorité des personnes étudiées avaient encore des marqueurs détectables de l'immunité, mais une faible proportion de cas n'avait pas établi de taux d'anticorps détectables ou les taux d'anticorps avaient baissé en moins de six mois.

Risque de réinfection :

- Les meilleures données probantes à ce jour sur l'immunité protectrice naturelle proviennent des données sur la réinfection figurant dans une étude clinique et dans 29 études de cohorte prospectives et rétrospectives.
- Les études incluses indiquent que la présence d'anticorps découlant d'une infection antérieure est associée à une protection contre la réinfection pouvant atteindre huit mois (Tableau 1).
- Les cohortes qui n'ont utilisé que des cas confirmés de réinfection dans leurs estimations du risque ont déclaré des niveaux de protection plus élevés (96 à 99 %) (17 à 20) que celles qui incluaient des cas soupçonnés de réinfection (83 à 96 %) (21 à 28).
    - Les analyses ajustées du risque de réinfection dans certaines grandes cohortes comprenaient : des études effectuées au Qatar 0,01 % (IC à 95 % : 0,01 à 0,02 %, n = 1 366) (18), au Royaume-Uni 0,7 % (IC à 95 % : 0,6 à 0,8, n = 36 509) (29) et au Mexique 0,26 % (n = 100 432) (30), respectivement.
    - De petites études de cohorte ont cependant indiqué une protection complète pendant 5 à 10 mois (31 à 33).
    - Selon les cohortes avec réinfection confirmée et soupçonnée, les personnes qui avaient reçu un diagnostic clinique ou de laboratoire d'infection antérieure ont affiché pendant un maximum de dix mois des taux d'attaque de l'infection beaucoup plus faibles lors du suivi que celles qui avaient obtenu un taux séronégatif ou un résultat négatif au test RT-PCR au départ (0 % à 3,4 % c. 1,29 % à 28,7 %) (17, 21, 23 à 26, 31 à 38).
- La protection contre la réinfection était la même pour les variants originaux et pour le B.1.1.7 (29). Aucune protection contre la réinfection par le VP B.1.351 n'a été signalée dans un essai effectué en Afrique du Sud (39).
- Le temps médian entre l'infection initiale et la réinfection dans les cohortes avec réinfection confirmée variait entre 52 et 201 jours (plage de 15 à 297) (18, 19, 22) et, dans les cohortes avec réinfection soupçonnée, entre 56 et 241 jours (plage de 40 à 345 jours) (22, 23, 27, 28, 30, 40 à 42). Ces dernières données peuvent inclure des points de données mal classés représentant plutôt des résultats positifs ou récurrents ayant tous deux été recensés dans la littérature.
- Les personnes réinfectées (environ 50 %) étaient plus susceptibles d'être asymptomatiques que les personnes qui en étaient à leur première infection (19,2 %) (22, 27).
- Plusieurs études indiquent que les personnes qui n'ont pas eu de séroconversion n'ont peut-être pas le même degré de protection contre la réinfection que celles qui ont des titres d'anticorps élevés (17, 34, 43). Toutefois, après la réinfection, la majorité des cas ont montré une réponse par anticorps IgG (34).
- Une réponse par anticorps IgG plus élevée et prolongée a donc été corrélée avec un risque plus faible de réinfection. Un plus grand âge (p = 0,001), la durée des symptômes (p = 0,002) et le nombre de

symptômes (p < 0,001) ont été corrélés avec des réponses par anticorps IgG plus élevées après l'infection primaire (43).

- Des données contradictoires sur l'âge comme facteur de risque de réinfection ont été rapportées dans toutes les études, certaines indiquant des groupes plus âgés (plus de 65 ans) et d'autres, des groupes plus jeunes (10 à 29 ans) (30, 41, 42, 44).
- Des maladies chroniques sous-jacentes ont été associées à la réinfection (30).

Infection sporadique après une vaccination complète :

- Des essais contrôlés randomisés et des études d'observation en situation réelle ont démontré que l'infection sporadique associée au virus de type sauvage et au variant B.1.1.7 était moins virulente après l'administration de deux doses de vaccin (tableau 2).
- Dans des études en situation réelle, lorsque les vaccins Pfizer-BioNTech, Moderna ou Oxford-AstraZeneca étaient utilisés, cela a réduit l'incidence de l'infection par le SRAS-CoV-2 de plus de 90 % alors que l'immunité naturelle après l'infection entraînait une réduction de l'incidence de 85 % (45-47).
- Les essais cliniques et les investigations en situation réelle portant sur les vaccins Pfizer-BioNTech et Oxford-AstraZeneca ont démontré une protection efficace et similaire (p > 0,05) contre le variant B.1.1.7 par rapport au variant original (45, 48).

Marqueurs de réponse immunitaire plus de six mois après l'infection :

- Trente-sept études comprenant un suivi avec plus de 30 observations effectué plus de six mois après l'infection (jusqu'à douze mois) fournissent des preuves basées sur les taux d'anticorps circulants et les taux de lymphocytes B et T contre le SRAS-CoV-2 (tableau 3). La relation spécifique entre ces corrélations d'immunité et de protection contre l'infection par le SRAS-CoV-2 ou la réinfection n'est cependant pas bien comprise.
- Onze études font état d'une réponse immunitaire cellulaire liée aux lymphocytes B mémoires (soit les cellules immunitaires qui produisent les virus qui ciblent les anticorps) et aux lymphocytes T mémoires (c.-à-d. les cellules immunitaires qui guident les réponses immunitaires adaptatives des cellules) après une infection naturelle qui confère probablement une certaine immunité à long terme contre les réinfections ultérieures.
    - Le fait que le niveau d'activité des lymphocytes B et T mémoires était élevé et qu'il se soit poursuivi pendant plus six mois après l'infection pourrait constituer une meilleure mesure de l'immunité protectrice que les anticorps circulants dont le niveau diminue avec le temps, une fois la personne rétablie après l'infection par le SRAS-CoV-2 (49 à 52).
    - De façon générale, la portée et l'ampleur des réactions des lymphocytes T se sont maintenues (et augmentaient parfois) au-delà de six mois après l'infection ou l'apparition des symptômes (49 à 54). Une étude signale que les lymphocytes T de 95 % des cas bénins sont demeurés sensibles à au moins un bassin de peptides du SARS-CoV-2, et a quantifié une médiane de

200 cellules par million de cellules mononuclées de sang périphérique (PBMC) (ou 1 cellule sur 5 000) pour être spécifique au SRAS-CoV-2 après un suivi de 6 mois (55).

- Elle a permis de voir chez 80 % des personnes qui avaient eu une forme bénigne à modérée de l'infection par la COVID-19 une fréquence élevée de lymphocytes B mémoires totaux spécifiques contre le domaine de liaison au récepteur (RBD) du virus SRAS-CoV-2 (56).
- Dans certaines études, on a constaté que les lymphocytes T CD8+ étaient moins robustes que les réponses des lymphocytes T CD4+ obtenues plus de six mois après l'infection (49, 54, 56, 57), mais les répercussions de ces résultats sur les réponses à long terme des lymphocytes T n'ont pas encore été établies.

- La cinétique des anticorps à long terme a été décrite dans 33 études menées de 6 à 12 mois après l'apparition des symptômes.
  - Les études font régulièrement état du fait que la majorité (entre 70 et 99 %) des personnes ont continué à obtenir des résultats positifs pour les anticorps neutralisants spécifiques au SRAS-CoV-2, les anticorps IgG contre la protéine S ou les anticorps IgG anti-RBD six mois après l'infection (32, 43, 52, 56, 58, 59, 59, 59, 60, 60 à 65).
  - Une étude a mentionné des résultats semblables obtenus six mois après la vaccination complète chez les personnes ayant reçu le vaccin Moderna (64).
  - Les taux d'anticorps neutralisants étaient plus élevés et les taux d'IgG contre la protéine S étaient plus faibles chez les personnes qui avaient eu une forme grave de la COVID-19 que chez celles dont l'infection avait été bénigne ou modérée (43, 52, 56, 58 à 60, 60 à 63).
  - Les taux d'IgG spécifiques contre la protéine N étaient très variables (25 % à 98 %) dans les échantillons de l'étude inclus obtenus plus de six mois après l'infection (37, 59, 61, 62, 66).
  - Les enfants présentaient des niveaux plus faibles d'anticorps IgG contre les protéines S et N et dans une étude, la proportion globale d'anticorps contre les protéines accessoires était plus élevée et plus stable chez les enfants que chez les adultes (67).

Revues :

- Les revues rapides et systématiques pertinentes comprennent la recherche sur la COVID-19 effectuée entre juin et décembre 2020 sur les corrélations avec l'immunité figurant dans des études menées au début de la pandémie (tableau 4). Elles sont incluses comme ressources pour la recherche effectuée à chacun des temps de mesure, soit avant les six derniers mois.

Vue d'ensemble des éléments de preuve

Les études sur la réinfection comprenaient des cohortes prospectives, dont certaines grandes études multicentriques, qui présentent un faible risque de biais et une capacité de généralisation élevée. Des analyses à variables multiples conçues pour tenir compte de la confusion possible n'ont pas toujours été effectuées, ce qui peut donc fausser les résultats. Des cohortes rétrospectives comprenant des données tirées des dossiers médicaux ou des données de surveillance recueillies de façon régulière sur le COVID-19 ont également été incluses. Certaines de ces études semblaient avoir une bonne capacité de généralisation, car elles utilisaient de grandes bases de données nationales. D'autres se concentraient davantage sur les travailleurs de la santé dans un seul centre hospitalier ou sur des groupes de patients spécifiques. Les cohortes rétrospectives présentent toutefois un risque plus élevé de biais en raison de la nature rétrospective de l'étude, des données manquantes et des facteurs de confusion possible.

Les études sur les infections ayant percé ou sporadiques comprenaient des essais contrôlés randomisés, des études de cohorte prospectives et des études cas-témoins. Les essais contrôlés en double aveugle avec placebo constituent l'étalon-or pour mesurer les répercussions d'une intervention, mais ils ne fournissent pas nécessairement d'estimation précise de l'efficacité de la vaccination dans le monde réel, et ne sont pas non plus aussi susceptibles de se produire pendant un scénario actuel de pandémie. Bien que les études d'observation fournissent une évaluation réelle à propos d'une intervention, elles peuvent également présenter un plus grand nombre de biais. Cela inclut notamment la nature rétrospective des études cas-témoins et la dépendance aux symptômes autodéclarés dans de nombreuses études de cohorte.

Les études sur l'immunité à long terme comprenaient surtout des données longitudinales tirées d'études d'observation, notamment de cohortes prospectives, de séries de cas et d'études transversales, qui présentent un risque modéré à élevé de biais de sélection et de confusion. Ainsi, la plupart des études ont fait état de la gravité de l'infection clinique chez les participants ayant pris part à l'étude, mais bon nombre d'entre elles ne semblent pas avoir tenu compte des différences dans l'état immunitaire de référence dans leurs échantillons, état qui peut être influencé par différentes comorbidités (p. ex., cancer, problèmes cardiaques, maladie rénale, diabète, etc.). Tout comme la réponse immunitaire à l'infection initiale varie grandement, les réponses immunitaires obtenues six mois après une infection au SRAS-CoV-2 sont également très variables. Les différences dans les données démographiques des participants à l'étude, l'état immunitaire de référence, la gravité clinique des infections, les résultats immunitaires étudiés, le temps de suivi et les méthodes de mesure ont probablement contribué à une partie de l'hétérogénéité que nous avons observée. La variabilité peut également découler du recours à différentes méthodes de détection des anticorps et des cellules immunitaires utilisant divers paramètres de sensibilité et de spécificité des tests. Tous ces facteurs font en sorte qu'il est difficile de comparer les résultats entre les études (61).

Lacunes dans les connaissances :

- Il n'y a pas d'études de grande qualité sur la durée, l'efficacité potentielle et l'efficacité réelle de la protection fournie par les anticorps neutralisants.

- Il est difficile de comprendre la corrélation entre les mesures immunologiques (p. ex., les titres d'anticorps neutralisants) et la protection. Des données sur l'efficacité clinique seront aussi requises pour fournir une évaluation définitive de la protection assurée par le vaccin.
- Le rôle des anticorps spécifiques et des lymphocytes B et T dans l'élimination de l'infection n'a pas été déterminé de façon définitive chez les humains.
- La majorité des éléments de preuve sur l'immunité protectrice contre les variants préoccupants actuels sont associés au variant B.1.1.7. Il faudra des preuves supplémentaires à propos des autres variants préoccupants en plus des expériences préliminaires *in vitro* et des modèles animaux.

TABLE DES MATIÈRES

RISQUE DE RÉINFECTION

Le Centre européen de prévention et de contrôle des maladies a créé un organigramme pour évaluer la réinfection (2) et d'autres définitions visant à établir une distinction entre la réinfection confirmée et la rechute/réactivation et la récidive ont également été proposées (3) ou sont en cours d'élaboration. Les définitions utilisées dans cette revue sont donc fondées sur ces lignes directrices publiées.

Une réinfection confirmée exige : une infection initiale confirmée par test RT-PCR ET une deuxième infection confirmée par test RT-PCR ET un ou des résultats négatifs au test RT-PCR effectué entre la première et la deuxième infection ET des données de séquence génomique provenant des deux épisodes qui permettront de distinguer deux isolats viraux différents.

Une réinfection présumée exige : un résultat positif au test RT-PCR obtenu plus de 90 jours après le premier épisode (confirmé cliniquement ou en laboratoire) OU un résultat positif au test RT-PCR obtenu moins de 90 jours entre les épisodes, avec une preuve épidémiologique de réexposition au SRAS-CoV-2.

Les meilleures données probantes à ce jour sur l'immunité protectrice proviennent de quelques études de cohorte sur le risque de réinfection ayant récemment été publiées. Bien que les rapports/séries de cas de petite envergure présentant les détails des réinfections présumées aient été exclus, les cas de réinfection confirmée jusqu'au 11 février 2021 ont été résumés dans une version antérieure de cette revue rapide disponible par l'entremise du Secrétariat des sciences émergentes de l'ASPC.

Résultats des études sur la réinfection (n = 30) :

- Les anticorps créés après une infection antérieure semblent être associés à une protection contre la réinfection pouvant durer jusqu'à huit mois, mais une faible proportion de personnes ont cependant été réinfectées. Les raisons de la réinfection ou de l'absence d'immunité protectrice ne sont pas bien comprises.
- Seules trois études ont calculé les estimations du risque de réinfection à partir des cas confirmés de réinfection. Elles ont fait état d'une estimation élevée de protection contre la réinfection dans les cohortes du Royaume-Uni (> 96 %) et du Qatar (> 99 %) (17 à 19). En outre, dans une cohorte comprenant 6 771 personnes infectées pendant la première vague en France (de janvier à mai 2020), seulement 31 réinfections confirmées (0,47 %) ont eu lieu pendant la période de suivi (juin 2020 à janvier 2021) (20).
- D'importantes cohortes prospectives avec réinfections présumées (n < 1 000) provenant du Royaume-Uni et de la France ont montré que l'infection antérieure par le SRAS-CoV-2 offrait une immunité protectrice pendant un maximum de sept mois chez 83 à 96 % des personnes (21 à 23, 26). Quant aux cohortes rétrospectives provenant des États-Unis, du Royaume-Uni et de l'Autriche, elles ont permis de voir que 90 à 94 % des personnes précédemment infectées avaient bénéficié d'une protection pouvant aller jusqu'à six ou huit mois (24, 25, 27, 28). Il existe de multiples petites études de cohorte portant sur des personnes déjà infectées (n < 150) qui n'ont déclaré aucun cas de réinfection pendant la période de 5 à 10 mois utilisée à des fins de suivi (protection complète) (31 à 33).
- Une vaste étude de surveillance menée au Danemark a révélé que la protection contre la réinfection dans la population était supérieure à 80 % chez les personnes âgées de moins de 65 ans lors du suivi de 7 mois, mais qu'elle était beaucoup plus faible (47 %) chez les personnes âgées de 65 ans et plus (68). Une étude menée en Israël a révélé que le plus grand nombre de réinfections s'était produit chez des personnes âgées de 10 à 29 ans (environ 50 %) (41). Le risque de réinfection parmi les différents groupes d'âge est probablement lié à un certain nombre de facteurs, y compris la tendance épidémiologique/comportementale en vigueur dans la région à ce moment-là (p. ex., les populations plus jeunes semblaient être plus touchées pendant la deuxième vague de COVID-19), ainsi que la possibilité d'une baisse de l'immunité chez les adultes plus âgés.
- Le risque de réinfection était faible dans toutes les études fondées sur de vastes cohortes rétrospectives composées de la population en général. Au Qatar, le risque ajusté de réinfection confirmée était de 0,01 % (IC à 95 % : 0,01 à 0,02 %, n = 133 266) (18). Les estimations du risque étaient légèrement plus élevées dans les cohortes qui incluaient la réinfection présumée. Ainsi, au Royaume-Uni, il était de 0,7 % (IC à 95 % : 0,6 à 0,8, n = 36 509) (29) alors qu'au Mexique, le risque était de 0,26 % (n = 100 432) (30).
- Le temps de réinfection était une médiane de 52 à 65 jours (intervalle de 15 à 212 jours) dans les cohortes avec réinfection confirmée (18, 19) comparativement à 56 à 241 (intervalle de 40 à 345 jours) dans les cohortes avec réinfection présumée (22, 27, 30, 40 à 42). Ces dernières données peuvent

inclure des points de données mal classés représentant plutôt des résultats positifs ou récurrents ayant tous deux été recensés dans la littérature.

- Les personnes qui ont eu un diagnostic clinique ou en laboratoire d'infection antérieure ont affiché pendant un maximum de neuf mois des taux d'attaque de l'infection beaucoup plus faibles lors du suivi que celles qui avaient obtenu un taux séronégatif ou un résultat négatif au test PCR au départ (0 % à 3,4 % c. 1,29 % à 41,2 %) (17, 21, 23 à 26, 34 à 38). Plusieurs études indiquent que les personnes qui n'ont pas eu de séroconversion n'ont peut-être pas le même degré de protection contre la réinfection que celles qui ont des titres d'anticorps élevés (17, 34, 43). Toutefois, après la réinfection, la majorité des cas ont montré une réponse par anticorps IgG (34).
    - Les travailleurs de la santé qui avaient des réponses IgG positives contre le SRAS-CoV-2 présentaient des taux plus faibles de résultats positifs au test PCR après 31 semaines de suivi comparativement aux travailleurs de la santé qui n'avaient aucune réponse IgG au début de l'étude (0,13 c. 1,09 par 10 000 jours-risque) (21). Une tendance semblable a été observée dans une cohorte provenant de la population générale en Suisse (0,3 c. 4,8 par 10 000 jours à risque) (38).
- Une réponse par anticorps IgG plus élevée et prolongée a donc été corrélée avec un risque plus faible de réinfection. Un plus grand âge ($p = 0,001$), la durée des symptômes ($p = 0,002$) et le nombre de symptômes ($p < 0,001$) ont été corrélés avec des réponses par anticorps IgG plus élevées après l'infection primaire (43).
- Deux études ont indiqué que l'immunité obtenue après l'infection initiale protégeait contre la réinfection par le variant B.1.1.7 (22, 29). Le volet avec placebo d'un essai contrôlé randomisé portant sur le vaccin Novavax n'a vu aucune différence dans l'infection ou la réinfection entre les sujets séronégatifs et séropositifs, même si la majorité des cas (92,7 %) étaient causés par le variant B.1.351, ce qui indique que l'infection antérieure ne protégeait pas contre la réinfection par le variant B.1.351 (39). Deux autres études ont relevé un pic de réinfection en décembre 2020 et en janvier 2021, ce qui pourrait être lié à l'émergence des variants préoccupants (25, 41)
- La symptomatologie déclarée pendant la réinfection a été très variable :
    - Une étude a révélé que le plus grand âge et les comorbidités étaient associés à une réinfection plus sévère (30). Cette étude a également indiqué que les patients ayant eu une atteinte initiale grave étaient plus susceptibles de développer des symptômes graves pendant la réinfection. Toutefois, comme aucun dépistage de masse n'était en vigueur, les cas asymptomatiques à la suite de la réinfection par le SRAS-COV-2 ne seront probablement pas identifiés. De nombreux rapports de réinfection peuvent être biaisés vers l'identification de cas plus graves.
    - Les sujets qui avaient déjà eu une forme grave de la COVID-19 présentaient un risque de 20 % supérieur d'avoir des symptômes graves lors d'une réinfection.

- Une étude a révélé qu'un plus grand nombre de cas étaient symptomatiques pendant le deuxième épisode (84 %) que pendant le premier (53 %) (42). Une autre étude a révélé que 88,5 % des cas présentaient plus de symptômes lors de la réinfection que lors de l'infection initiale, mais la gravité globale des symptômes n'a pas été indiquée (34).
- Des admissions aux soins intensifs et des décès après des réinfections ont été signalés en France (4 sur 46, 8,7 %) (20). Cette étude a aussi révélé que la majorité des réinfections présentaient soit un état clinique similaire dans les deux épisodes (22 sur 46, 47,8 %) ou une forme plus légère lors du deuxième épisode (14 sur 46, 30,4 %).
- Deux études n'ont révélé aucune différence statistiquement significative dans la gravité des symptômes, l'hospitalisation ou les caractéristiques de laboratoire entre les deux épisodes ($p > 0,05$) (40, 69).
- Deux études ont indiqué que la réinfection était moins grave que les infections primaires (18, 19).

Tableau 1 : Études évaluant le risque de réinfection avec le SRAS-CoV-2 (n = 30)

ÉTUDE	MÉTHODE	PRINCIPAUX RÉSULTATS
Réinfection confirmée (n=4)		
Abu-Raddad (2021) (19) *Prépublication* Étude de cohorte rétrospective Qatar Avril à décembre 2020	Les personnes positives à l'anticorps du SRAS-CoV-2 qui ont eu un écouvillonnage positif 14 jours ou plus après le premier résultat positif au test de détection des anticorps ont été suivies pendant une période médiane de 17 semaines (intervalle de 0 à 45) pour pouvoir obtenir des preuves de réinfection (n = 43 044). On a également suivi des personnes séronégatives (n = 149 923) pour déterminer l'incidence de l'infection. Le séquençage du génome	Écouvillonnage de sécrétions rhinopharyngées et oropharyngées – 314 personnes séropositives ont eu un résultat d'écouvillon positif 14 jours ou plus après le premier résultat positif au test de détection des anticorps. – 32 cas présumés sur 314 présentaient de bonnes preuves de réinfection (Ct ≤ 30 avec écouvillonnage positif pour la réinfection), 97 cas comprenaient quelques preuves (Ct > 30 avec écouvillonnage positif pour la réinfection), tandis que les preuves étaient faibles pour les 185 cas restants. – Dans les cas où l'on trouvait de bonnes preuves de réinfection (32 sur 314, 10,2 %), le temps médian entre le premier résultat positif au test de détection des anticorps et l'écouvillonnage positif pour la réinfection était de 52 jours (intervalle de 15 à 212 jours). Les réinfections étaient moins graves que les infections primaires. – Le séquençage du génome a démontré que 5 cas sur 16 pour lesquels des spécimens jumelés étaient disponibles ont été jugés être des réinfections confirmées, soit un taux confirmé de 31,6 %. – Le risque de réinfection parmi les cas confirmés par des anticorps était de 0,10 % (IC à 95 % : 0,08 à 0,11 %)

	viral a été effectué pour des spécimens viraux jumelés (n = 16) afin de confirmer la réinfection.	alors que le taux d'incidence de la réinfection était de 0,66 par 10 000 semaines-personnes (IC à 95 % : 0,56 à 0,78). – Le risque d'infection pour les personnes séronégatives a été estimé à 2,15 % (IC à 95 % : 2,08 à 2,22 %), avec une incidence d'infection de 13,69 pour 10 000 semaines-personnes (IC à 95 % : 13,22 à 14,14). – Une tendance à la baisse du taux d'incidence de réinfection pendant chacun des mois de suivi supplémentaires a démontré que l'immunité protectrice n'avait pas diminué en sept mois. – L'efficacité de l'infection naturelle contre la réinfection a été estimée à 95,2 % (IC à 95 % : 94,1 à 96,0 %). -
Abu-Raddad (2020) (18) *Prépublication* Étude de cohorte rétrospective Qatar Février à août 2020	Tous les cas d'infection au SRAS-CoV-2 confirmés en laboratoire et ayant obtenu au moins un écouvillonnage positif lors du test RT-PCR 45 jours ou plus après un premier écouvillonnage positif ont fait l'objet d'une enquête individuelle pour trouver des preuves de réinfection (n = 133 266 cas). Le séquençage du génome viral des spécimens viraux appariés, soit le premier résultat positif et le résultat de réinfection, a été effectué pour confirmer la réinfection dans un petit sous-ensemble de cas (n = 12).	Écouvillonnage de sécrétions rhinopharyngées et oropharyngées – 243 personnes (0,18 %) ont obtenu un résultat positif à l'écouvillonnage effectué 45 jours ou plus après le premier écouvillonnage positif. De ce nombre, 54 cas (22,2 %) présentaient des preuves solides ou valables de réinfection (la positivité du résultat du test PCR était associée à des preuves contextuelles appuyant l'état de réinfection). – Le temps médian entre le premier écouvillonnage et celui effectué pour vérifier la réinfection était de 64,5 jours (entre 45 et 129 jours). – Une seule personne a été hospitalisée lors de la réinfection, alors qu'il n'avait été atteint que d'une forme bénigne de l'infection. – Seuls quatre cas de réinfection ont été confirmés par séquençage du génome viral. – Le risque de réinfection a été estimé à 0,01 % (IC à 95 % : 0,01 à 0,02 %) et le taux d'incidence de réinfection a été estimé à 0,36 (IC à 95 % : 0,28 à 0,47) par 10 000 semaines-personnes. Les auteurs concluent que la réinfection est un phénomène rare et que l'immunité contre la réinfection dure probablement au moins quelques mois après la première infection.
Brouqui (2021) (20) *nouvelle*	Les cas confirmés de COVID-19 pendant les	Sécrétions rhinopharyngées prélevées par écouvillonnage

Cohorte rétrospective. France Janvier 2020 à janvier 2021	deux vagues (janvier à mai 2020 et juin 2020 à janvier 2021) ont été analysés à des fins de preuve de réinfection. La réinfection a été définie comme le fait d'avoir obtenu deux résultats positifs pour le SRAS-CoV-2 au test qRT-PCR effectué sur des échantillons recueillis à plus de 90 jours d'intervalle après rétablissement clinique, ainsi qu'avoir obtenu au moins un résultat négatif au test qPCR après le premier résultat positif. Le génotypage du virus a également été effectué.	- Pendant la première vague, 6 771 sur 90 602 personés testées ont obtenu un résultat positif au test qRT-PCR. Conformément à la définition, 46 cas ont été jugés être des réinfections. De ce nombre, 31 ont reçu un diagnostic de réinfection confirmée fondé sur des preuves génomiques (0,47 %). - Parmi les réinfections, 22 sur 46 (47,8 %) présentaient un état clinique similaire lors des deux épisodes, 14 sur 46 (30,4 %) ont eu une forme plus légère de la maladie lors du deuxième épisode et 10 sur 46 (21,7 %) ont vu leur situation s'aggraver passant d'une maladie asymptomatique à une forme légère ou modérée ou grave ou critique. Quatre cas ont été admis aux soins intensifs ou sont décédés lors du deuxième épisode.
Jeffery-Smith (2021) (17) Enquête sur des poussées et étude longitudinale Royaume-Uni Avril à octobre 2020	Deux foyers de soins de longue durée dans lesquels une éclosion s'était produite pendant la première vague de COVID-19 ont connu une deuxième éclosion. Des enquêtes sur des poussées et la sérologie du SRAS-CoV-2 ont été effectuées pour évaluer le rôle des anticorps antérieurs dans la protection contre la réinfection au SRAS-CoV-2.	Écouvillonnage du nez -1,1 % (1 sur 88) des personnes qui avaient eu une exposition antérieure confirmée au SRAS-CoV-2 (séropositivité ou résultat positif au test PCR) lors de la première éclosion (5 mois plus tôt) ont obtenu un résultat positif lors de la deuxième éclosion, comparativement à 24,7 % (18 sur 73) des personnes qui avaient un statut séronégatif après la première éclosion. – L'efficacité protectrice de l'exposition antérieure était de 96,2 % (IC à 95 % : 72,7 % à 99,5 %) contre l'infection pendant la deuxième éclosion, pour un rapport de risque estimé de 0,038 (IC à 95 % : 0,005 à 0,273; p < 0,0001). - – Le séquençage du génome entier a révélé que la deuxième éclosion de COVID-19 avait été causée par des souches de SRAS-CoV-2 génétiquement différentes des souches trouvées pendant les premières éclosions dans chacun des foyers.

Réinfection soupçonnée (n=26)		
Hall (2021) (22) *nouveaux résultats* Cohorte prospective Royaume-Uni Juin 2020 à janvier 2021	Les membres du personnel asymptomatiques et symptomatiques (n = 25 661) qui travaillent dans les hôpitaux participant à l'étude SARS-CoV-2 Immunity and Reinfection Evaluation (SIREN) ont été suivis pendant sept mois afin d'estimer l'incidence relative des résultats positifs au test PCR selon les résultats initiaux du PCR ou les résultats initiaux obtenus pour les anticorps. Une réinfection possible a été définie comme toute personne qui a obtenu deux résultats positifs lors de tests PCR effectués sur des échantillons recueillis après un intervalle de 90 jours ou un participant positif aux anticorps dont le résultat du nouveau test PCR était positif au moins quatre semaines après le premier résultat positif aux anticorps. Un cas probable exige en outre des données sérologiques	Écouvillonnage de sécrétions nasales et oropharyngées - 8 278 (32 %) participants avaient des preuves d'infection antérieure et ont donc été ajoutés à la cohorte positive alors que 17 383 (68 %) participants qui n'avaient aucune preuve d'infection antérieure ont plutôt été affectés à la cohorte négative. - 13 401 participants (52,2 %) de la cohorte ont été vaccinés pendant la période de suivi (entre décembre 2020 et le 11 janvier 2021). Ce chiffre comprenait 9 468 personnes faisant partie de la cohorte négative et 3 933 de la cohorte positive. - Lors du suivi, on a détecté 1 704 nouvelles infections dans la cohorte négative et 155 réinfections. De ce nombre, 19,7 % des nouvelles infections et 49,7 % des réinfections étaient asymptomatiques. - La densité d'incidence était de 7,6 par 100 000 dans la cohorte positive et de 57,3 par 100 000 dans la cohorte négative. - Les participants de la cohorte positive présentaient un risque de nouvelle infection 99,8 % inférieur à celui des participants de la cohorte négative, RTI ajusté (RTIa) de 0,002 (IC à 95 % de 0,00 à 0,01). - Lorsqu'on limite les infections uniquement aux personnes ayant eu des symptômes de COVID-19, les participants de la cohorte positive présentaient une incidence de nouvelle infection inférieure de 93 % à celle des participants de la cohorte négative, RTIa 0,074 (IC à 95 %, 0,06 à 0,10). - En utilisant la définition la plus sensible de la réinfection, soit celle qui inclut également les cas possibles ou probables, les participants de la cohorte positive avaient une incidence de nouvelle infection inférieure de 84 % à celle des participants de la cohorte négative, RTIa 0,159 (IC à 95 %, 0,13 à 0,19).

	quantitatives ou des données génomiques virales au soutien obtenues à partir des échantillons disponibles. L'effet du variant B.1.1.7 a été inclus dans l'analyse en créant une variable binaire indiquant à quel moment le PCR de la négativation de la détection du gène S (SGTF) représentait 50 % ou plus des résultats positifs pour chacune des régions.	- L'infection asymptomatique (RTIa 0,48 IC à 95 %, 0,37 à 0,63) est celle qui a fourni la moins bonne protection. - Les auteurs n'ont trouvé aucune preuve que la prévalence accrue du variant B.1.1.7 a eu un effet négatif sur les taux de réinfection pendant le suivi. Les modèles suggéraient cependant que l'effet protecteur de l'infection précédente augmentait lorsque le variant était dominant (RTI de 0,18, IC à 95 %, 0,15 à 0,23) comparativement au RTI de 0,13 (0,10 à 0,17). - L'intervalle médian entre la date historique du résultat positif au test PCR ou la date de l'infection primaire et la date du résultat positif au test PCR pour la réinfection était de 201 jours (entre 95 et 297) ou de 241 jours (entre 90 et 345), respectivement.
Lumley (2021) (45) *Prépublication* *nouvelle* Cohorte prospective Royaume-Uni Septembre 2020 à février 2021	Des travailleurs de la santé ont été suivis afin d'étudier et de comparer la protection contre l'infection par le SRAS-CoV-2 que conférait la vaccination (résultats présentés dans le tableau 2) et l'infection antérieure (déterminée à l'aide de la teneur en anticorps anti-spicule). Le suivi a débuté de plus de 60 jours après le premier test positif de détection des anticorps obtenu soit avec un test PCR positif ou après la réception du premier vaccin. Pour évaluer	Écouvillonnage de sécrétions nasales et oropharyngées - Comparativement à 1 travailleur de la santé séropositif (0,08 %) sur 1 273, 294 travailleurs de la santé séronégatifs sur 10 513 (2,7 %) ont eu une infection symptomatique pendant la période de suivi. L'incidence était donc 98 % inférieure chez les travailleurs de la santé séropositifs (RTI ajusté : 0,02 (IC à 95 % : < 0,01 à 0,18; p < 0,001). - Les taux de résultats positifs au test PCR, sans égard aux symptômes, étaient les plus élevés chez les travailleurs de la santé séronégatifs non vaccinés (635 cas), avec une incidence inférieure de 85 % chez les travailleurs de la santé séropositifs non vaccinés (12 cas, RTIa = 0,15 (IC à 95 % : 0,08 à 0,26, p < 0,001). - Rien n'indique que la SGTF ait modifié l'étendue de la protection contre une infection ayant donné un résultat positif au test PCR chez les travailleurs de la santé séropositifs (RTIa c. non-SGTF, 0,43 (IC à 95 %, 0,12 à 1,52; p = 0,19). Rien n'indique non plus que le

	l'incidence du variant B.1.1.7 sur le risque d'infection ou de réinfection, les auteurs ont analysé les résultats positifs du test PCR avec et sans négativation de la détection du gène S (SGTF) alors que le séquençage du génome a été utilisé pour les résultats confirmés comme étant associés au variant B.1.1.7.	variant B.1.1.7 a modifié l'étendue de la protection détectée par tout résultat positif au test PCR chez les personnes séropositives (RTIa c. non-B.1.1.7 = 0,40 (IC à 95 %, 0,10 à 1,64; p = 0,20). - Les travailleurs de la santé séronégatifs avaient la charge virale la plus élevée (valeur Ct médiane : 18,3) alors que les travailleurs séropositifs non vaccinés avaient la charge virale la plus faible (valeur Ct médiane : 27,2).
Lumley (2020) (21) Étude de cohorte prospective Royaume-Uni Avril à novembre 2020	Suivi du personnel asymptomatique et symptomatique (n = 12 541) dans les hôpitaux de l'Université d'Oxford pendant un maximum de 31 semaines pour estimer l'incidence relative des résultats positifs au test PCR et des nouvelles infections symptomatiques à l'aide de l'état des anticorps.	Écouvillonnage de sécrétions nasales et oropharyngées – Les travailleurs de la santé qui ont obtenu des résultats positifs lors des épreuves biologiques effectuées sur les anticorps IgG anti spicule pour le SRAS-CoV-2 ont obtenu moins de résultats positifs au test PCR effectué lors du suivi que ceux dont les résultats de départ étaient négatifs (0,13 par rapport à 1,09 par 10 000 jours-risque). – L'incidence des résultats positifs aux tests PCR a été inversement associée aux titres d'anticorps anti spicule, ce qui suggère que l'infection antérieure qui a entraîné la création d'anticorps au SRAS-CoV-2 est associée à une protection contre la réinfection durant au moins six mois. -Des trois travailleurs de la santé séropositifs qui ont ensuite obtenu des résultats positifs au test PCR pour l'infection par le SRAS-CoV-2, un seul avait déjà obtenu un résultat positif pour le SRAS-CoV-2 190 jours auparavant. Asymptomatique lors d'une possible réinfection, ce cas a obtenu des résultats négatifs aux tests RT-PCR effectués deux et quatre jours plus tard et aucune augmentation subséquente n'a été remarquée lors du titrage des anticorps. - – Les résultats indiquant une réinfection peuvent être compatibles avec une réexposition au SRAS-CoV-2 n'ayant pas entraîné de symptômes, mais ils peuvent être des faux positifs. Il faut donc faire

		preuve de prudence au moment d'interpréter les résultats de cette étude.
Clarke (2021) (37) Étude de cohorte prospective Royaume-Uni Février 2020 à janvier 2021	Patients recevant de l'hémodialyse dans un centre (n = 356) qui ont été soumis à une sélection longitudinale pour la séropositivité au SRAS-CoV-2 (anticorps anti-NP ou anti-RBD) et un résultat positif au test RT-PCR. Les résultats positifs au test PCR obtenus plus de 60 jours après un test sérologique initial ont été enregistrés pour éviter de détecter une infection virale persistante plutôt qu'une réinfection.	Sécrétions rhinopharyngées prélevées par écouvillonnage – Les patients qui avaient obtenu des résultats séropositifs initiaux étaient beaucoup moins susceptibles d'obtenir un résultat positif au test PCR effectué au moment du suivi que ceux qui avaient obtenu au départ un résultat sérologique, soit 3,4 % (5 sur 129) comparativement à 13,2 % (30 sur 227), p < 0,005. - – Les réactions immunitaires à l'infection naturelle par le SRAS-CoV-2 chez les patients atteints d'hémodialyse ont duré jusqu'à six mois, même chez ceux qui ont eu une forme bénigne ou asymptomatique de l'infection.
Krutikov (2021) (26) *Prépublication* *nouvelle* Cohorte prospective Royaume-Uni Juin 2020 à février 2021	Les résidents (n = 682) et les membres du personnel (n =1 429) de 100 établissements de soins de longue durée ont subi chaque semaine et chaque mois des tests RT-PCR afin de détecter le SRAS-CoV-2. Toute personne qui obtenait un résultat positif n'a pas eu à repasser le test dans les 90 jours suivants. L'on a demandé aux participants s'ils acceptaient qu'on prélève trois échantillons	Sécrétions rhinopharyngées prélevées par écouvillonnage - Des anticorps de référence ont été détectés chez 226 résidents (33 %) et 408 membres du personnel (29 %). - Chez les résidents, un total de 93 personnes négatives aux anticorps ont obtenu un résultat positif au test PCR de suivi (0,054 par mois à risque) comparativement à 4 personnes positives aux anticorps (0,007 par mois à risque). - Au sein du personnel, un total de 111 personnes négatives aux anticorps ont obtenu un résultat positif au test PCR de suivi (0,042 par mois à risque) comparativement à 10 personnes positives aux anticorps (0,009 par mois à risque). - Dans l'analyse de régression de Cox, les rapports de risque ajustés relatifs pour un test PCR positif à

	de sang à trois temps de mesure à des intervalles de six à huit semaines en juin (prélèvement de référence), en août et en octobre 2020 afin d'obtenir les titres d'anticorps. Tous les résultats positifs aux tests PCR effectués après octobre 2020 ont été jugés indiquer une infection ou une réinfection.	l'infection étaient de 0,15 (0,05 à 0,44) pour les résidents séropositifs par rapport aux résidents séronégatifs et de 0,39 (0,19 à 0,82) pour le personnel séropositif par rapport au personnel séronégatif. - La majorité des réinfections étaient symptomatiques (11 sur 14), mais personne n'a été admis à l'hôpital ou n'est décédé à cause de l'infection. - La valeur Ct médiane des cas de réinfection était de 36 (plage de 30,1 à 37,0).
Dimeglio (2021) (23) *Lettre à la rédaction* Étude de cohorte prospective France Juin à décembre 2020	Après la première vague de l'épidémie (juin/juillet), les travailleurs de la santé (n = 8 758) ont fait l'objet de titres pour les anticorps neutralisants et les anticorps anti spicule du SRAS-CoV-2. Cette sérologie a ensuite été étudiée et de nouvelles infections ont été déterminées lors du suivi en novembre/décembre.	Type d'écouvillon non indiqué – Le suivi médian était de 167 jours (EI : 156 à 172). – Lors du suivi, 1,8 % (5 participants sur 276) du groupe séropositif a été déclaré positif comparativement à 12,1 % (1 028 sur 8 482) du groupe séronégatif ($p < 0,01$). – Parmi les cinq personnes séropositives initialement, puis infectées pendant la période de suivi, les titres d'anticorps neutralisants étaient faibles ou indétectables après la première infection pour deux d'entre elles alors que les titres des trois autres étaient supérieurs à la médiane. - Les données indiquent que l'infection précédente a fourni une immunité protectrice pendant au moins 167 jours.
Barbaro (2021) (33) *Prépublication* *nouvelle* Cohorte prospective Italie Avril à octobre 2020	Les travailleurs de la santé (n = 344) ont subi des tests de détection de l'ARN du SARS-CoV-2 combinés à la détection des anticorps IgM et IgG, une fois par semaine pendant quatre semaines consécutives.	Sécrétions rhinopharyngées prélevées par écouvillonnage - Un total de 14 travailleurs sur 344 (4,07 %) ont eu des résultats positifs pour le SRAS-CoV-2 avec le test RT-PCR. Le résultat du test de détection des anticorps IgG ou IgM était positif chez 12 des 14 (85,7 %) et négatif chez 15 des 330 (4,55 %) sujets positifs pour le SRAS-CoV-2.

	Les participants qui ont obtenu des résultats positifs à la sérologie du SRAS-CoV-2 ont fait l'objet d'un suivi pendant cinq mois avec tests RT-PCR et sérologies.	- 25 sujets ont été suivis pendant cinq mois, mais aucune réinfection n'a été détectée.
Dehgani-Mobaraki (2021) (31) *Prépublication* Cohorte prospective Italie Mars à novembre 2020	Les personnes qui ont reçu un résultat positif au test RT-PCR pour le SRAS-CoV-2 pendant le mois de mars 2020 (n = 30) ont fait l'objet d'un suivi pendant 10 mois afin d'obtenir des preuves de la présence et de la persistance des anticorps spécifiques au SRAS-CoV-2.	Écouvillons respiratoires - Aucun cas de réinfection n'a été signalé dans cette cohorte. - Remarque : cette étude ne décrit pas la méthode utilisée pour détecter les réinfections potentielles (aucune description des tests RT-PCR effectués lors du suivi).
Dobaño (2021) (43) *Preprint* Prospective cohort Spain Mar-Nov 2020	Évalue la séroprévalence et les niveaux d'anticorps de 149 à 270 jours après l'apparition des symptômes dans une cohorte de 173 agents de soins de santé primaires atteints d'une infection confirmée (par test RT-PCR) pendant le premier pic de la pandémie (mars et avril 2020). Trois points temporels de prélèvement de sang veineux entre septembre et novembre 2020 ont été utilisés pour évaluer	Écouvillons respiratoires - Lors du suivi, le pourcentage obtenu de séropositivité combinant les antigènes RBD et S était de 60,69 % pour l'IgM, de 76,30 % pour l'IgA et de 90,17 % pour l'IgG. - Il y a eu 2,3 % de réinfections (4 travailleurs sur 173). Deux cas symptomatiques étaient séronégatifs avant la réinfection alors qu'un cas asymptomatique était séropositif et que l'état sérologique d'un autre était inconnu. Les réinfections se sont produites entre trois et huit mois après l'infection initiale. - Le fait d'avoir été admis à l'hôpital, de faire de la fièvre, de l'anosmie ou de l'hypogueusie et avoir eu des allergies antérieures a été associé à des niveaux plus élevés d'anticorps pendant le suivi (cinq à neuf mois plus tard). - Une corrélation a été effectuée entre des IG plus élevés et l'âge avancé, la durée des symptômes et le nombre de symptômes.

	l'immunité et la réinfection possible chez ces travailleurs de la santé dans le cadre d'une étude de cohorte ayant duré un an et demi.	
Garcia-Abellan (2021) (32) *Prépublication* *nouvelle* Cohorte prospective Mars à décembre 2020 Espagne	Des échantillons de sang et des échantillons provenant d'écouvillons nasopharyngiens ont été utilisés pour mesurer l'ARN du SRAS-CoV-2 et les anticorps IgG contre la protéine S et contre la protéine N pendant le séjour à l'hôpital, puis 1, 2 et 6 mois après le congé. Le séquençage du génome du SRAS-CoV-2 a aussi été effectué. La réinfection présumée du SRAS-CoV-2 a été définie en fonction des critères établis par le CDC. Des preuves plus solides de réinfection exigeraient des preuves génomiques provenant de deux lignées distinctes.	Sécrétions rhinopharyngées prélevées par écouvillonnage - Parmi 146 patients inclus dans l'analyse, 11,8 % (valeur Ct médiane = 38) et 3 % (valeur Ct médiane = 36) ont obtenu un résultat positif au test RT-PCR pour le SRAS-CoV-2 après 2 mois et 6 mois, respectivement, mais aucune réinfection n'a été démontrée.
Shinde (2021) (39) *nouvelle* Essai clinique randomisé	Essai de phase 2b du NVX-CoV2373, un vaccin à nanoparticules. Au total, 4 877 participants randomisés ont pris part à l'étude et ont reçu au moins une fois une dose du vaccin. De ce	Écouvillonnage du nez - Parmi les cas associés aux critères d'évaluation principale pour lesquels le séquençage du génome entier était disponible, le variant B.1.351 a été trouvé dans 38 (92,7 %) cas sur 41. - En ce qui concerne les participants qui ont reçu le placebo, l'incidence de COVID-19 symptomatique

Afrique du Sud Août à novembre 2020	nombre, 2 199 ont reçu le vaccin NVX-CoV2373 et 2 188, un placebo. La sérologie au niveau de référence a été déterminée et des tests RT-PCR de suivi ont également été effectués. Le séquençage du génome du virus entier a été effectué sur des échantillons provenant du nez des participants.	était semblable pendant les deux premiers mois du suivi chez les participants séronégatifs et séropositifs de référence avec des taux de 5,3 % (IC à 95 %, 4,3 à 6,6) et de 5,2 % (IC à 95 %, 3,6 à 7,2) respectivement, ce qui indique que l'infection antérieure ne protégeait pas contre la réinfection par le variant B.1.351.
Graham (2021) (29) *Prépublication* Étude de surveillance longitudinale Royaume-Uni Mars à décembre 2020	Les données longitudinales sur la population en général recueillies prospectivement grâce à l'application COVID Symptom Study ont été combinées à des données de surveillance provenant du Covid-19 UK Genetics Consortium pour étudier le taux de réinfection et d'autres caractéristiques de la COVID-19. La réinfection a été définie comme deux résultats positifs aux tests RT-PCR effectués à plus de 90 jours d'intervalle avec une période asymptomatique de plus de sept jours entre les tests PCR. L'évaluation du risque de réinfection pour le nouveau variant B.1.1.7 a été obtenue en	Type d'écouvillon non indiqué – 304 personnes ont obtenu deux résultats positifs aux tests effectués à un intervalle supérieur à 90 jours, dont 249 ont eu une période sans symptôme entre les deux tests, pour un taux de réinfection estimé à 0,7 % (IC à 95 % : 0,6 à 0,8) (249 personnes sur 36 509). – Le taux de réinfection n'a pas varié selon les régions ou avec le temps. La réinfection était corrélée de façon plus positive avec l'augmentation régionale globale des cas plutôt qu'avec l'augmentation régionale du pourcentage du variant B.1.1.7, ce qui indique que l'immunité cumulée après l'infection initiale pourrait aussi offrir une protection contre le variant B.1.1.7.

	calculant les corrélations entre le nombre de réinfections possibles et la proportion de nouveaux cas de variants au fil du temps.	
Hansen (2021) (68) *nouvelle* Étude de surveillance et cohorte rétrospective Danemark Février à décembre 2020	Analyse des données tirées de la base de données danoise sur la microbiologie (MiBa) pour toutes les personnes ayant subi un test PCR pour le SRAS-CoV-2. Les taux d'infection pendant la deuxième vague ont été comparés chez les personnes ayant obtenu un résultat positif ou négatif au test pendant la première vague. L'analyse principale a exclu les personnes qui avaient obtenu un premier résultat positif entre les deux flambées et celles qui sont décédées avant la deuxième. Une analyse alternative dans le cadre de laquelle chaque personne ayant obtenu un résultat au test PCR a fait l'objet d'un suivi de la date de son premier test jusqu'au 31 décembre 2020, ou 90 jours après tout	Prélèvements de gorge - Pendant la première vague, 533 381 personnes ont été testées, dont 11 727 (2,2 %) ont obtenu un résultat positif au test PCR. Pendant la deuxième, 3,48 millions de personnes ont été testées, dont 150 159 (4,32 %) ont obtenu un résultat positif. - Le taux quotidien d'infection pendant la deuxième vague chez les personnes qui avaient déjà obtenu un résultat positif au test était de 5,35 par 100 000. - Le taux quotidien d'infection au cours de la deuxième vague chez les personnes n'ayant pas obtenu de résultat positif au test était de 27,06 par 100 000. - Le ratio de risque d'infection ajusté était de 0,195 (IC à 95 %, 0,155 à 0,246) chez celles qui avaient déjà obtenu un résultat positif comparativement à celles qui n'en avaient pas obtenu. - La protection contre la réinfection a été estimée à 80,5 % (IC à 95 %, 75,4 à 84,5). - L'analyse de l'autre cohorte a donné des estimations semblables, soit RR ajusté de 0,212 (0,179 à 0,251), protection estimée à 78,8 % (74,9 à 82,1). - La protection était plus faible chez les 65 ans et plus, avec un niveau observé de 47,1 % (IC à 95 %, 24,7 à 62,8). - On a également pu voir une différence de protection selon le sexe. - Le suivi a permis de voir que la protection n'avait cependant pas diminué avec le temps puisqu'elle atteignait 69,3 % (74,4-83,3) de 3 à 6 mois après le début du suivi contre 77,7 % (70,9-82,9) à 7 mois.

	résultat positif à un nouveau test.	
Leidi (2021) (38) *Prépublication* *nouvelle* Cohorte rétrospective appariée Suisse Avril 2020 à janvier 2021	Entre avril et juin 2020, un échantillon aléatoire formé de personnes représentatives (n = 8 344) ont pris part à un essai sérologique pour le SARS-CoV-2. Les participants ont été répartis en deux groupes, selon leur taux d'anticorps de référence. Les participants séropositifs ont été jumelés à deux cas-témoins de contrôle séronégatifs. Tous les participants séropositifs lors du test de dépistage du SRAS-CoV-2 effectué pendant le suivi ont fait l'objet d'une exploration clinique axée sur la réinfection. La probabilité de réinfection était fondée sur le jugement clinique, la symptomatologie et l'évolution de la valeur ou du temps en fonction du seuil établi pour le cycle de tests RT-PCR.	Écouvillonnage oropharyngé ou nasopharyngien - Des 8 344 personnes incluses dans la sérologie effectuée entre avril et juin 2020, 498 avaient des anticorps IgG anti-sous-unité S1 de la protéine S pour le SARS-CoV-2 et on avait suffisamment de données à leur égard pour les inclure dans l'étude. - Ces cas ont été appariés à 996 cas-témoins séronégatifs. - Parmi toutes les personnes séropositives incluses dans l'étude, cinq cas étaient probablement des réinfections (1 %, 5 sur 498), ce qui correspond à une incidence de 0,3 (IC à 95 %, 0,1 à 0,7) par 1 000 semaines-personnes. - Le taux d'infections confirmées par le SRAS-CoV-2 était beaucoup plus élevé chez les personnes séronégatives (15,5 %, 154 sur 996), ce qui correspond à un taux d'incidence de 4,8 (IC à 95 %, 4,6 à 6,2) par 1 000 semaines-personnes (p < 0,001). - Les sujets séropositifs étaient 94 % moins susceptibles d'avoir une infection par le SRAS-CoV-2 ayant été confirmée par virologie comparativement aux sujets n'ayant pas d'anticorps contre le SARS-CoV-2 détectables au départ (rapport de danger = 0,06, IC à 95 %, 0,02 à 0,14, p < 0,001).
Breathnach (2021) (25) *Lettre à la rédaction* Étude de cohorte rétrospective	On a analysé des données de laboratoire afin de comparer le risque d'obtenir un résultat positif au test PCR pour le SRAS-CoV-2	Type d'écouvillon non indiqué – Seuls huit patients ayant des preuves d'un COVID-19 antérieur ont obtenu un résultat positif au test PCR pendant la deuxième vague (0,07 %, 8 sur 10 727). La positivité au test PCR était plus élevée pendant la deuxième vague chez les patients qui n'avaient eu

Royaume-Uni Février à décembre 2020	pendant la deuxième vague de la pandémie chez des patients qui avaient eu des preuves de COVID-19 (positivité ou séropositivité au test PCR) pendant la première vague (n = 10 727) comparativement à d'autres qui avaient déjà obtenu un résultat négatif au test PCR ou un résultat négatif au test de détection des anticorps (n = 55 274). Les cas dans lesquels le deuxième résultat positif s'est produit 90 jours ou moins après la première vague ont été exclus.	aucune preuve de COVID-19 durant la première vague (1,29 %, 713 sur 55 274). - – Cela sous-entend un effet protecteur et un risque relatif de 0,06 (IC à 95 % : 0,03 à 0,12) pour les personnes ayant présenté des preuves d'infection durant la première vague.
Hanrath (2020) (36) *Lettre à la rédaction* Étude de cohorte rétrospective Royaume-Uni De mars à novembre 2020	Analyse des données d'analyse pour les travailleurs de la santé pendant la première vague (du 10 mars au 6 juillet 2020) et après la deuxième vague (du 7 juillet au 20 novembre 2020) de la pandémie afin de déterminer si l'infection au SRAS-CoV-2 antérieure pouvait être associée à une protection. Le principal indicateur de résultat de l'analyse était une infection symptomatique	Écouvillonnage de sécrétions rhinopharyngées et oropharyngées -1 038 travailleurs de la santé présentant des signes d'infection antérieure (résultat positif au test PCR ou Ab) et 10 137 sans aucun signe (Ab négatif, sans résultat positif au test PCR) ont été sélectionnés pendant la première vague. – Au cours de la deuxième vague, 2 433 travailleurs de la santé ont subi des tests PCR afin de déceler des symptômes. 128 d'entre eux avaient déjà été infectés alors que 2 115 ne l'avaient pas été. – Aucune réinfection n'a été décelée chez les personnes qui avaient déjà été infectées (positivité de 0 % au test) au cours de la deuxième vague, médiane de 173 jours de suivi (EI : 162 à 229) tandis que le niveau de tests positifs chez les personnes qui n'avaient pas été infectées auparavant était de 13,7 % (290 sur 2 115, IC à 95 % : 12,3 à 15,2). – Si l'on tient compte de l'ensemble de la population, la positivité au test était de 0 sur 1 038 (0 % [IC à 95 % : 0 à

	au SRAS-CoV-2 confirmée par un test RT-PCR pendant la deuxième vague. Le dépistage asymptomatique par PCR a également été effectué dans le cadre d'un projet pilote.	0,4) pour celles qui ont eu la COVID-19 comparativement à 290 sur 10 137 (2,9 % [IC à 95 % : 2,6 à 3,2) pour celles qui ne l'ont pas eu (P < 0,0001)). - – Des résultats semblables ont été observés dans le test pilote chez les asymptomatiques puisqu'il n'y a eu aucun résultat positif dans le groupe ayant déjà eu une infection (0 sur 106) (0 %, IC à 95 % : 0 à 3,5), comparativement à 22 sur 375 (5,9 %, IC à 95 % : 3,9 à 8,7, P = 0,011) ayant obtenu des résultats positifs dans le groupe de personnes n'ayant pas eu le virus.
Sheehan (2021) (27) *nouvelle* Cohorte rétrospective. États-Unis Mars 2020 à février 2021	Les patients qui ont passé un test PCR de détection de la COVID-19 ont été inclus. La réinfection a été définie comme se produisant 90 jours après l'infection initiale.	Type d'écouvillon non précisé - 612 611 tests ont été effectués auprès de 386 336 personnes, dont 9,9 % ont donné un résultat positif. - Après au moins 90 jours, 1 278 (14,4 %) des patients positifs ont passé un nouveau test et 62 réinfections ont alors été notées. - Sur ces 62 réinfections, 31 étaient symptomatiques (50 %). - L'intervalle de réinfection moyen était de 138,9 ± 46,3 jours (plage : 90,2 à 294,9 jours). - Parmi les personnes ayant obtenu des résultats négatifs aux tests initiaux, 27,9 % (39 487 sur 141 480) ont passé un nouveau test et 5 449 d'entre elles (13,8 %) ont obtenu un résultat positif. - La protection contre la réinfection associée à l'infection antérieure était de 81,8 % (IC à 95 % 76,6, 85,8). - La protection globale contre l'infection symptomatique était de 84,5 % (IC à 95 % 77,9, 89,1) alors qu'elle était supérieure à 90 % entre 6 et 8 mois après l'infection. - Le risque de réinfection a été le plus élevé juste après 90 jours (ce qui peut représenter une excrétion virale prolongée), puis a diminué (voir la figure 3 dans les articles).
Harvey (2020) (24)	Analyse d'un échantillon national obtenu à partir	Type d'écouvillon non précisé

Étude de cohorte rétrospective États-Unis Janvier à août 2020	d'un ensemble de données dépersonnalisé fondé sur des analyses de laboratoire commerciales, des réclamations et des dossiers médicaux (n = 3 257 478). Au départ, les patients ont été déterminés comme étant positifs aux anticorps du SRAS-CoV-2, soit négatifs aux anticorps. Ils ont ensuite été évalués à des intervalles de 30 jours (jusqu'à plus de 90 jours) pour déterminer la positivité du test d'amplification des acides nucléiques (TAAN).	– On a suivi des patients séronégatifs (n = 2 876 773) pendant une période médiane de 47 jours (EI : 8 à 88) alors que les patients séropositifs (n = 378 606) ont été suivis pendant une période médiane de 54 jours (EI : 17 à 92). - 18,4 % des patients sont passés d'un état initialement séropositif à séronégatif pendant le suivi de 90 jours ou plus après le premier test de détection des anticorps. – Les patients séropositifs qui ont subi un test TAAN pendant le suivi (n = 41 587) présentaient un risque réduit d'avoir le SRAS-CoV-2. Résultats positifs pour le TAAN : 2,7 % de 31 à 60 jours, 1,1 % de 61 à 90 jours et 0,3 % pour plus de 90 jours. En revanche, environ 3 % des personnes séronégatives ont obtenu un résultat positif au test TAAN effectué pendant chacune des périodes de suivi. - – Cela correspond à un ratio de résultats positifs au TAAN pour les patients qui ont obtenu un résultat positif au test d'anticorps à l'indice comparativement à ceux qui ont obtenu un résultat négatif au test d'anticorps à l'indice, soit 0,67 (IC à 95 % : 0,6 à 0,74) entre 31 et 60 jours; 0,29 (IC à 95 % : 0,24 à 0,35) entre 60 et 90 jours et 0,10 (IC à 95 % : 0,05 à 0,19) après plus de 90 jours.
Pilz (2021) (28) *nouvelle* Cohorte rétrospective. Autriche Février à novembre 2020	Comparaison des probabilités de réinfection par le SRAS CoV 2 de 19 survivants qui ont eu la COVID pendant la première vague (de février au 30 avril 2020) par rapport aux probabilités d'infection du reste de la population générale à l'aide du suivi des infections confirmées par PCR dans les deux groupes pendant la deuxième vague (du	Type d'écouvillon non précisé - 40 réinfections possibles ont été découvertes dans le groupe des survivants (0,27 %) par rapport à 253 581 nouvelles infections dans la population en général (2,85 %), ce qui correspond à un rapport des cotes de 0,09 (IC à 95 %, 0,07 à 0,13) pour les infections dans le groupe des survivants par rapport à la population en général. - - L'intervalle moyen entre la première infection et la réapparition provisoire était de 212 jours (écart-type ± 25 jours). - 8 patients ont été hospitalisés lors de la première infection et 5 lors de la réinfection.

	1er septembre au 30 novembre 2020).	
Salehi (2021) (40) *Prépublication* *nouvelle* Cohorte rétrospective. Iran Mars 2021*	On a évalué les résultats des tests RT-PCR utilisés pour détecter le SRAS-CoV-2 pendant les six premiers mois de la pandémie. Les patients qui avaient obtenu deux résultats positifs à trois mois d'intervalle, avec un résultat négatif au test PCR entre les deux tests, ont été inclus.	Type d'écouvillon non précisé - Au total, 32 567 tests ont été effectués. 37 cas ont été inclus dans l'étude. - Il n'y avait aucune différence statistiquement significative dans la gravité des symptômes, l'hospitalisation ou les caractéristiques de laboratoire entre les deux épisodes (p > 0,05). - L'intervalle moyen qui s'est écoulé entre les deux épisodes était de 117 ± 61,42 jours.
Sadr (2021) (69) *Prépublication* *nouvelle* Cohorte rétrospective. Iran Mai à septembre 2020	Des tests RT-PCR et des évaluations des symptômes ont été effectués pendant une période de suivi de 6 mois chez des patients ayant obtenu un résultat positif de COVID-19 confirmé par test PCR. Le diagnostic de réinfection était basé sur les résultats des tests RT-PCR, les symptômes types et le long laps de temps (supérieur à 90 jours) entre les deux résultats positifs au test RT-PCR.	Sécrétions rhinopharyngées prélevées par écouvillonnage - Une réinfection associée à des symptômes légers a été détectée chez 3 des 82 patients (3,7 %). - Tous les patients se sont rétablis sans complication et aucun n'a nécessité de réadmission ou d'autre traitement médical. - Les problèmes médicaux sous-jacents, les antécédents récents d'utilisation de médicaments immunosuppresseurs, la gravité de la maladie, la durée de l'admission et le besoin d'être admis aux soins intensifs pendant le premier épisode de l'infection n'étaient pas significativement différents entre les patients qui avaient un résultat positif au test RT-PCR lors du suivi et ceux qui n'en avaient pas eu (p > 0,05).
Ali (2020) (34) *Prépublication* Cohorte rétrospective	Étudie l'impact du niveau d'immunoglobuline (IgG) sur la réinfection chez les sujets rétablis	Écouvillons pharyngés – Sur les 87 patients qui se sont révélés négatifs à l'IgG après leur rétablissement initial, 25 (28,7 %) ont été jugés avoir été réinfectés, ce qui a été confirmé par un résultat positif au test RT-PCR. Ce taux était plus élevé que dans le groupe de 742 patients dont le test de

Irak Mai à octobre 2020	Les niveaux d'IgG par rapport au SRAS-CoV-2 ont été mesurés juste après le rétablissement (un résultat négatif au test RT-PCR étant défini une valeur Ct > 36,7) chez des patients rétablis qui ont attrapé la COVID-19 (n = 829 patients admis entre mai et octobre dans un seul centre) et ont probablement été suivis pour en évaluer la réinfection.	dépistage de l'IgG était positif après le rétablissement initial (1 patient sur 742, soit 0,13 %). Cela suggère que les patients qui présentaient de faibles taux d'IgG après une infection initiale pourraient être plus sujets à une réinfection. – La réinfection dans le groupe s'est produite entre 26 et 138 jours après guérison de l'infection initiale. – 88,5 % des cas présentaient plus de symptômes lors de la réinfection que lors de l'infection initiale, mais la gravité globale des symptômes n'a pas été indiquée. – 95 % des cas étaient positifs pour l'IgG après la réinfection. - – Les résultats de cette étude sont préliminaires et les méthodes utilisées ont été mal décrites. L'on ne sait pas si les patients ont été inscrits et suivis prospectivement ou si l'état de réinfection est fondé sur leurs dossiers médicaux. Il faut donc faire preuve de prudence au moment d'interpréter les résultats de cette étude.
Perez (2021) (41) *Prépublication* *nouvelle* Cohorte rétrospective. Israël Mars 2020 à janvier 2021	Utilisation des données de la base de données informatisée centrale de Maccabi Healthcare Services pour sélectionner des patients ayant obtenu deux résultats positifs au test PCR à au moins 100 jours d'intervalle.	Type d'écouvillon non précisé - Au total, parmi les 149 735 personnes dont les données figuraient dans le MHS et qui avaient obtenu un résultat positif au test PCR, 154 avaient obtenu deux résultats positifs à au moins 100 jours d'intervalle et ont donc été incluses dans cette étude, ce qui représente une proportion de 0,1 % de réinfection. - Soixante-treize personnes (47,4 %) présentaient des symptômes au moment où les deux résultats positifs aux tests PCR ont été obtenus. - Le nombre de réinfections a atteint un sommet en janvier 2021. - 30 personnes ont alors été réinfectées plus de 200 jours après leur premier résultat positif au test PCR. - Le plus grand nombre de réinfections a eu lieu chez les personnes âgées de 10 à 19 ans (environ 46, 30 %), suivies des 20 à 29 ans (environ 30, 19 %) (voir la figure 1 dans l'article).

Mukherjee (2021) (42) *nouvelle* Cohorte rétrospective. Inde De janvier à octobre 2020	La base de données d'essais en laboratoire pour la COVID-19 disponible auprès du Indian Council of Medical Research (ICMR) a été utilisée pour déterminer les participants admissibles à l'étude. Les personnes ayant été réinfectées par le SRAS-CoV-2 ont été jointes par téléphone et ont répondu à des questions sur les symptômes ressentis pendant les différents épisodes. La réinfection a été définie comme toute personne ayant obtenu un résultat positif au test de dépistage du SRAS-CoV-2 à deux occasions distinctes, soit par des tests moléculaires ou un test d'antigène rapide, à un intervalle d'au moins 102 jours, avec un test moléculaire négatif entre les deux.	Type d'écouvillon non précisé - Des 9 533 637 personnes testées avant le 30 juin, 693 297 avaient obtenu un résultat positif (7,3 %). 1 300 (1,4 %) personnes ont subi un autre test moléculaire dans l'intervalle provisoire de 102 jours. Cinquante-huit des 1 300 tests (4,5 %) ont donné un résultat positif à deux reprises à un intervalle de 102 jours, ainsi qu'un résultat négatif provisoire. Trente-huit patients susceptibles d'avoir été réinfectés (38 sur 58, 65,5 %) ont pu être rejoints dans le cadre du sondage téléphonique. - La plupart des réinfections présumées sont apparues chez les hommes (29, 76,3 %) appartenant au groupe d'âge des 20 à 40 ans (30, 78,9 %). Douze d'entre eux (31,6 %) étaient des travailleurs de la santé. - L'intervalle médian (EI) entre les deux épisodes avec résultat positif au test de détection du SRAS-CoV-2 était de 119 jours (108,75 à 144,25) et variait entre 102 et 160 jours. - Pendant le deuxième épisode, on a vu un plus grand nombre de cas symptomatiques (32, 84,2 %) que lors du premier (20, 52,6 %). Des 18 participants asymptomatiques lors du premier épisode, 12 ont signalé des symptômes lors du deuxième épisode et la moitié d'entre eux a indiqué avoir eu des symptômes plus graves alors que l'autre moitié a plutôt déclaré des symptômes plus légers ou sans différence. La durée des symptômes ne différait pas entre les deux épisodes. - Parmi les 13 participants pour lesquels la valeur Ct appariée pour l'un ou l'autre des gènes de confirmation (RdRp/ORF) pour les deux épisodes était disponible, neuf (69 %) avaient une valeur inférieure lors du deuxième épisode.
Murillo-Zamora (2020) (30)	Le test RT-PCR a été réalisé sur des	Écouvillonnage du nez ou écouvillonnage nasal profond – On a déterminé 258 cas de « réinfection » confirmés en laboratoire (0,26 %).

Prépublication Cohorte rétrospective. Mexique Mars à juillet 2020	échantillons provenant de 100 432 patients. La réinfection a été définie comme la réapparition des symptômes de la COVID-19 plus de 28 jours après le premier test positif pour la COVID-19. Des données cliniques et épidémiologiques d'intérêt ont été récupérées des dossiers médicaux et des certificats de décès. Des modèles de régression linéaire ont été utilisés pour évaluer les facteurs associés au risque de réinfection symptomatique et à une forme grave du SRAS-CoV-2.	– L'intervalle entre le premier et le deuxième épisode était de 56 jours (EI : 40 à 81). Aucune différence significative n'a été observée entre les patients atteints d'une atteinte initiale grave ou non. – Lorsqu'on a comparé les réinfections graves ou non, les patients atteints d'une atteinte initiale plus grave étaient plus susceptibles d'avoir des symptômes graves (39,5 % c. 5,5 %, p < 0,001), tout comme ceux qui étaient âgés de 50 ans et plus (52,6 % c. 12,3 %, p < 0,001). – Dans de multiples analyses, les facteurs associés à une réinfection symptomatique plus grave étaient l'âge, les antécédents personnels d'obésité, l'asthme, le diabète sucré de type 2 et les maladies rénales chroniques. - Les sujets qui avaient déjà eu une forme grave de la COVID-19 présentaient un risque de 20 % supérieur d'avoir des symptômes graves lors d'une réinfection.
Xu (2020) (35) Étude de cohorte rétrospective Chine Janvier à avril 2020	Les patients qui ont eu la COVID-19 (n = 185) et qui avaient subi des tests de détection des anticorps ont été suivis toutes les deux semaines afin d'évaluer leurs réactions immunitaires (IgG et IgM) et la réinfection au fil du temps. La durée moyenne du suivi était de 45,7 jours.	Écouvillons pharyngés et anaux – Aucune réinfection ni aucun signe de transmission ne se sont produits chez les patients ayant eu leur congé. – Sur les 35 cas ayant obtenu des résultats positifs pour IgM, 12 ont été négatifs pendant le suivi. - – 154 patients (82,4 %) ont obtenu des résultats d'IgG positifs alors que 33 patients (17,6 %) ont obtenu des résultats négatifs 53 jours après le début de la maladie. Comparativement au groupe ayant eu des résultats négatifs pour l'IgG, les patients du groupe positif étaient plus âgés, avaient séjourné plus longtemps à l'hôpital, avaient pris une plus grande proportion d'antibiotiques, représentaient une proportion plus élevée de cas graves et

		présentaient un plus grand nombre d'anomalies lors du Ct.

RBD= protéine de liaison de récepteur

INFECTIONS SPORADIQUES

Bien que les vaccins contre la COVID-19 soient extrêmement efficaces pour prévenir les maladies graves, on s'attend à ce que certains cas sporadiques se produisent après la vaccination et à ce que le degré dans lequel la vaccination prévient l'infection soit encore à l'étude. Il est important de faire le suivi des infections sporadiques, en particulier celles qui causent des maladies graves, des hospitalisations et des décès, pour comprendre l'immunité protectrice que fournit la vaccination.

La présente étude a donc utilisé la définition de cas établie par les CDC pour les infections sporadiques (4) : Personne dont l'ARN ou l'antigène du SRAS-CoV-2 a été détecté dans un échantillon respiratoire prélevé 14 jours ou plus après la fin de la première série de vaccins contre la COVID-19. Les études qui ne comprenaient que des estimations des infections symptomatiques à la suite de la vaccination, plutôt que le nombre total global d'infections sporadiques (c.-à-d. asymptomatiques ou symptomatiques), ont donc été exclues.

- Deux essais cliniques randomisés sur l'efficacité du vaccin ont démontré que l'infection sporadique de type sauvage et celle associée au variant B.1.1.7 après deux doses de vaccin étaient faibles.
    - Oxford-AstraZeneca a démontré une efficacité de 61,7 % (IC à 95 % : 36,7 à 76,9) par rapport au variant B.1.1.7 et de 77,3 % (IC à 95 % : 65,4 à 85,0) pour les autres lignées (48).
    - Des estimations d'efficacité plus élevées pour Oxford-AstraZeneca ont également été signalées (90 %) (46).
- Cinq études d'observation de l'efficacité réelle des vaccins démontrent également que l'infection sporadique de type sauvage et celle associée au variant B.1.1.7 étaient plus faibles à court terme après deux doses de vaccin.
    - On a pu voir, chez les personnes qui ont reçu les vaccins Pfizer, Moderna ou Oxford-AstraZeneca, une réduction de plus de 90 % de l'incidence de l'infection par le SRAS-CoV-2, ce qui signifie que les infections sporadiques sont rares (45 à 47).
    - La protection était encore plus élevée pour les travailleurs de la santé vaccinés chez qui on avait détecté des preuves d'infection par le SRAS-CoV-2 avant la vaccination (efficacité de 96 % pendant une période de suivi de 39 222 jours-personnes) (45).
    - Comparativement à l'immunité naturelle après l'infection (réduction de 85 %) vue chez les travailleurs de la santé, la vaccination a permis de réduire de 90 % l'incidence de résultats positifs aux tests PCR plus de 14 jours après la deuxième dose de vaccin (2 cas, RTIa = 0,10 (IC à 95 % : 0,02 à 0,38; p < 0,001) (45).
    - Deux études ont fait état de niveaux élevés de protection (supérieurs à 90 %) contre l'infection tant chez les personnes plus jeunes que chez les personnes âgées ayant reçu le vaccin Pfizer (46, 70).

- Les données préliminaires indiquent que l'efficacité du vaccin est semblable tant pour les variants de type sauvage que pour le B.1.1.7 (45). Dans une étude sur les infections sporadiques associées aux variants en Israël, on n'a dénombré aucun cas d'infection causé par le variant B.1.351 14 jours après l'administration de la deuxième dose du vaccin Pfizer (71). Il faut faire preuve de prudence en ce qui concerne cette conclusion puisque le variant B.1.351 ne représentait que 1 % des variants en circulation lorsque cette étude a été effectuée et que seulement 8 des infections qui sont produites sur 79 avaient eu lieu dans le groupe de personnes vaccinées dans les 14 jours suivant l'administration de la deuxième dose du vaccin.

TABLEAU 2 : *NOUVELLES* Études évaluant les infections sporadiques ayant percé après la vaccination (N = 7)

ÉTUDE	MÉTHODOLOGIE	PRINCIPAUX RÉSULTATS
Essais (n = 2)		
Emary (2021) (48) Essai clinique randomisé Royaume-Uni Octobre 2020 à janvier 2021	Des volontaires (âgés de 18 ans et plus) qui se sont inscrits aux phases 2 et 3 des études sur l'efficacité du vaccin au Royaume-Uni ont reçu aléatoirement (1:1) le médicament ChAdOx1 nCoV-19 ou un vaccin conjugué contre le méningocoque de sérogroupe C (MenACWY) et fourni des écouvillons des voies respiratoires supérieures chaque semaine, échantillons qui ont également été examinés afin de voir si les volontaires développaient des symptômes de COVID-19. Des volontaires qui ont reçu deux doses standards (groupe	- Entre le 1er octobre 2020 et le 14 janvier 2021, 520 participants sur 8 534 ont contracté une infection par le SRAS-CoV-2, soit 173 personnes vaccinées et 347 cas-témoins. L'estimation de l'efficacité globale pour tous les cas (n = 520) était de 50,9 % (IC à 95 %, 41,0 à 59,0). - Il y a eu 75 cas associés au variant B.1.1.7, dont 21 dans le groupe des personnes vaccinées et 54 dans le groupe témoin, pour une efficacité du vaccin de 61,7 % (IC à 95 %, 36,7 à 76,9). - Il y a eu 144 cas associés à d'autres variants, dont 27 dans le groupe des personnes vaccinées et 117 dans le groupe témoin, pour une efficacité du vaccin de 77,3 % (IC à 95 %, 65,4 à 85,0). - Parmi les cas pour lesquels il n'y a pas eu de résultats de séquence (n = 301), l'infection par le SRAS-CoV-2 a été signalée chez 125 personnes vaccinées et 176 témoins.

	SD/SD) ou une faible dose suivie d'une dose standard (groupe LD/SD) ont également été inclus dans l'analyse. L'analyse d'efficacité incluait notamment la forme symptomatique de la COVID-19 qui a été détectée chez les participants séronégatifs dont l'écouvillon évalué par la technique d'amplification des acides nucléiques (TAAN) a donné un résultat positif plus de 14 jours après avoir reçu une deuxième dose de vaccin.	
Miron (2021) (72) Nouvelle analyse des essais cliniques randomisés Israël Juillet à décembre 2020	On a analysé l'efficacité à l'aide des données tirées de deux essais cliniques de phase 3 portant sur les vaccins à ARNm BNT162b2 et ARNm 1273. Les valeurs cumulatives de l'infection ont été extraites par jour après la vaccination. L'essai sur le BNT162b2 comprenait 21 720 participants (âgés de 16 à 91 ans) ayant reçu une deuxième dose le 21e jour, tandis que l'essai sur le vaccin ARNm 1273 comprenait	- Dans le cas du BNT162b2, l'incidence cumulative de COVID-19 a augmenté en moyenne de 0,01 % par semaine entre les jours 21 et 111 pour atteindre 0,29 %, comparativement aux témoins chez qui l'incidence a atteint 2,22 % le jour 111. L'efficacité du BNT162b2 les jours 7, 14 et 21 était de 12 %, de 80 % et de 94 % respectivement, avec une efficacité moyenne de 94 % jusqu'au jour 111. - Dans le cas du vaccin avec ARNm 1273, l'incidence cumulative de COVID-19 a augmenté en moyenne de 0,01 % par semaine entre les jours 21 et 111 pour atteindre 0,19 %, comparativement aux témoins chez qui l'incidence a atteint 2,84 % le jour 111. L'efficacité du vaccin avec ARNm 1273 les jours 7, 14 et 21 était de 33 %, de 62 % et de 90 % respectivement, avec une efficacité moyenne de 95 % jusqu'au jour 111.

	15 181 participants (âgés de 18 à 95 ans) ayant reçu une deuxième dose le 28e jour. Les participants ont été jumelés à des participants témoins ayant reçu le placebo. L'efficacité du vaccin a été évaluée chaque jour (jour 0 à 111), avec une moyenne mobile de 7 jours. L'efficacité a été comparée à celle du vaccin ChAdOx sans ARNm.	- L'efficacité du ChAdOx à dose unique a atteint 90 % au jour 80, alors qu'avec la double dose, elle a atteint 90 % au jour 110.
Études d'observation (n = 5)		
Lumley (2021) (45) *Prépublication* Étude de cohorte prospective Royaume-Uni Septembre 2020 à février 2021	Des travailleurs de la santé (n = 13 109) ont été suivis afin d'étudier et de comparer la protection contre l'infection par le SRAS-CoV-2 conférée par deux doses de vaccin (soit le vaccin Pfizer-BioNTech ou le vaccin Oxford-AstraZeneca) lorsque les symptômes apparaissaient au moins 14 jours après l'admission de la deuxième dose. La protection contre une infection antérieure a également été examinée (résultats dans le tableau 1). Le personnel est demeuré exposé au	- Au total, 940 travailleurs de la santé séronégatifs ont été suivis après l'administration d'une deuxième dose du vaccin Pfizer-BioNTech ou du vaccin Oxford-AstraZeneca (suivi de 39 222 jours-personnes). - La vaccination a réduit de 90 % l'incidence de toute réponse positive lors du test PCR effectué plus de 14 jours après l'administration de la deuxième dose du vaccin (2 cas, RTIa = 0,10 (IC à 95 % : 0,02 à 0,38; p < 0,001), comparativement à une réduction de 85 % obtenue grâce à l'immunité naturelle après l'infection. L'incidence était également inférieure de 96 % chez les travailleurs de la santé séropositifs ayant déjà été vaccinés (1 cas, RTIa = 0,04 (IC à 95 % : 0,01 à 0,27; p = 0,001). - L'effet des estimations des variants préoccupants n'a été calculé qu'après la première dose de vaccin. Rien n'indique cependant que la SGTF ou le variant B.1.1.7 a modifié l'étendue de la protection contre toute infection donnant un résultat positif lors du test PCR chez les travailleurs de la santé déjà

	risque d'infection jusqu'à la fin de l'étude, ou jusqu'à ce que le résultat du test PCR soit positif. Pour évaluer l'incidence du variant B.1.1.7 sur le risque d'infection ou de réinfection, les auteurs ont analysé les résultats positifs du test PCR avec et sans négativation de la détection du gène S (SGTF) alors que le séquençage du génome a été utilisé pour les résultats confirmés comme étant associés au variant B.1.1.7. La protection a été calculée comme 100*(1-RTI).	séronégatifs après l'administration d'une première dose de vaccin (p > 0,05).
Aran (2021) (46) *Prépublication* Analyse des données de surveillance Israël Décembre 2020 à février 2021	Les cas quotidiens de SRAS-CoV-2 positifs et le nombre d'hospitalisations en raison des formes graves ou critiques de la maladie ont été téléchargés de la base de données publique sur la COVID-19 du ministère israélien de la Santé. Le nombre de cas positifs chez les personnes ayant reçu le vaccin BNT162b2 est stratifié par âge, soit 60 ans et plus et moins de 60 ans selon le	- 2 918 008 personnes ont reçu leur deuxième dose du vaccin BNT162b2. Parmi toutes les personnes vaccinées, 52 014 ont obtenu un résultat positif au test de dépistage du SRAS-CoV-2. - À compter du jour 14 après l'administration de la deuxième dose, on a vu une réduction de 96 % du nombre de cas chez les personnes de 60 ans et plus alors que cette réduction a atteint 94 % chez les personnes de moins de 60 ans. - Même si on ne tient compte que des personnes pour qui il s'est écoulé plus de 20 jours après l'administration de la deuxième dose pour calculer le nombre prévu de cas, l'efficacité vaccinale pour les personnes de 60 ans et plus atteint toujours 91 % pour les cas positifs.

	nombre de jours qui s'est écoulé depuis la vaccination : entre le jour 0 et le jour 13 après l'administration de la première dose (groupe 1), entre le jour 14 et le jour 20 après l'administration de la première dose (groupe 2), entre le jour 0 et le jour 6 après l'administration de la deuxième dose (groupe 3), entre le jour 7 et le jour 13 après l'administration de la deuxième dose (groupe 4) et à compter du jour 14 (groupe 5). L'efficacité des vaccins a été analysée.	
Haas (2021) (70) Analyse des données de surveillance Israël Janvier à mars 2021	Les données de surveillance de la santé publique à l'échelle nationale ont été utilisées pour surveiller la couverture vaccinale et l'incidence de la COVID-19, ainsi que pour estimer l'efficacité du vaccin BNT162b2. La prévalence du variant B.1.1.7 du SARS-CoV-2 a été déterminée à l'aide de la négativation de la détection du gène S (SGTF) dans certains spécimens.	- Jusqu'au 6 mars 2021, 51,5 % (n = 3 335 261) des personnes âgées de 16 ans et plus en Israël ont reçu deux doses du vaccin BNT162b2. - Parmi toutes les infections par le SRAS-CoV-2 détectées chez les personnes âgées de plus de 15 ans, 102 012 (72,9 %) n'avaient pas été vaccinées et 4 543 (3,2 %) avaient reçu deux doses et l'infection était apparue plus de 7 jours après la deuxième dose. - Les estimations de l'efficacité du vaccin calculées plus de 7 jours après l'administration de la deuxième dose étaient les suivantes : 94,1 % (IC à 95 %, 93,4 à 94,7) contre l'infection par le SRAS-CoV-2, efficacité qui a ensuite augmenté jusqu'à atteindre 96,2 % (IC à 95 %, 95,9 à 96,5) plus de 14 jours après

		administration de la deuxième dose du vaccin BNT162b2. - Dans tous les groupes d'âge, à mesure que la couverture vaccinale augmentait, l'incidence du SRAS-CoV-2 diminuait considérablement chez les personnes vaccinées. Des baisses plus marquées et plus soutenues ont été observées dans les groupes de personnes plus âgées ayant une couverture vaccinale plus élevée.
Kustin (2021) (71) *Prépublication* Étude cas/témoin Israël Janvier 2020 à mars 2021	Examen de la répartition des variants du SRAS-CoV-2 parmi les infections détectées chez les personnes vaccinées et parmi les infections correspondantes chez les personnes non vaccinées. Les auteurs ont effectué l'analyse en utilisant les infections sporadiques qui sont définies comme les personnes qui ont obtenu un résultat positif lors d'un test PCR effectué au moins une semaine après avoir reçu la deuxième dose du vaccin (dénommée comme étant pleinement efficace ou PE). Ils indiquent également le nombre de cas d'infection détectée plus de 14 jours après l'administration de la deuxième dose. Ils ont effectué le séquençage PCR et du génome viral	- Le variant B.1.1.7 était la souche de virus prédominante en Israël pendant toute la période d'échantillonnage et avec le temps, il a pris de plus en plus de place. La souche B.1.351 représentait, quant à elle, moins de 1 % de l'échantillon total. - Il n'y avait aucune différence statistiquement significative dans les taux d'infection par le B.1.1.7 dans les cas « entièrement vaccinés » par rapport aux témoins non vaccinés (RC : 6:4, p = 0,38). - On trouvait cependant une proportion beaucoup plus élevée de B.1.351 dans les cas « entièrement vaccinés » par rapport aux témoins non vaccinés (RC : 8:1, p = 0,02). - 79 (49 %) des personnes « entièrement vaccinées » ont obtenu des résultats positifs les jours 7 à 13 qui ont suivi l'administration de la deuxième dose alors que 76 (51 %) en obtenaient encore, plus de 14 jours après la deuxième dose. - Sur les huit cas « entièrement vaccinés » chez qui on a détecté la souche de B.1.351, tous ont été infectés entre 7 et 13 jours après l'administration de la deuxième dose. Aucun cas associé à la souche B.1.351 n'a été vu 14 jours après réception de la deuxième dose.

	sur 149 paires de personnes « entièrement vaccinées » et sur 147 paires de personnes « partiellement vaccinées » (une seule dose)	
Thompson 2021 (47) Étude de cohorte prospective États-Unis Décembre 2020 à mars 2021	Des cohortes prospectives formées de membres du personnel œuvrant dans les soins de santé, de premiers intervenants et d'autres travailleurs essentiels et de première ligne dans huit emplacements aux États-Unis ont été incluses. Une surveillance active des symptômes associés à la COVID-19 a été effectuée par l'envoi chaque semaine de messages textes et de courriels, ainsi que par des déclarations directes reçues des participants et l'accès à leurs dossiers médicaux. Les participants ont effectué eux-mêmes chaque semaine un écouvillonnage avec cornet nasal moyen, et ce, qu'ils aient ou non des symptômes associés à la COVID-19, en plus d'effectuer un prélèvement nasal	- Au total, l'étude a analysé les échantillons provenant de 3 950 participants pour évaluer l'efficacité du vaccin. - Trois infections confirmées par PCR se sont produites pendant les 78 902 jours-personnes avec vaccination complète (14 jours après l'administration de la deuxième dose; taux d'incidence = 0,04 par 1 000 jours-personnes). - La vaccination complète avec deux doses de vaccins ARNm a permis d'obtenir une protection efficace à 90 % (IC à 95 % = 68 % à 97 %) contre l'infection par le SRAS-CoV-2 confirmée par test RT-PCR.

	supplémentaire et de fournir un échantillon de salive dès l'apparition des symptômes associés à la COVID-19. L'efficacité du vaccin a été analysée chez des participants ayant reçu une immunisation complète avec deux doses des vaccins avec ARNm (BNT162b2 de Pfizer-BioNTech et ARNm 1273 de Moderna) contre la COVID-19.	

MARQUEURS DE RÉPONSE IMMUNITAIRE À LONG TERME (PLUS DE SIX MOIS)

Cette section résume trente-six études qui font état des réponses immunitaires mesurées longitudinalement pendant six mois ou plus (jusqu'à neuf mois) après l'infection par le SRAS-CoV-2. Les études incluses se limitaient à celles qui ont déclaré plus de 30 observations obtenues plus de 6 mois après l'infection par le SRAS-CoV-2. Vingt-cinq études ont examiné les niveaux d'anticorps sériques circulants ou la séropositivité après l'infection, trois études ont porté exclusivement sur les marqueurs ou les niveaux d'activité des lymphocytes T, alors que huit études ont fait état de multiples marqueurs immunitaires pour les cellulaires et les anticorps (c.-à-d. lymphocytes B, lymphocytes T ou anticorps) dans le même échantillon. La majorité des études incluses étaient des cohortes prospectives ou des séries de cas qui suivaient la sérologie des cas dans lesquels des tests RT-PCR ont confirmé la COVID-19 au fil du temps.

Dans l'ensemble, on a vu beaucoup de variabilité entre les études en raison des différences entre les participants à l'étude, de la gravité de l'infection par la COVID-19, de la fréquence et de la durée du suivi, des résultats immunitaires étudiés et des méthodes de mesure, ce qui limite la synthèse des résultats entre les études. En outre, le lien entre les marqueurs immunitaires à long terme mesurés et la protection contre la réinfection face aux variants préoccupants et à la souche sauvage est en grande partie inconnu.

Principaux résultats pour les réponses immunitaires des lymphocytes B et T obtenues six mois après l'infection (n = 11) :

- les lymphocytes B mémoires (soit les cellules immunitaires qui produisent les virus qui ciblent les anticorps) et les lymphocytes T mémoires (c.-à-d. les cellules immunitaires qui guident les réponses immunitaires adaptatives des cellules) après une infection naturelle confèrent probablement une certaine immunité à long terme à toute réinfection (1, 63, 73). Les cibles, l'activité et le nombre des antigènes viraux de ces cellules mémoires ont été le plus souvent mesurés au moyen de techniques d'analyse des cellules de cytométrie de flux et de diverses épreuves biologiques. La variabilité des techniques de biologie moléculaire et les marqueurs d'antigènes viraux utilisés dans les études limitent cependant la comparabilité des résultats.
- Les lymphocytes B sont les cellules immunitaires responsables de la production d'anticorps ciblant les antigènes du SRAS-CoV-2 (1, 63, 73). Elles peuvent être réparties globalement en cellules sécrétrices d'anticorps (cellules plasmatiques) et en cellules mémoires (73). Les cellules plasmatiques activées produisent et sécrètent des anticorps circulants qui ciblent les antigènes du SRAS-CoV-2 tant que ces derniers ne sécrètent pas activement d'anticorps, mais conservent ces éléments en mémoire pour se protéger contre les infections subséquentes et créer une immunité à long terme (73).
- Quatre études mesurent et indiquent l'activité des lymphocytes B et des anticorps circulants plus de six mois après l'infection (51, 52, 56, 62). La cytométrie de flux est la méthode la plus fréquemment utilisée pour détecter la spécificité et l'activité des lymphocytes B.
    - Les lymphocytes B mémoires spécifiques à la protéine S et à la protéine N, ainsi que les antigènes viraux RBD, ont été détectés chez les participants lors du suivi effectué plus de six mois après l'infection, ce qui indique que le nombre de cellules est demeuré stable ou a grandement augmenté et que les clones des lymphocytes B mémoires se sont étendus et ont évolué (51, 52, 56, 62).
    - 80 % (n = 29 personnes sur 36) des cas bénins à modérés de COVID-19 présentaient des fréquences élevées de lymphocytes B mémoires totaux spécifiques aux anticorps RBD (IgG+, IgM+ ou IgA+) (56) plus de 180 jours après l'infection.
    - Dans une cohorte où l'on trouve des cas de COVID-19 ayant déjà été hospitalisés, les pourcentages de lymphocytes B étaient les plus élevés chez les participants négatifs aux anticorps IgG et IgM (intervalle de 16,1 ± 6,4 à 16,7 ± 5,5) comparativement aux participants positifs à ces anticorps (intervalle de 7,2 ± 3,1 à 7,5 ± 3,8) (51)
    - Une seule étude mentionne la réduction des anticorps contre la protéine S qui sécrètent les lymphocytes B et une augmentation des lymphocytes B mémoires qui ciblent les antigènes viraux SRAS-CoV-2, dans les formes graves et bénignes de COVID-19 (62). Cette étude a également révélé que les lymphocytes B du RBD du SRAS-CoV-2 présentaient une réaction croisée minimale avec d'autres antigènes du coronavirus humain (62).

- Les lymphocytes T sont des cellules immunitaires classées en fonction des récepteurs de surface CD4+ ou CD8+. Le rôle principal des lymphocytes T peut être divisé selon qu'ils produisent des anticorps par activation des lymphocytes B (lymphocytes T CD4+) ou détruisent les cellules infectées présentant certains antigènes (lymphocytes T CD8+) (73, 74). Les lymphocytes T sécrètent également des cytokines pour coordonner les réponses immunitaires dans les cellules immunitaires (73, 74). Les études incluses ont isolé des cellules mononuclées de sang périphérique à partir d'échantillons sériques, avant de mesurer le nombre de lymphocytes T, les phénotypes ou l'activité après simulation avec divers bassins de séquences peptidiques du SARS-CoV-2 (c.-à-d. les acides aminés qui constituent les protéines virales) (49-51, 53 à 57). La variabilité ou le manque de détails sur les séquences de peptides utilisées dans les études de simulation limitent la comparabilité des résultats.
- Neuf études font état des résultats associés à la présence des lymphocytes T dans des cas infectés plus de six mois après l'infection (37, 49-51, 53 à 57).
    - L'ampleur des réponses des lymphocytes T mémoires s'est maintenue (et a même augmenté dans certains échantillons) plus de six mois après l'infection ou l'apparition des symptômes (37, 49 à 51, 53 à 55, 57). Une étude mentionne que les lymphocytes T présents dans 95 % de l'échantillon à l'étude provenant de cas légèrement symptomatiques sont demeurés sensibles à au moins un bassin de peptides du SARS-CoV-2, et quantifie donc un total médian de 200 cellules par million de cellules mononuclées de sang périphérique (ou 1 cellule sur 5 000) spécifiques au SRAS-CoV-2 lors du suivi effectué après six mois (55).
    - Dans certaines études, on a constaté que les lymphocytes T CD8+ étaient moins robustes que les réponses des lymphocytes T CD4+ obtenues plus de six mois après l'infection (49, 54, 56, 57). L'activité des lymphocytes T CD8+ a été détectée dans 50 % des cas bénins à modérés de six à huit mois après l'infection, tandis que l'activité des lymphocytes T mémoires CD4+ a continué d'être détectée chez 92 % des personnes du même échantillon (56).
    - Une étude a révélé une corrélation entre l'activité des lymphocytes T CD8+ et la séropositivité à l'IgG et de l'IgM pendant toute la durée de l'infection par COVID-19 dans un échantillon de personnes atteintes d'une forme grave de COVID-19 (51). Une autre étude a, quant à elle, signalé une forte corrélation entre la protéine S, les anticorps IgG contre le RBD et les lymphocytes T CD4+ spécifiques à la protéine N et à la protéine S du SARS-CoV-2 (54).
    - L'IL-2 était la cytokine dominante libérée par les lymphocytes T CD4+ six mois ou plus après l'infection (55, 57).

Principaux résultats tirés des réponses immunitaires aux anticorps circulants six mois ou plus après l'infection (n = 33) :

- l'immunité humorale, aussi appelée immunité à médiation humorale ou immunité médiée par les anticorps, désigne généralement les anticorps circulants qui sont envoyés vers les antigènes viraux (1, 63, 73). Parmi les études incluses, les anticorps circulants qui se trouvaient dans les échantillons de sérum ont été mesurés par des épreuves biologiques visant à établir l'affinité envers les anticorps, des essais de neutralisation des pseudovirus, la cytométrie de flux et d'autres techniques fondées sur la biologie moléculaire. Les résultats déclarés en ce qui concerne les anticorps comprenaient les anticorps totaux, les anticorps neutralisants, la catégorie d'anticorps (c.-à-d. IgG, IgM, IgA) qui étaient fréquemment décrits plus en détail par les sous-catégories (c.-à-d. IgG1, IgG3) ou l'affinité de liaison avec les antigènes viraux du SRAS-CoV-2. De nombreuses études ont souvent précisé les antigènes viraux cibles des anticorps Ig ayant été mesurés, ce qui inclut les protéines structurales virales comme la protéine de spicule (S), les sous-unités S1 ou S2 de la protéine S, les protéines de nucléocapsides (N), l'enveloppe (E), les protéines de la membrane (M), le domaine de liaison au récepteur (RBD) des protéines et les protéines accessoires. (c.-à-d. les protéines de cadre de lecture ouvert (ORF)).
- Des études ont révélé que des anticorps spécifiques au SRAS-CoV-2 étaient détectables chez la majorité des personnes infectées plus de six mois après l'infection, mais la séroprévalence des différents types d'anticorps était variable. Les tendances longitudinales des anticorps évaluées plus de six mois après l'infection sont décrites ci-dessous, selon la spécificité de l'antigène viral et la gravité clinique.
- Les anticorps neutralisants ciblent la protéine S ou le RBD du SRAS-CoV-2 pour neutraliser la liaison du virus avec les récepteurs ACE2 des cellules hôtes potentielles (59, 60, 75, 76). Les anticorps neutralisants ont été détectés dans 53,4 % à 100 % des cas examinés de 6 à 8 mois après l'infection (53, 56, 59, 61, 77 à 79). Les taux sont restés élevés chez les personnes ayant eu une forme grave de la COVID-19, comparativement aux personnes ayant eu une forme moins grave (52, 53, 58, 78, 79).
    - Une nouvelle étude a révélé que, comparativement aux cas ayant eu la forme légère de la maladie, la probabilité de persistance des anticorps neutralisants six mois après l'infection était 30 fois plus élevée (RC 30,3 (IC à 95 %, 10,0 à 107,9)) chez les personnes ayant eu la forme grave et 5 fois plus élevée (RC 5,2 (IC à 95 %, 1,8 à 16,7)) chez celles qui ont eu la forme modérée (53).
    - Un petit essai de phase 1 a révélé que l'immunité obtenue après la vaccination avec Moderna après 6 mois et, comme dans le cas de l'infection, les résultats indiquaient que les anticorps anti-RBD et les anticorps neutralisants étaient détectables 6 mois plus tard chez tous les participants (64).

- Les taux d'IgG de la protéine S étaient constamment élevés et détectables dans toutes les études, alors qu'ils étaient stables ou élevés chez 86 % à 99 % des personnes atteintes de formes moins graves (43, 56, 59, 60, 60, 28, 28 à 30). La présence à long terme de l'IgG contre la protéine S dans le sérum après six mois d'infection semble cependant être plus faible chez les personnes ayant eu une forme grave de l'infection (50, 81 à 83).
- Les anticorps IgG contre le RBD et les anticorps IgG contre la protéine S ont été détectés dans 76 à 90 % des formes bénignes à modérées de COVID-19, ainsi que chez les patients en hémodialyse (37, 43, 56, 84).
    - Une étude a révélé que les taux d'anticorps IgG contre RBD diminuent et se stabilisent environ 9 mois après l'infection (89 % des échantillons étaient positifs 6 ou 7 mois après l'infection et 81 % l'étaient encore 11 ou 12 mois après l'infection), même si les titres obtenus étaient 70 % inférieurs aux valeurs obtenues 1 mois après l'infection (84).
    - De multiples études confirment la corrélation entre les anticorps Ig RBD (toutes les classes d'Ig) et l'activité de neutralisation ciblant le SRAS-CoV-2 (59, 60). Cette association était cohérente avec les données obtenues pour les personnes ayant été atteintes des formes bénignes à graves de la COVID-19.
- Les anticorps à base de protéine N (variable de classe ou variable non précisée) ont diminué plus rapidement que les anticorps neutralisants, la protéine S et les anticorps RBD (32, 37, 59, 61, 62, 83)
    - Lademi-vie des anticorps IgG contre la protéine N a été estimée entre 59 et 76,4 jours (IC à 95 % : 55 à 90 jours) dans l'ensemble des études, soit une durée bien plus courte que la demi-vie relative estimée des autres anticorps (56, 58, 59, 80).
    - Une seule étude signale que la persistance des taux élevés d'Ig contre la protéine N environ cinq mois après l'infection pourrait être associée à des effets à long terme de la COVID-19, comme la fatigue, l'anosmie et l'agueusie (50).
- Une étude a comparé les anticorps circulants chez des enfants et chez des adultes ayant été infectés (67) et a permis de voir que les enfants présentaient des niveaux plus faibles d'anticorps contre les protéines S et N (la classe Ig des anticorps mesurés n'a pu être identifiée) et que la proportion d'anticorps globaux contre les protéines accessoires était plus grande et plus stable chez les enfants que chez les adultes (67).

Tableau 3 : Réactions immunitaires observées plus de six mois après l'infection par le SRAS-CoV-2 (n = 36)

ÉTUDE	MÉTHODOLOGIE	PRINCIPAUX RÉSULTATS
Anticorps circulants, réponses immunitaires des lymphocytes B et T		
Chia 2021 (53) *nouvelle* Cohorte prospective Singapour Janvier 2020 à janvier 2021	Les participants qui ont pris part à cet échantillon longitudinal (n = 164) ont été recrutés entre le 30 janvier 2020 et le 14 août 2020 à partir de cas ayant obtenu un résultat positif au test PCR de détection du SRAS-CoV-2 et a recueilli des échantillons de sang entre 30 et 60 jours, puis 90 jours et 180 jours après l'apparition des symptômes. Différents types de COVID-19, allant de la forme légère à la forme grave, ont été inclus. Un test ELISA de neutralisation du virus de substitution a été utilisé pour mesurer les anticorps IgG alors que le test IFN-γ-ELISpot avec six bassins de peptides du SARS-CoV-2 a été effectué sur les lymphocytes T provenant des cellules mononuclées de sang périphérique pour en déterminer la réactivité.	128/164 cases had a day 180 sample. Neutralization was considered significant at 30%. Five distinct groups were identified (predicted longevity of NAb in days): - 12% did not develop NAb - 27% had variable antibodies that waned by 6 months (median 96 days) - 28% had slow waning antibodies that were positive at 6 months (median 201 days) - 32% had minimal NAb decay at 6 months (median 580 days) - 2% had a delayed response where NAb levels peaked >90 days In a multivariable model disease severity was an independent predictor of persistent antibodies at 180 days: - Moderate disease OR= 5.2 (95%CI 1.8-16.7) - Severe disease OR= 30.3 (10.0 -107.9) Levels of RBD IgG antibody avidity correlated with NAb levels. Cytokine Levels: - 180 days post-symptom onset, higher levels of pro-inflammatory cytokines (IFN-γ, IL-12p70, and IL-17A), pro-inflammatory chemokine (IP-10), and growth factors (human growth factor) were observed in the persistent group compared with all other groups. T-cell activity (23 samples from each group): - All patients in each group had substantial specific T-cells at 180 days with no difference between groups.

		T-cell response was multi-specific and reacted to N protein, M protein, and S protein.
Peluso (2021) (54) *Prépublication* *nouvelle* Étude transversale États-Unis Avril 2020 et 2021	Les taux de lymphocytes T, d'anticorps neutralisants et d'anticorps spécifiques au SRAS-CoV-2 ont été mesurés chez des personnes présentant différents niveaux de gravité de l'infection tout comme les déclarations mentionnant des séquelles associées à la COVID longue (n = 70). Des échantillons de sérum ont été prélevés longitudinalement de 1 (médiane de 53 jours) à 8 mois après l'apparition des symptômes. Les lymphocytes T CD4+ et CD8+ ont été simulés dans des bassins peptiques contenant des protéines S et N, avant que l'activité cellulaire ne soit mesurée par les dosages biologiques AIM et ICS. On a également mesuré les taux d'anticorps IgG spécifiques contre la protéine S, la protéine N et le RBD (test Luminex) et l'activité des anticorps neutralisants (test avec pseudovirus). Des analyses de corrélation de Spearman et de régression linéaire ont été utilisées pour déterminer les corrélations entre les marqueurs immunitaires mesurés.	Résultats immunitaires obtenus de 6 à 8 mois après l'infection identifiés dans l'étude : - Une médiane de 23,1 % (EI 10,3, 36,6) pour les lymphocytes T d'IFNγ+ CD8+ (protéine N et protéine S) et 61,5 % (EI 44,4, 76,0) des lymphocytes T d'IFNγ CD4+ (protéine N et protéine S) ont produit du TNFα à chacun des points temporels échantillonnés (P < 0,001). - Les réponses des lymphocytes T CD 4+ et CD 8+ sont demeurées stables chez les participants, indépendamment de la gravité de la maladie. - L'ampleur des réponses précoces des lymphocytes T CD4+, des taux plus élevés de protéine N, de protéine S et d'anticorps IgG contre le RBD dépendait de la gravité initiale de l'infection. - Les niveaux d'anticorps contre la protéine S et le RBD sont fortement corrélés avec les lymphocytes T CD4+ spécifiques aux protéines N et S. - Il y a eu une corrélation entre la réponse des anticorps neutralisants et celles des lymphocytes T CD4+. - On a signalé que des réponses plus élevées à long terme des lymphocytes T CD8+ étaient liées à des comorbidités préexistantes de maladie pulmonaire. Les chercheurs n'ont pas été en mesure de déterminer des différences importantes dans les réponses des lymphocytes T ou des anticorps du SRAS-CoV-2 au fil du temps en fonction des séquelles laissées par l'infection aiguë.

Dan (2021) (56) Étude transversale États-Unis Mars à novembre 2020	Une évaluation des réponses immunitaires de protection, fondée sur les lymphocytes T mémoires CD4+ et CD8+, les lymphocytes B mémoires et les niveaux d'anticorps, a été effectuée parmi des personnes rétablies, dont la COVID-19 a été confirmée par test RT-PCR (n = 188). À noter que 93 % des participants n'ont pas été hospitalisés. Certains échantillons de sérum (n = 43 sur 188) ont été prélevés entre six et huit mois après l'infection. On a utilisé le test ELISA, des épreuves de neutralisation des anticorps par pseudovirus et la cytométrie en flux pour détecter les anticorps et les fréquences et activités des cellules immunitaires. Les lymphocytes T mémoires CD8+ du SRAS-CoV-2 ont été mesurés à l'aide d'une série d'ensembles de peptides couvrant l'ensemble des protéines de cadre de lecture ouvert (ORF) du SRAS-CoV-2, les plus courants étant la protéine S, la protéine M, la protéine N et l'ORF3a.	Résultats immunitaires obtenus de 6 à 8 mois après l'infection identifiés dans l'étude : Dynamique des anticorps - Les IgA contre la protéine S étaient détectables chez la majorité des participants. - Les titres d'IgG et d'IgG contre la protéine S et d'IgG contre le RBD ont affiché des baisses modestes, mais étaient relativement stables. - La proportion de participants positifs à l'IgG contre la protéine S, est passée de 98 % (54 sur 55) à 90 % (36 sur 40), d'un mois à six ou huit mois après l'infection. - 88 % (35 sur 40) des participants étaient positifs pour l'IgG contre le RBD. - 90 % (36 sur 40) des participants étaient positifs pour les anticorps neutralisants. Activité des lymphocytes B mémoires spécifiques du SRAS-CoV-2 - Les lymphocytes B mémoires spécifiques à la protéine S, à la protéine N, au RBD et aux antigènes viraux ont été détectées chez presque tous les participants, et étaient plus abondants lors du suivi post-infection. - 80 % (n = 29 participants sur 36) présentaient des fréquences plus élevées de lymphocytes B mémoire totaux (IgG+, IgM+ ou IgA+) plus de 180 jours après l'infection. Activité des lymphocytes T mémoires spécifiques au SRAS-CoV-2 - 70 % (40 sur 57) des participants avaient des lymphocytes T CD8+ un mois après l'infection, tandis que 50 % (18 sur 36) des participants ont obtenu des résultats positifs pour ces lymphocytes plus de six mois après l'infection. - 93 % (53 sur 57) des participants avaient des lymphocytes T mémoires CD4+ un mois après l'infection, tandis que 92 % (33 sur 36) des participants ont obtenu des résultats positifs pour ces lymphocytes plus de six mois après l'infection. En résumé, malgré l'hétérogénéité des réponses immunitaires associées au niveau d'anticorps

		circulants pour le SRAS-CoV-2, l'immunité cellulaire a pu être établie plus de six mois après l'infection grâce aux lymphocytes B et T mémoires.
Shen (2021) (51) Série de cas Chine Juillet et août 2020	Des échantillons de sérum ont été prélevés à de multiples moments après l'admission en centre de rétablissement (c.-à-d. 0, 2 et 4 semaines) d'un groupe de participants ayant déjà été infectés (n = 110) et dont le congé de l'hôpital après une forme aiguë du SRAS-CoV-2 avait eu lieu au moins six mois auparavant. Les infections ont été confirmées par des tests RT-PCR. Les niveaux des anticorps sériques IgM et IgG, d'IL6, de CD3+, des lymphocytes T CD8+, CD4+, des cellules NK et des lymphocytes B ont été mesurés par des essais et une cytométrie en flux. Des différences notables dans le pourcentage de lymphocyte T sériques CD3+, CD8+ et CD4+, de cellules NK et de lymphocytes B (aucun détail supplémentaire fourni), par la positivité des anticorps IgM et IgG, ont été confirmées par l'analyse de corrélation.	- Dans l'ensemble, 29,1 % (32 sur 110) des participants étaient positifs pour les anticorps IgM et IgG, 34,5 % (38 sur 110) étaient seulement positifs pour l'IgG et 36,4 % (n = 40) étaient négatifs pour les anticorps IgM et IgG. - Il n'a pas été possible de cerner de différences significatives entre les groupes ayant obtenu des résultats positifs et négatifs en ce qui concerne la démographie, la présentation clinique ou les comorbidités. Dynamique des lymphocytes T, six mois et plus après l'hospitalisation, selon la positivité des anticorps : les lymphocytes T CD8+ ont légèrement diminué pendant la période d'échantillonnage. - Le pourcentage de lymphocytes T CD8+ était le plus élevé (de 48,6 ± 7,3 à 43,7 ± 9,7) chez les participants positifs aux anticorps IgG et IgM à tous les moments pendant le suivi. - Le pourcentage de lymphocytes T CD8+ était le plus faible (de 25,5 ± 9,3 à 25,9 ± 10,1) chez les participants négatifs aux anticorps IgG et IgM. - Les cellules NK ont légèrement augmenté au cours de la période d'échantillonnage. - L'augmentation du pourcentage de cellules NK était la plus élevée chez les participants négatifs aux anticorps IgG et IgM à tous les moments pendant le suivi (intervalle de 25,7 ± 6,3 à 27,1 ± 8,3), et la plus faible chez les participants positifs aux anticorps IgG et IgM (de 13,7 ± 7,4 à 15,0 ± 9,6). Dynamique des lymphocytes B, six mois et plus après l'hospitalisation, selon la positivité des anticorps : les concentrations de lymphocytes B sont demeurées stables chez les participants positifs aux anticorps et chez ceux qui étaient négatifs, mais ont augmenté de façon significative chez les participants positifs aux IgM et aux IgG au moment des différents suivis.

		- Les pourcentages de lymphocytes B étaient les plus élevés chez les participants négatifs aux anticorps IgG et IgM (intervalle de 16,1 ± 6,4 à 16,7 ± 5,5) comparativement aux participants positifs à ces anticorps (intervalle de 7,2 ± 3,1 à 7,5 ± 3,8). - Les auteurs concluent que la perte d'anticorps IgM dans le sérum a entraîné une amélioration graduelle de l'immunité cellulaire liée aux cellules NK et aux lymphocytes B. Ils suggèrent que les pourcentages de lymphocytes sériques (CD3+, CD8+ et CD4+, de lymphocytes T, de cellules NK et de lymphocytes B) sont corrélés avec les changements des niveaux des anticorps sériques IgM et IgG, mais non liés aux cytokines inflammatoires ou à la gravité de l'infection (c.-à-d. Hs-CRP ou IL6), chez les patients qui ont été hospitalisés, puis se sont rétablis.

Gaebler (2020) (52)
 	
Série de cas
 	
États-Unis
Avril à octobre 2020
	Des échantillons de sérum ont été prélevés 1,3 et 6,2 mois (de 165 à 223 jours) après l'infection chez des personnes séropositives au SRAS-CoV-2 (n = 87). L'infection et les séroconversions ont été confirmées par test RT-PCR, et 10 % des personnes appartenant à l'échantillon ont été hospitalisées en raison de l'infection. Les concentrations d'anticorps IgG, IgM, IgA RBD et d'anticorps neutralisants ont été mesurées au moyen du test ELISA et d'une épreuve de neutralisation du pseudovirus. Les niveaux et l'activité des lymphocytes B ont été mesurés par cytométrie en flux.	Les niveaux d'anticorps RBD avaient grandement diminué six mois après l'infection. Dans l'ensemble, la diminution du niveau d'anticorps était inversement proportionnelle aux niveaux initiaux d'anticorps (c.-à-d. les personnes dont les niveaux d'anticorps étaient les plus élevés au début de l'infection et qui ont connu la plus forte diminution) et directement corrélée avec ceux-ci.
		- Dynamique des anticorps six mois après l'infection identifiée dans l'étude :
		  - Réduction de 53 % de l'IgM contre le RBD
		  - Réduction de 33 % de l'IgG contre le RBD
		  - Réduction de 15 % de l'IgA contre le RBD
		  - L'activité des anticorps neutralisants était cinq fois moindre.
		Le nombre de lymphocytes B mémoires spécifiques au RBD est demeuré inchangé pour la majorité des personnes. Toutefois, ces cellules présentaient une maturation, une expansion clonale variée et un renouvellement entre 1,3 et 6,2 mois après l'infection.
		Les auteurs concluent que les changements observés dans les lymphocytes B mémoires sont

		révélateurs d'une immunité à long terme, ainsi que de la capacité de créer des réponses immunitaires rapides et efficaces à la réinfection.
Sokal (2020) (62) Série de cas France Mars à octobre 2020	Des échantillons de sérum ont été prélevés chez des personnes infectées (n = 39) à trois moments, soit le premier mois, puis trois mois et six mois après l'apparition des symptômes. Environ 53 % (n = 21) des patients dans l'échantillon ont été atteints d'une forme grave de l'infection. Le test ELISA a été utilisé pour mesurer les concentrations d'anticorps contre les protéines N et S et les concentrations d'IgG contre le RBD. Les réponses des lymphocytes B mémoires spécifiques aux antigènes viraux ont été mesurées par des tests ELISA avec séquençage et cytométrie en flux des récepteurs des lymphocytes B.	Résultats immunitaires obtenus à 6 mois après l'apparition des symptômes identifiés dans l'étude : Dynamique des anticorps - Les anticorps IgG contre la protéine N ont rapidement diminué chez les personnes ayant eu des formes bénignes et graves de l'infection. Cette réduction était plus prononcée dans les cas bénins, et après six mois, les IgG contre la protéine N dans les titres étaient indétectables chez 50 % des participants légèrement symptomatiques. - Les anticorps IgG contre la protéine S étaient stables au fil du temps puisque seulement 9 % des personnes ayant eu une forme bénigne présentaient des niveaux d'anticorps indétectables au suivi de six mois. Les niveaux d'anticorps étaient beaucoup plus élevés chez les participants atteints d'une forme grave de l'infection dans les trois à six mois suivants. Activité des lymphocytes B : - les clones des lymphocytes B spécifiques à la protéine S et au RBD, ainsi que les clones de lymphocytes B à réaction croisée issus d'expositions antérieures au virus bêta-corona ont subi une maturation somatique et une expansion importante. - Tant pour les formes graves que bénignes de l'infection, les cellules sécrétrices d'anticorps contre la protéine S étaient marginalement détectables à six mois, alors que les lymphocytes B de la protéine S résidaient principalement dans le compartiment des lymphocytes B mémoire CD21+CD27+CD38-CD71$^{int/-}$ au repos pour les formes graves et bénignes. - Les lymphocytes B actifs sont demeurés détectables jusqu'à six mois après l'infection.

		On présume que ces clones de lymphocytes B contribuent à l'immunité à long terme chez les patients en convalescence.
Bilich (2020) (50) *Prépublication* Série de cas Allemagne *Printemps 2020	Les convalescents atteints d'une forme bénigne à modérée (n = 51) de l'infection ont fait l'objet d'un suivi longitudinal environ un mois (médiane 40 jours; intervalle de 35 à 56 jours) et cinq mois (médiane 159 jours; intervalle de 141 à 183 jours) après avoir obtenu un résultat positif au test RT-PCR. L'activité des lymphocytes T a été mesurée par les essais IFN-g ELISPOT et la cartographie de l'épitope unique. Les niveaux d'anticorps IgG et IgA ont, quant à eux, été mesurés au moyen d'un essai immunologique.	La dynamique des anticorps effectuée environ cinq mois après les résultats du test RT-PCR mentionnés dans l'étude a permis d'obtenir les résultats suivants : - on a observé une diminution du double des anticorps IgG et IgA contre la protéine S chez un pourcentage de participants variant entre 31 et 44 % entre les deux dates du suivi. - Jusqu'au deuxième suivi, une réduction inférieure à deux fois les niveaux d'anticorps dans la protéine N a été notée chez 13 % des participants. - Des titres d'anticorps protéiques à teneur élevée en protéine N, effectués cinq mois après l'infection, ont été associés à une prévalence plus élevée de symptômes post-infection, comme la fatigue, l'anosmie et l'agueusie. Réactions immunitaires des lymphocytes T 5 mois après l'infection : - le pourcentage de participants ayant des lymphocytes T détectables propres aux antigènes viraux a augmenté de 93 % à 100 % lors du deuxième suivi. Un sous-groupe de lymphocytes T ciblant des épitopes viraux spécifiques dérivés des ORF (épitopes HLA-RD; épitopes HLA classe 1), associés à l'immunité post-infection à long terme contre le SRAS-CoV-2, a persisté chez certains participants jusqu'à six mois après l'infection.
Clarke (2021) (37) Cohorte prospective Royaume-Uni Février 2020 à janvier 2021	Les patients en hémodialyse atteints d'une maladie rénale en phase terminale ont fait l'objet d'un dépistage afin de détecter la présence des anticorps du SRAS-CoV-2, et les résultats présentés dans le présent article portent sur les anticorps au temps 0 (n = 356), puis six mois plus	De tous les participants, 190 ont obtenu un résultat négatif pour les anticorps à base de protéine N alors que 129 autres ont obtenu un résultat positif à la date 0. Après six mois, des échantillons prélevés dans le groupe ayant obtenu un résultat positif aux anticorps de la protéine N (111 sur 129), ont été utilisés pour examiner l'immunité à long terme :

	tard (n = 301). Les infections ont été confirmées par des tests PCR. Les anticorps des protéines N et IgG RBD ont été mesurés à l'aide des tests CIMA et ELISA. L'activité des lymphocytes T a été mesurée par un test ELISPOT effectué chez des participants ayant eu une sérologie à six mois (n = 11). La gravité clinique de l'infection chez les participants ayant fait l'objet d'un suivi à six mois n'a pas été indiquée.	- les anticorps IgG à base de protéine N n'ont pu être détectés chez 36 % (n = 40) des participants ayant obtenu initialement un résultat positif. - Les anticorps IgG contre le RBD étaient plus persistants que les anticorps IgG contre la protéine N puisque 87 % (n = 97) des personnes faisant partie de l'échantillon séropositif initial ont continué à obtenir un résultat positif pour les anticorps IgG contre le RBD (y compris 70 % (n = 28) des personnes ayant obtenu un résultat négatif pour l'IgG contre la protéine N). - 64 % (n = 71) des participants ont continué d'être séropositifs pour les anticorps à base de protéine N, mais les concentrations étaient considérablement plus faibles comparativement au point de dépistage initial (p < 0,0001). 10 % (n = 12) des participants séropositifs initiaux étaient séronégatifs pour les anticorps RBD et de la protéine N, mais 80 % de ces personnes ont démontré une activité des lymphocytes T spécifiques de l'antigène du SRAS-CoV-2.
Réponses immunitaires des lymphocytes T		
Zuo (2021) (55) *nouvelle* Étude transversale Royaume-Uni Mars 2020	Des échantillons de sérum ont été prélevés chez des cas confirmés par RT-PCR (n = 100) six mois après l'infection. Aucune personne faisant partie de l'échantillon de l'étude n'a été hospitalisée pendant la phase aiguë de l'infection. Les lymphocytes T ont été simulés avec des bassins de protéine S de protéine N et de protéine M du SARS-CoV-2. L'ampleur et les phénotypes des lymphocytes T ont été	Réponses des lymphocytes T 6 mois après l'infection : - 95 % des lymphocytes T (n = 90 sur 95) de l'échantillon ont répondu à au moins un des peptides testés, avec un total médian de 200 cellules par million de cellules mononuclées de sang périphérique (ou 1 sur 5 000 cellules) spécifiques au SRAS-CoV-2. - Les réponses des lymphocytes T aux bassins peptidiques testés sont corrélées avec les taux maximaux d'anticorps. - 18 % des lymphocytes T de l'échantillon n'étaient pas sensibles à la protéine S alors que 8 % de l'échantillon n'a pas réagi aux peptides protéiques N et M.

	mesurés à l'aide du test ELISPOT et de la cytométrie de flux.	- L'IL-2 était la cytokine dominante libérée par les lymphocytes T CD4+. - Les réponses médianes des lymphocytes T à toutes les concentrations de peptides testées étaient environ 50 % plus élevées chez les participants qui avaient eu une infection symptomatique; 42 % plus élevées pour la protéine S et 55 % plus élevées pour les protéines N et M. - Aucune différence n'a été observée dans le rapport CD4:CD8 pour les infections symptomatiques. Les chercheurs ont donc conclu que la gravité de l'infection primaire établissait un « point fixe » pour l'immunité cellulaire pouvant encore persister six mois après l'infection.
Breton (2020) (57) Cohorte prospective États-Unis Mars à octobre 202	Des échantillons de sérum jumelés ont été prélevés jusqu'à six mois après l'infection chez des participants atteints d'une forme peu grave de l'infection ayant obtenu un résultat positif au SRAS-CoV-2 (n = 41). Les infections ont été confirmées par des tests RT-PCR. Les échantillons de sérum des participants infectés ont été comparés à ceux des individus non infectés (n = 20). Les phénotypes des lymphocytes T et la spécificité de l'antigène du SRAS-CoV-2 ont été mesurés par cytométrie en flux, avec le test ELISPOT et d'autres tests.	Comparativement aux participants non infectés, on a observé des changements importants dans les compartiments des lymphocytes T CD4+ et CD8+ circulants qui ont persisté six mois après l'infection par le SRAS-CoV-2. Activité des lymphocytes T du SRAS-CoV-2 jusqu'à six mois après l'infection : - à 6,1 mois, les proportions de lymphocytes T CD8+ et CD4+ étaient presque revenues aux niveaux physiologiques. - Les lymphocytes T CD4+ spécifiques à l'antigène qui exprimaient des marqueurs mémoire, ainsi que les réponses pour IL-2, IFN-g, TNF-a, CD154 et pour la cytokine polyfonctionnelle ont été nettement plus élevées dans le sérum des convalescents, comparativement aux participants non infectés, alors que la fréquence relative des cellules avait, quant à elle, diminué (22 à 32 %) lors du suivi de 6,1 mois. - Les lymphocytes T CD8+ qui ont produit des réponses pour Mip-1b, CD107a, IL-2, INF-g et TNF-a étaient encore détectables au suivi de 6,1 mois, bien qu'à des niveaux inférieurs aux mesures précédentes.

		- 95 à 97 % des sérums de participants ayant déjà été infectés ont fourni des preuves d'activité des lymphocytes T spécifiques aux antigènes CD4+ et CD8+ 1,3 et 6,1 mois après l'infection. Comparativement à l'activité des lymphocytes T CD4+ à 6,1 mois, les réponses des lymphocytes T CD8+ étaient beaucoup plus variables et généralement moins robustes.
Li (2020) (49) *Prépublication* Étude transversale Chine Avril à septembre 2020	L'étude a porté sur des personnes ayant eu la COVID-19 (n=31) et sur des témoins non exposés (n = 11) (l'état d'exposition ayant été confirmé par un test RT-PCR). La période médiane entre l'apparition de la maladie et le prélèvement sérique était de 169 jours (intervalle de 83 à 274 jours). L'analyse a examiné les différences entre les réponses des lymphocytes T pendant les six premiers mois, puis pendant les six à neuf mois qui ont suivi l'infection. 56,6 % (17 sur 31) des cas infectés ont été hospitalisés alors que 19 % (6 sur 31) étaient asymptomatiques. L'activité des lymphocytes T a été mesurée par cytométrie en flux alors que les séquences de protéines virales S, N et M ont été utilisées pour la simulation cellulaire.	- Une proportion des lymphocytes T ont réagi faiblement aux protéines virales chez les personnes non infectées, mais à un niveau beaucoup plus faible que la réaction observée chez les personnes ayant déjà été infectées. - Lors du dernier suivi, 45 % des personnes précédemment infectées étaient encore séropositives à l'IgG et 29 %, à l'IgG et à l'IgM. On a aussi remarqué que les réponses des lymphocytes T CD4+ étaient plus fortes chez les personnes ayant eu un résultat négatif pour les anticorps IgG. - Une perte dans le nombre de réponses des lymphocytes T mémoires CD4+ et CD8+ a été observée chez 16,13 % et 25,81 % des personnes précédemment infectées. La perte de lymphocyte T mémoires CD4 s'est révélée plus fréquente chez les personnes asymptomatiques. - Les réponses des lymphocytes T CD4+ et CD8+ étaient très variables. De façon générale, la portée et l'ampleur des réactions cellulaires augmentaient avec le temps suivant l'apparition des symptômes. Dynamique des lymphocytes T, au cours des six premiers mois suivant l'apparition des symptômes, comparativement à la période de six à neuf mois suivant l'apparition des symptômes : - au cours des 6 premiers mois après l'apparition de la maladie, on a noté une réduction de l'ampleur des lymphocytes T CD4+

		productrices de cytokines par rapport aux protéines S, N et M. Elle a ensuite augmenté pendant la période de six à neuf mois suivant l'infection. - Aucun changement n'a été observé chez les lymphocytes T CD8+ produisant de la cytokine. - Il y a eu une augmentation marquée du nombre de bains de lymphocyte T mémoire CD8+ réactifs (c.-à-d. la portée et l'ampleur des réponses) entre 6 et neuf mois après les symptômes.
Réponses immunitaires associées aux anticorps circulants		
Doria-Rose (2021) (64) Lettre à la rédaction *nouvelle* Essai clinique randomisé États-Unis Août 2020 à mars 2021	L'immunité du vaccin a été évaluée chez 33 participants adultes en bonne santé dans le cadre d'un essai en cours de phase 1 portant sur des anticorps et effectué 180 jours après avoir reçu la deuxième dose du vaccin ARNm-1273 de Moderna.	Six mois après l'administration, l'activité des anticorps était élevée chez tous les participants (données indiquées dans le graphique) et était semblable dans tous les groupes d'âge. Une activité a pu être détectée par un test de pseudo-neutralisation chez presque tous les participants alors chez tous les participants, le test avec colorant mNeonGreen a généré une activité de neutralisation par réduction des foyers de virus vivants. - Les résultats de neutralisation étaient plus faibles chez les participants âgés de plus de 55 ans (P < 0,02).
Li (2021) (84) *Prépublication* *nouvelle* Cohorte prospective Chine Février 2020 à janvier 2021	Dans le cadre d'une transfusion de plasma de convalescent, 869 donneurs ont été recrutés et échantillonnés pendant une période allant jusqu'à 12 mois. Tous avaient obtenu un diagnostic confirmé de COVID-19. L'ensemble de détection des anticorps IgG portant le marquage CE a été utilisé	Taux de positivité des anticorps IgG contre le RBD après le diagnostic (seuil du titre < 1:80) : - 89,4 % après 6 ou 7 mois - 81,4 % après 11 ou 12 mois - 5,4 % des donneurs de plasma de convalescent n'ont jamais eu de titres détectables. Après 9 mois, les titres d'anticorps IgG contre le RBD ont commencé à se stabiliser à un TMG d'environ 200. Le titre d'anticorps IgG contre le

	pour tester le titre de l'IgG spécifique au RBD.	RBD après 12 mois était 70 % plus bas que la valeur obtenue le premier mois après le diagnostic.
den Hertog (2021) (85) *nouvelle* Cohorte basée sur la population Pays-Bas Avril à octobre 2020	Au cours des sept mois qui ont suivi l'infection, 353 personnes séroconverties qui ont pris part à une étude de sérosurveillance pour des personnes de tout âge ont été examinées afin de déceler la désintégration des anticorps. L'avidité des anticorps IgG contre la sous-unité S1 de la protéine S du SARS-CoV-2 a été étudiée comme marqueur de l'immunité cellulaire sous-jacente. Dosage biologique : test immunitaire avec billes fluorescentes effectué à l'interne, capable de mesurer les taux d'IgG, d'IgM et d'IgA.	Nombre d'anticorps présents pendant le premier mois suivant la séroconversion de l'IgG et nombre d'anticorps présents après 6 mois : - IgG 99 % contre 92 % (IC à 95 %, 89 à 95) - IgM 64 % contre 33 % (28 à 39) - IgA 62 % contre 37 % (31 à 43) - On a estimé que la diminution des taux d'IgG avait doublé en 158 jours (IC à 95 %, 136 à 189) et que l'indice d'avidité des anticorps IgG contre la sous-unité S1 de la protéine S du SARS-CoV-2 avait augmenté de plus du double pendant ces 7 mois. Après 6 mois, les personnes dont les anticorps IgG avaient fait l'objet d'une séroréversion étaient plus susceptibles d'avoir été asymptomatiques ou d'avoir été atteints de la forme bénigne alors que celles qui avaient eu une forme symptomatique de COVID-19 étaient plus susceptibles d'être positifs à l'IgM ou à l'IgA et d'afficher une plus forte augmentation de l'indice d'avidité des anticorps IgG contre la sous-unité S1 de la protéine S du SARS-CoV-2 pendant les 7 mois (p = 0,02).
L'Huillier (2021) (65) *nouvelle* Cohorte prospective Suisse Mars à octobre 2020	Les travailleurs de la santé dont le SRAS-CoV-2 a été confirmé entre le 17 mars et le 15 avril 2020 ont été recrutés dans un seul hôpital. Des prélèvements sanguins de suivi ont été effectués dans 196 cas sur 200 au mois 1, au mois 3 et au mois 6 après le diagnostic. Les anticorps dirigés contre le SARS-CoV-2 ont été mesurés à l'aide du test	Nombre d'anticorps présents pendant le premier mois suivant la séroconversion de l'IgG et nombre d'anticorps présents après 6 mois : - Tous les participants avaient des anticorps anti-RBD au mois 6. Le taux géométrique médian a augmenté entre le mois 1 et le mois 6 pour atteindre 123,3 U/ml (IC à 95 % : 103,4 à 147,0; p < 0,001) et seulement 4,6 % des participants ont vu leurs valeurs d'anticorps anti-RBD diminuer. - Au mois 6, 98 % (192 sur 196) des participants avaient des anticorps contre la protéine N. La moyenne géométrique a diminué entre le

	immunologique Elecsys pour la détermination qualitative dirigé contre le RBD et du test immunologique Elecsys pour la détermination semi-quantitative anti-N (des tests qui mesurent tous deux les taux d'immunoglobuline totale). Un test de neutralisation du virus substitut offert sur le marché et un test de neutralisation par réduction des plages ont été utilisés pour à des fins de neutralisation.	mois 3 et le mois 6 pour atteindre (34,0, IC à 95 % : 28,0 à 41,3). - Les titres des anticorps inhibiteurs de la région de liaison ACE2 sur le RBD (Ig totale) ont diminué au fil du temps dans l'ensemble de la cohorte. Au mois 6 : - 7,7 % (15 sur 196) avaient des titres d'anticorps inhibiteurs au moins deux fois plus élevés qu'au mois 1 - 58,2 % (114 sur 196) avaient des titres deux fois moindres - 34,2 % (67 sur 196) des titres sont demeurés stables (variation de 0,5 à 2 fois) Les résultats du PRNT indiquent une activité de neutralisation dans 92,9 % de PRNT90 et dans 99,5 % de PRNT50.
Garcia-Abellan (2021) (32) *Prépublication* *nouvelle* Cohorte prospective Espagne Mars à décembre 2020	146 cas confirmés de SRAS-CoV-2 ont été recrutés pour un échantillonnage en série effectué 1, 2 et 6 mois après le congé de l'hôpital. Les anticorps IgG de la protéine N et de la sous-unité S1 de la protéine S ont été mesurés avec les tests Anti-SARS-CoV-2 NCP ELISA (IgG) et Anti-IgG/A/M SARS-CoV-2 ELISA, Euroimmun, Lubeck, Allemagne.	On a suivi 134 cas pendant 6 mois. 7,8 % de ces cas ont signalé des symptômes persistants associés à la COVID-19 et 3 % (4 sur 134) ont obtenu un résultat positif au test RT-PCR (valeur Ct médiane = 36). Aucune réinfection n'a eu lieu, comme cela a été confirmé par le séquençage. - La séroréversion s'est produite chez 29 patients. 27 (27,6 %) patients avaient des anticorps IgG contre la protéine N alors que 6 (6 %) avaient des anticorps IgG contre la protéine S au mois 6. Les données présentées dans les graphiques indiquent que les anticorps IgG contre le RBD étaient stables jusqu'au mois 6, mais que les anticorps IgG contre la protéine N avaient diminué par rapport à la valeur obtenue 30 jours après l'infection.
Dispinseri (2021) (78) *Prépublication* *nouvelle*	150 cas ont été inscrits à l'étude de cohorte clinique-biologique (COVID-BioB) avec	46 cas ont pris part à des visites supplémentaires effectuées six mois ou plus (médiane de 204 jours, plage de 145 à 250) après l'infection.

Cohorte prospective Italie Février à novembre 2020	points d'échantillonnage fixés 1 (n = 87), 3 (n = 77) et 6 (n = 46) mois après la date de congé. 12 autres cas non hospitalisés ont été suivis jusqu'à un maximum de 5 visites. Un test d'immunoprécipitation en phase liquide révélé par la luciférase (LIPS) a été utilisé pour mesurer les anticorps. Le test de neutralisation du SARS-CoV-2 basé sur un vecteur lentiviral a été utilisé pour examiner la neutralisation de la protéine S comme bon marqueur substitut pour les anticorps neutralisants.	- Les titres d'anticorps neutralisants diminuaient l'ID50 dans 1/660 (plage de 1/< 40 à 10 900) et aucun cas n'était négatif. - Les anticorps neutralisants et les anticorps IgG de la protéine S ont persisté chez la grande majorité des patients rétablis, peu importe la gravité de la maladie, l'âge et les comorbidités pendant un maximum de huit mois après l'apparition des symptômes (données dans les graphiques). Dans les cas où la personne a été hospitalisée, il y avait une corrélation entre les anticorps neutralisants et la forme grave de la maladie.
Van Elslande (2021) (80) *Lettre à la rédaction* *nouvelle* Cohorte prospective Belgique Printemps 2021*	Des échantillons de sérum ont été prélevés chez des travailleurs de la santé dont le diagnostic avait été confirmé par la méthode RT-PCR (n = 118) entre 1 et 3 mois (28 à 103 jours) et entre 7 et 10 mois (209 à 315 jours) après le diagnostic. La majorité des cas échantillonnés présentaient des symptômes légers, et six personnes ont dû être hospitalisées en raison d'une infection aiguë.	Résultats immunitaires de 7 à 10 mois après le diagnostic : - La positivité des anticorps IgG contre la protéine S a été observée dans 92,4 % de l'échantillon alors que la positivité des anticorps IgG contre la protéine N a été observée dans 17,8 %. - - La demi-vie moyenne a été estimée à 76,4 jours (IC à 95 %, 68,3 à 86,7) pour les anticorps IgG contre la protéine N, et à 198,8 jours (IC à 95 %, 143,6 à 323) pour les anticorps IgG contre la protéine S. - On estime que 50 % des patients sont devenus séronégatifs pour les anticorps contre la

	Les anticorps IgG spécifiques contre la protéine S et la protéine N du SRAS-CoV-2 ont été mesurés à l'aide de tests IgG II Quant. La demi-vie des anticorps a été estimée par régression linéaire.	protéine N 201,2 jours (IC à 95 %, 179,9 à 228,3) après le diagnostic alors que 50 % des patients sont également devenus séronégatifs pour les anticorps contre la protéine S 803,2 jours (IC à 95 %, 580,2 à 1305,0) après le diagnostic.
De Giorgi (2021) (86) *Prépublication* *nouvelle* Cohorte prospective États-Unis Avril à novembre 2020	105 donneurs de plasma convalescent pour la COVID-19 sur 202 ont fourni des échantillons répétés (tous les 28 jours ou plus) pendant un maximum de 9 mois après leur diagnostic. 91 % d'entre eux avaient eu une forme légère de la COVID-19. Les échantillons de plasma ont été utilisés pour effectuer des tests sur le SARS-CoV-2. Les anticorps totaux et les anticorps IgG ont également été analysés. Un essai de neutralisation par réduction de la fluorescence a été utilisé pour déterminer les titres de neutralisation.	Lors de l'évaluation initiale, 97,5 %, 74,3 % et 73,8 % des échantillons présentaient une activité totale, une activité associée aux anticorps IgG et une activité neutralisante. - 93 % des 105 donneurs présentaient des taux détectables d'anticorps IgG 9 mois après le rétablissement. - Les taux des anticorps IgG ont diminué lors du suivi chez 30,7 % des donneurs, mais la séroconversion était rare (3,8 %). - 63 % des donneurs avaient des anticorps neutralisants détectables jusqu'à 9 mois après le rétablissement. - 25 % des donneurs avaient eu une séroréversion pendant le suivi, alors que 12 % n'avaient pas d'anticorps neutralisants détectables. - Chez ceux qui avaient des titres de départ élevés, 82,9 % ont maintenu des titres détectables au fil du temps comparativement à ceux qui avaient des titres de départ faibles puisque seuls 39,6 % de ceux-ci sont restés détectables au fil du temps. Aucune réinfection ne s'est produite dans cette cohorte.
Noh (2021) (77) *nouvelle* Cohorte prospective	Des échantillons de sérum ont été prélevés chez des cas dont le diagnostic de COVID-19 a été confirmé par test RT-PCR (n = 97) présentant	Résultats immunitaires obtenus 6 mois après le diagnostic indiqués dans l'étude : - Deux mois après le diagnostic, les taux d'IgG sont passés de 91,7 % à 66 %. De même, le titre géométrique médian de l'IgG obtenu

Corée Juin 2020 à janvier 2021	différentes gravités d'infection (cas asymptomatiques (n = 14), symptomatiques/non symptomatiques (n = 42) et pulmonaires (n = 41) 8 semaines, 9 à 20 semaines et 22 à 27 semaines après le diagnostic. Le nombre médian de jours entre le diagnostic et le prélèvement final de l'échantillon de sérum était de 184 (plage de 182 à 185) jours. Des tests sur les anticorps IgG contre la protéine N et des tests de neutralisation par réduction des plages (PRNT) ont été utilisés pour mesurer les titres d'anticorps neutralisants. Les titres géométriques médians ont été calculés afin de comparer les titres IgG obtenus lors des différentes étapes de collecte.	après 6 mois était 46,2 % inférieur à celui obtenu après 2 mois. - Quant à la séropositivité, elle avait, elle aussi, diminué de 100 % par rapport au niveau obtenu après 2 mois jusqu'à atteindre 86,9 %. Quant au titre géométrique médian pour les anticorps neutralisants, il avait également diminué de 68,3 %, comparativement aux niveaux obtenus après 2 mois - Les anticorps neutralisants étaient cependant plus hauts dans les cas où l'on trouvait une excrétion virale durant plus de 21 jours. Les taux d'anticorps IgG et d'anticorps neutralisants étaient plus élevés six mois après le diagnostic dans les cas pulmonaires, comparativement aux cas moins graves.
Ortega (2021) (87) *Prépublication* *nouvelle* Cohorte prospective Espagne Mars à octobre 2020	Des échantillons de sérum ont été prélevés et la cinétique des anticorps a été mesurée chez des travailleurs de la santé séropositifs et symptomatiques (n = 76) 1, 3 et 6 mois après l'apparition des symptômes. Les taux d'anticorps IgG, IgM et IgA spécifiques à la protéine S du SRAS-CoV-2 (sous-unités S1, S2), à la RBD, à la protéine N et à	Séropositivité des anticorps 6 mois après l'apparition des symptômes : - La plupart des taux d'anticorps testés sont demeurés stables au fil du temps. 71 % des participants sont demeurés positifs pour les anticorps IgG contre la protéine S alors que 69 % le sont restés pour l'IgA. - Les taux d'anticorps IgM et IgG contre la protéine N ont diminué pendant la période de suivi. Plus de cinq mois après l'apparition des symptômes, on a pu voir que la séropositivité des anticorps IgM contre la protéine N était

	l'extrémité C terminale de la protéine N, ainsi que les antigènes HCoV ont été mesurés au moyen d'un test Luminex. La capacité des anticorps neutralisants par rapport au RBD-ACE-2 a été mesurée par cyrtométrie de flux.	à 34 % alors que celle des anticorps IgG était à 26 % contre cette même protéine N. - La capacité des anticorps neutralisants a augmenté pendant environ 3 mois après l'apparition des symptômes et est demeurée stable pendant 5,3 mois supplémentaires après l'apparition des symptômes. - Six mois après l'apparition des symptômes, les taux d'IgG et d'IgA pour tous les antigènes testés ont montré une corrélation modérée à forte avec la capacité des anticorps neutralisants (r_s = 0,24 à 0,76, p < 0,05). Les auteurs mentionnent que les taux d'IgG et d'IgA pour le HCoV étaient beaucoup plus élevés chez les individus séropositifs asymptomatiques que chez les individus séropositifs symptomatiques et ont donc conclu que la réactivité croisée aux antigènes HCoV endémiques pouvait avoir des effets protecteurs contre la gravité du virus SRAS-CoV-2.
Sakhi (2021) (83) *nouvelle* Cohorte prospective France Mars à octobre 2020	Des échantillons de sérum ont été prélevés chez des patients en hémodialyse et une sérologie des anticorps IgG contre la protéine N du SRAS-CoV-2 (n = 73) a été effectuée environ 51 jours après le diagnostic. 81 % (n = 60 sur 74) des échantillons de sérum de cet échantillon ont été prélevés six mois après le diagnostic. Les taux sériques de la protéine S du SRAS-CoV-2 et des anticorps IgG spécifiques contre la protéine N ont été mesurées.	Résultats immunitaires obtenus 6 mois après le diagnostic indiqués dans l'étude : - 25 % (n = 15 sur 60) de l'échantillon présentaient des taux indétectables des anticorps IgG contre la protéine N du SRAS-CoV-2 (c.-à-d. font l'objet d'une séroréversion). De ces cas, 21 % (n = 3/14) étaient également négatifs pour les anticorps contre la protéine S. - 97 % (n = 43 sur 45) des cas qui étaient séropositifs pour les anticorps IgG contre la protéine N du SRAS-CoV-2 sont également demeurés positifs pour les anticorps contre la protéine S. Un lien a ensuite été établi entre une infection aiguë non grave et une désintégration plus rapide

		des anticorps IgG contre la protéine S du SRAS-CoV-2.
Rockstroh (2021) (79) *nouvelle* Cohorte prospective Allemagne Mars 2020 à janvier 2021	Des échantillons de sérum ont été prélevés chez des cas dont le diagnostic avait été confirmé par RT-PCR (n = 57) moins de 2 mois après l'apparition des symptômes (médiane de 1 mois) et ont fait l'objet d'un suivi pendant 6 à 9 mois après l'apparition des symptômes (médiane de 7,9 EI de 6,6 à 8 mois). Ces cas comprenaient des personnes non hospitalisées (n = 38), des personnes hospitalisées qui avaient des symptômes graves (n = 15) et des personnes qui ont dû recevoir de l'oxygène (n = 4). Les anticorps IgG spécifiques contre le virion complet, la sous-unité S1 de la protéine S, la protéine N et les antigènes contre RBD du SARS-CoV-2 ont été mesurés à l'aide des tests ELISA et ELISpot. L'activité de l'anticorps neutralisant a été mesurée avec un virus actif.	Résultats immunitaires obtenus de 6 à 9 mois après l'apparition des symptômes : - Une réduction importante des titres d'anticorps neutralisants (réduction médiane de 4 fois, EI 2,7 à 10,7) a été observée chez les cas graves. Les titres d'anticorps neutralisant des patients non hospitalisés ont légèrement diminué (réduction médiane de 2,8 fois, EI 1,9 à 6). - Les anticorps neutralisants étaient indétectables (c.-à-d. séroréversion) dans 13,16 % (n = 5 sur 38) des cas non hospitalisés, mais tous les cas graves sont demeurés positifs pour les anticorps neutralisants de 6 à 9 mois après l'apparition des symptômes. - La sous-unité S1 de la protéine S et les anticorps IgG spécifiques contre la protéine N ont diminué, alors que les anticorps IgG spécifiques contre le RBD sont demeurés stables (ou ont même augmenté) pendant la période de suivi. - Les anticorps IgG contre la protéine N ont démontré une faible corrélation avec l'activité des anticorps neutralisants. - Les taux d'anticorps IgG contre la sous-unité S1 de la protéine S et l'activité des anticorps neutralisants étaient tous corrélés. Une corrélation positive significative entre la gravité de l'infection aiguë et les taux médians d'anticorps IgG pour tous les anticorps testés a été observée à tous les temps de mesure.
Levi (2021) (88) *Prépublication* Cohorte prospective	Mesure des changements dans les niveaux d'anticorps sériques dans une période de cinq mois, effectuée chez un échantillon de travailleurs de la santé provenant de	- Les concentrations d'IgG étaient plus élevées chez les travailleurs de la santé dont la COVID-19 était symptomatique, comparativement aux travailleurs de la santé asymptomatiques et paucisymptomatiques.

Italie Avril à août 2020	multiples établissements de soins de santé (n = 4 534). Les concentrations d'IgG spécifiques aux protéines S (S1 et S2) ont été mesurées par des dosages biologiques (dans lesquels le seuil a été fixé à 12 AU/ml pour l'IgG). Parmi les travailleurs de la santé dont les taux d'IgG étaient supérieurs au seuil, 14 % (n = 91 sur 613) étaient asymptomatiques. Les facteurs associés à la dynamique des anticorps ont été déterminés au moyen d'une analyse de régression logistique.	- Les symptômes associés à des taux d'IgG soutenus et plus élevés (évalués après cinq mois) incluaient de la fièvre, de la toux, des douleurs musculaires, de l'asthénie, de la tachycardie et de l'anosmie/dysgueusie. - L'analyse de régression a révélé un lien important entre un taux d'IgG constant et la présence d'anosmie ou de dysgueusie (RC 2,75, IC à 95 %, 1,753 à 4,301). Remarque : Les résultats de l'étude peuvent être biaisés, puisque des augmentations des niveaux d'anticorps des travailleurs de la santé ont été observées dans les régions les plus touchées par la SRAS-CoV-2 alors qu'elles étaient plus faibles dans les régions les moins touchées (c.-à-d. que les niveaux d'anticorps pourraient augmenter en raison des réinfections).
Dobaño (2021) (43) *Prépublication* Cohorte prospective Espagne Mars à décembre 2020	On a évalué les niveaux d'anticorps et la séropositivité dans un échantillon d'agents de soins de santé primaires (n = 173) de 149 à 270 jours après l'apparition des symptômes grâce à des prélèvements de sérum effectués à trois moments distincts. Les infections ont été confirmées par des tests PCR. La majorité des cas de l'échantillon comprenaient des travailleurs ayant eu des symptômes légers à moyens dont 14 % ont dû être hospitalisés. Les niveaux d'IgM, d'IgA et d'IgG contre la protéine S et le RBD ont été mesurés par dosage biologique (non précisé). Les	La dynamique des anticorps effectuée entre cinq et neuf mois après l'apparition des symptômes, comme cela est indiqué dans l'étude, a permis d'obtenir les résultats suivants : - 92,49 % des participants étaient positifs pour au moins un isotype d'immunoglobuline, ce qui indique une immunité très stable et persistante. - 60 % des participants étaient positifs pour l'IgM contre la protéine S et le RBD, 76,30 % pour l'IgA contre la protéine S et le RBD, et 90,17 % pour l'IgG contre la protéine S et le RBD. - Les facteurs associés à des niveaux plus élevés d'anticorps établis pendant le suivi incluaient l'admission à l'hôpital, de la fièvre, de l'anosmie ou de l'hypogueusie, et des allergies antérieures.

	facteurs associés à des niveaux plus élevés d'anticorps ont été déterminés par des analyses de régression multivariables par étapes.	
Wagner (2020) (60) *Prépublication* Cohorte prospective Autriche Avril à octobre 2020	Une importante étude sur la séroprévalence (n = 1 655) a permis de déterminer les personnes positives aux anticorps IgG ou IgA contre la protéine S (n = 168). Seulement 42 % des participants ont déclaré avoir éprouvé des symptômes compatibles avec l'infection au cours des trois mois précédant le recrutement. Des échantillons de sérum provenant de personnes séropositives ont été prélevés trois et six mois après les résultats initiaux du test (n = 1 292 sur 1 655). Les anticorps contre la sous-unité S1 de la protéine S, la protéine N et le RBD et les anticorps neutralisants ont été détectés par des tests sérologiques.	La dynamique des anticorps a été évaluée six mois après les résultats initiaux des tests séropositifs identifiés dans l'étude et a permis d'obtenir les résultats suivants : - les niveaux d'IgG contre la région S1, qui suggèrent une exposition plutôt qu'une immunité protectrice, ont persisté dans 90 % des cas séropositifs (9 sur 10). - Les niveaux d'IgG contre la protéine N n'étaient plus détectables dans 55,5 % de l'échantillon. - Après trois mois, le taux d'IgM contre le RBD avait diminué (par rapport aux résultats séropositifs initiaux) dans 53,3 % de l'échantillon, mais il est demeuré stable de 3 à six mois. - Au départ, 50 % des personnes ayant obtenu un résultat positif pour l'IgM contre le RBD et pour l'IgG contre la protéine N étaient séronégatifs à six mois. - Après six mois, l'IgA contre la protéine S1 avait diminué par rapport au niveau de référence. - Les anticorps totaux RBD avaient une meilleure corrélation avec les anticorps neutralisants (un marqueur substitut pour la protection contre le virus) et le niveau des deux était stable après six mois. - Les niveaux d'anticorps RBD n'ont révélé aucun lien avec les symptômes et de la gravité attribués à l'infection. - Les auteurs ont conclu que les dosages biologiques spécifiques aux anticorps RBD peuvent détecter de façon fiable des anticorps spécifiques au SRAS-CoV-2 pendant au moins six mois après l'infection.

Zhou (2020) (81) Cohorte prospective Chine Printemps 2020*	Les concentrations d'anticorps IgM et IgG contre la protéine S ont été testées dans des échantillons sériques de convalescence prélevés chez des participants ayant eu la COVID-19 (n = 165). Tous les participants avaient été hospitalisés et leurs infections confirmées par test RT-PCR. Le test ELISA a été utilisé pour mesurer les niveaux d'anticorps dans les échantillons de sérum. Tous les échantillons ont été prélevés entre le jour 1 et 7 mois après l'apparition des symptômes dont 28 échantillons de sérum ont été utilisés pour obtenir des données sept mois après l'infection.	La dynamique des anticorps a été évaluée jusqu'à sept mois après l'hospitalisation initiale, comme cela est indiqué dans l'étude et a permis d'obtenir les résultats suivants : - L'IgM contre la protéine S a diminué après avoir atteint un sommet aux alentours de 22 à 28 jours et 79 % des personnes étaient négatives pour ces anticorps sept mois après l'infection. - Les taux d'IgG contre la protéine S ont augmenté du jour 1 au jour 28, les niveaux de pointe se sont maintenus jusqu'à quatre mois après l'apparition des symptômes, mais ont fortement diminué après sept mois.
Vanshylla (2021) (89) *Prépublication* Cohorte prospective Allemagne Avril à décembre 2020	Concentrations d'anticorps dans un échantillon de personnes rétablies (n = 131 sur 963), détectées dans des échantillons sériques prélevés jusqu'à 10 mois après l'apparition des symptômes ou le diagnostic de confirmation. De ce nombre, 41,8 % des personnes convalescentes pour la COVID-19 avaient été hospitalisées et leur infection avait été confirmée par un test RT-PCR. Les concentrations d'IgG dans les anticorps neutralisants et dans la protéine S mesurées	La dynamique des anticorps effectuée entre quatre et dix mois après l'apparition des symptômes ou le diagnostic de confirmation, comme cela est indiqué dans l'étude, a permis d'obtenir les résultats suivants : - Les taux d'IgG contre la protéine S ont diminué entre un et quatre mois après l'infection, puis sont restés constants pendant le reste du suivi. - Alors qu'un mois après l'infection 86 % des personnes étaient encore positives à l'IgG contre la S1, ce pourcentage a atteint 73 % neuf à dix mois après l'infection. - La demi-vie de l'IgG a été estimée à 8,7 mois. Les niveaux et l'activité des anticorps neutralisants ont rapidement diminué au cours des deux premiers mois après l'infection, mais les fonctions neutralisantes des anticorps IgG purifiés, y compris contre la protéine S, ont été maintenues jusqu'à sept mois après l'infection. Ces résultats suggèrent

	par de multiples dosages biologiques ont permis de créer par modélisation une régression linéaire avec effets mixtes comprenant les estimations des demi-vies des anticorps.	un répertoire de cellules IgG et de lymphocytes B mémoires plus stable, ainsi que des niveaux stables d'IgG chez la majorité des individus qui se sont rétablis d'une infection.
Whitcombe (2020) (59) Série de cas Nouvelle-Zélande Printemps 2020*	Des échantillons de sérum tirés de tests RT-PCR effectués chez des convalescents ayant été atteints d'une forme bénigne ou modérée de la COVID-19 (n = 112) ont été recueillis. Des 80 des 189 échantillons prélevés à plusieurs reprises auprès de 50 participants ont permis d'avoir plus de détails sur les quatre à huit mois qui ont suivi l'apparition de l'infection. Une épreuve Triplex a été effectuée à l'interne pour analyser les échantillons et déterminer la présence des anticorps IgG, IgM et IgA et de leurs sous-catégories (IgG1, 2, 3 et 4) spécifiques à la protéine N, à la protéine S et au RBD, ainsi que des anticorps neutralisants.	La dynamique des anticorps dans les quatre à huit mois après l'apparition de l'infection par rapport aux niveaux de référence a permis de constater ce qui suit : - 99 % (79 sur 80) des prélèvements contenaient de l'IgG anti-RBD et 96 % (77 sur 80) contenaient de l'IgG anti-protéine S. - Les anticorps contre le RBD se sont maintenus dans 64 % (51 sur 80), tout comme les IgG1 contre la protéine S qui ont persisté dans 59 % (47 sur 80) des cas alors que les anticorps IgG3 contre la protéine S étaient encore présents dans 60 % (48 sur 80) des cas. - Moins de 30 % des participants ont continué à avoir des résultats positifs pour les anticorps contre la protéine N, avant que le niveau de ces derniers ne diminue rapidement. - 90 % (72 sur 80) des anticorps neutralisants étaient détectables. Pendant toute l'étude, ils étaient relativement stables et ont été corrélés avec l'IgA contre RBD (r ≥ 0,87 de Pearson). À l'aide d'échantillons de sérum appariés (n = 50 participants), on a pu estimer le taux de désintégration des anticorps neutralisants à 146 jours (IC à 95 % : 100 à 199), ce qui est considérablement plus court que les résultats prévus par les modèles de décroissance exponentielle (625 jours) ou de croissance-désintégration (425 jours).
Han (2021) (90) Cohorte prospective	Du plasma provenant de convalescents et de personnes en phase aiguë ayant été atteints d'une forme grave de COVID-19 confirmée	La dynamique des anticorps effectuée entre six et sept mois après l'apparition des symptômes a permis d'obtenir les résultats suivants : - Comparativement aux témoins sains, tous les anticorps spécifiques aux antigènes viraux

Chine Décembre 2019 à mars 2020	par test RT-PCR a été testé pour déterminer la présence d'IgG contre le RBD, la protéine S et la protéine N (n = 104). Le suivi a été effectué environ six à sept mois (médiane de 195 jours; intervalle de 188 à 201 jours) après l'infection. Des échantillons de sérum provenant de 31 témoins sains, sans suivi, ont également été inclus. Le taux d'anticorps a été mesuré à l'aide du test ELISA et par des épreuves de microneutralisation. Les corrélations entre les taux d'anticorps des convalescents et l'activité de neutralisation du virus ont été estimées par ANOVA.	mesurés étaient significativement plus élevés chez les personnes infectées qui en étaient au stade aigu et convalescentes. - Les anticorps spécifiques aux antigènes viraux ne présentaient pas de différences significatives selon l'âge ou le sexe des participants. - Les taux d'IgG contre le RBD et la protéine N étaient beaucoup plus bas pendant la convalescence ($p < 0,000$) que pendant la phase aiguë, mais aucune réduction significative n'a été décelée pour le taux d'IgG contre la protéine S. - Les réductions médianes pour le sérum de phase aiguë et celui de la convalescence ont été estimées à 15,90 % (EI, 7,83 à 30,91 %) pour l'IgG contre la protéine S, à 51,63 % (EI, 31,25 à 66,30 %) pour l'IgG contre la protéine N et à 58,98 % (EI, 48,15 à 68,25 %) pour l'IgG contre le RBD, - Des corrélations significatives ($p < 0,0001$) et fortes ont été effectuées entre l'activité de neutralisation du virus et les niveaux d'anticorps neutralisant avec les niveaux d'IgG contre le RBD, alors que des corrélations significatives ($p < 0,0001$) et modérées entre les niveaux d'IgG contre le RBD et contre la protéine N ont été notées dans le sérum de convalescence.
Choe (2021) (61) Étude transversale Corée du Sud Février à octobre 2020	Des échantillons de sérum provenant de personnes (n = 58) atteintes de COVID-19, dont 7 personnes asymptomatiques et 51 légèrement symptomatiques ont été prélevés huit mois après l'infection. Les niveaux d'anticorps ont été étudiés	Huit mois après l'infection, la dynamique des anticorps était la suivante : - 91,4 % des participants ont continué à avoir des résultats positifs pour les anticorps Ig contre la protéine N. - 25,9 % des participants ont continué à avoir des résultats positifs pour les anticorps Ig contre la protéine N. - 86 % des participants obtenaient des résultats positifs pour les anticorps IgG contre la protéine S alors que 69 % étaient positifs pour les anticorps IgG contre la protéine S1.

	grâce à de multiples essais immunologiques.	- 53,4 % des participants ont obtenu un résultat positif pour l'activité des anticorps neutralisants. On a confirmé que la détection des anticorps variait selon les méthodes d'immuno-essais utilisées.
Zhang (2020) (66) Série de cas Chine Janvier à juillet 2020	Des échantillons sériques ont été prélevés chez des convalescents (n = 54 sur 112) pour la COVID-19 entre 158 et 194 jours après l'apparition des symptômes et ils ont été comparés au niveau d'anticorps pendant la phase d'infection aiguë. L'infection chez tous les participants a été confirmée par un test RT-PCR et a indiqué que 77,7 % étaient des cas bénins et que 22,3 % étaient graves. Les taux d'anticorps IgG et IgM contre la protéine N et le RBD ont été mesurés à l'aide du test ELISA.	La dynamique des anticorps effectuée entre cinq et six mois après l'apparition des symptômes a permis d'obtenir les résultats suivants : - Tous les participants étaient positifs pour les anticorps contre la protéine N (catégorie d'Ig non précisée) et les niveaux des anticorps avaient diminué par rapport aux titres effectués pendant la phase d'infection aiguë. Tant les groupes atteints d'une forme bénigne de l'infection (médiane de 46,31 % (EI de 5,37 % à 68,96 %) que ceux qui avaient une forme grave (médiane de 46,02 % (EI de 11,01 % à 65,75 %) ont vu des réductions semblables dans les titres d'anticorps contre la protéine N.
Kwada (2020) (91) *Prépublication* Série de cas Japon Avril à novembre 2020	Des échantillons de sérum prélevés chez des travailleurs de la santé séropositifs à la suite d'une éclosion dans un hôpital, dont 42 sur 45 ont été confirmés par test RT-PCR et dont la gravité n'a pas été déclarée, ont fait l'objet d'un suivi mensuel jusqu'à sept mois après le diagnostic (n = 45). Les concentrations totales d'anticorps contre les protéines N et S ont été	La dynamique des anticorps effectuée environ sept mois après le diagnostic de l'infection a permis d'obtenir les résultats suivants : - chez 33 % (n = 15) des travailleurs, les taux d'Ig contre la protéine N ont augmenté de façon significative et se sont maintenus à ce niveau; chez 33 % (n = 16) d'entre eux, le taux qui avait augmenté à l'origine a ensuite diminué, alors que chez 31 % (n = 14) des travailleurs, ils n'ont augmenté que de peu et sont restés à ce niveau. - Les personnes qui avaient des taux élevés d'anticorps Ig contre la protéine N qui se sont ensuite maintenus, présentaient également des taux plus élevés d'anticorps contre la

	mesurées jusqu'à sept mois après l'infection (n = 45).	protéine S sept mois après le diagnostic. Les concentrations d'anticorps contre la protéine N n'ont montré aucune corrélation apparente avec le contact avec la COVID-19 ou avec les symptômes. - Les auteurs suggèrent que les niveaux d'anticorps pan-Ig contre la protéine N ne sont peut-être pas liés au rétablissement après la maladie.
Dehgani-Mobaraki (2020) (31) Cohorte prospective Italie Mars à janvier 2021	Des échantillons de sérum ont été prélevés à cinq points dans le temps, soit entre un et dix mois après le diagnostic chez des participants (n = 114) dont l'infection par la COVID-19 avait été confirmée par test RT-PCR. Les six échantillons de sang en série qui devaient être obtenus dans les 10 mois suivant l'infection (mois 2, 3, 5, 7, 8 et 10) n'ont pu être prélevés que chez 30 personnes. Dosages : Test MAGLUMI® 2019-nCoV IgM/IgG CLIA pour les cinq premiers tests et MAGLUMI® SARS-CoV-2 S-RBD IgG CLIA pour le dernier.	L'analyse effectuée sur les 30 personnes incluait différents points de données obtenus dans les dix mois qui ont suivi l'infection. - L'IgG contre la protéine S et RBD a été détecté dans 76,7 % des cas après 8 mois et dans 63,3 % des cas après 10 mois. - Dans l'ensemble, l'IgM était inférieur au seuil (> 83 %) alors que l'IgG était supérieur au seuil (> 63 %) de 1,10 pendant la période d'échantillonnage. Les niveaux de ces anticorps n'ont pas changé de façon significative pendant les points d'échantillonnage. Aucune différence n'a été notée en ce qui concerne la gravité, l'âge, le sexe, le groupe sanguin de type O ou le fait qu'il s'agissait d'un travailleur de la santé.
Pradenas (2020) (58) Cohorte prospective Espagne Avril à octobre 2020	Des échantillons de sérum ont été prélevés au moment du diagnostic, puis à trois et à six mois, chez 210 cas confirmés de COVID-19 par test RT-PCR (106 cas bénins et 104 hospitalisations). Seulement 28 participants sur 210 ont contribué aux données longitudinales. Les anticorps IgG contre le RBD, la protéine S S2, la	La dynamique des anticorps effectuée jusqu'à six mois après l'apparition des symptômes ou l'obtention du diagnostic, comme cela est indiqué dans l'étude, a permis d'obtenir les résultats suivants : - Plus de 30 jours après l'apparition de l'infection, l'on a estimé la demi-vie de l'IgG contre le RBD à 86 jours, celle de l'IgG contre la protéine S 2 à 108 jours et celle de l'IgG contre la protéine N à 59 jours. - Chez les participants atteints d'une forme bénigne ou asymptomatique de l'infection, les

	protéine N, ainsi que les concentrations d'anticorps neutralisant, ont été mesurées à l'aide du protocole ELISA et avec une épreuve de pseudovirus.	niveaux d'anticorps neutralisant étaient 10 fois inférieurs à ceux que l'on retrouvait chez les personnes atteintes d'une forme grave, et sont demeurés stables avec une désintégration négligeable jusqu'à six mois. - Comparativement aux participants ayant eu la forme bénigne ou asymptomatique de l'infection, les participants hospitalisés ont obtenu des titres d'anticorps neutralisant plus élevés jusqu'à la fin du suivi. Ces niveaux d'anticorps ont subi un déclin rapide initial qui s'est ensuite ralenti pour se stabiliser après 80 jours. - Les auteurs, en se fondant sur un seuil d'activité présumé de 1:250 pour prévenir la réinfection, suggèrent que les participants hospitalisés ont une plus grande capacité de neutralisation à long terme et de prévention de l'infection.
Hachim (2021) (67) *Prépublication* Cohorte prospective Hong Kong Avril à novembre 2020	Des échantillons de sérum d'enfants (n = 122) et d'adultes (n = 36) infectés, dont les infections ont été confirmées par test RT-PCR, ont été comparés à des échantillons de participants jamais infectés (n = 33). Parmi les échantillons, 36 % provenaient d'enfants et 25 % provenaient d'adultes asymptomatiques. Les échantillons de sérum ont été prélevés de 0 à 206 jours après l'apparition des symptômes (écart-type moyen de +/- 39±47 jours) chez les enfants alors qu'ils ont été prélevés de 24 à 123 jours après l'apparition des symptômes (écart-type moyen de +/- 54±20 jours) chez les adultes.	- Le modèle d'anticorps spécifiques obtenu pour les échantillons pédiatriques (n = 58 sur 122) jusqu'à six mois indique que les anticorps des deux protéines structurales (S1, S2, S2', M, E et N) et non structurales (NSP1, ORF3a, ORF3b et ORF7a ORF6, ORF8 et ORF10) étaient à un niveau stable ou avaient augmenté. - Les anticorps spécifiques à la protéine accessoire ORF7b ont diminué considérablement.

	Le suivi à long terme a été effectué de 58 à 122 jours jusqu'à 206 jours après l'apparition du symptôme. Seuls 16 échantillons sur 122 avaient des points de données entre quatre et six mois après l'apparition du symptôme et ont été utilisés pour orienter un modèle linéaire à effets mixtes. Les échantillons de sérum ont subi les tests LIPS et ELISA qui ciblent la protéine S, les sous-unités S1 et S2, la protéine N, la protéine E, la protéine M, alors que les anticorps spécifiques aux protéines non structurelles et accessoires, soit les protéines NSP1, et aux ORF ont été mesurés.	

AIM = marqueur induit par activation, ELISA = technique de dosage d'immunoabsorption par enzyme liée, protéine E = enveloppe, Ig = anticorps immunoglobulines, LTE = lettre, LIPS = dosage du système d'immunoprécipitation de la luciférase, protéine M = membrane, protéine N = nucléocapside, ORF = cadre de lecture ouvert, S = protéine de spicule ou Spike, RBD = domaine de liaison du récepteur

REVUE DE LA LITTÉRATURE

Les revues indiquées présentent des sommaires des données connues sur les marqueurs d'immunité à long terme disponibles entre juin et décembre 2020. Les études incluses dans ces revues comprennent également des recherches préliminaires sur les résultats immunitaires pertinents obtenus moins de 6 mois après le diagnostic initial de COVID-19.

Tableau 4 : Revue systématique et revue rapide concernant l'immunité (n = 4)

STUDY	METHOD	KEY OUTCOMES
Arkhipova-Jenkins (2021) (5) *nouvelle*	Une revue rapide qui vise à synthétiser les données probantes sur la prévalence, les taux et la durabilité	- Les données probantes indiquent que la plupart des adultes développent des taux détectables d'anticorps (c.-à-d. IgM, IgG et anticorps neutralisants) qui culminent entre 20 et 30 jours après l'apparition des symptômes.

Revue rapide en direct S.O. Mars 2021*	des anticorps détectables après l'infection par le SRAS-CoV-2 afin de déterminer si les anticorps contre le SRAS-CoV-2 confèrent une immunité naturelle. La documentation pertinente diffusée entre le 1er janvier et le 15 décembre 2020 a été incluse dans la revue. 444 études d'observation ont été incluses dans la revue.	- La durée estimée était de 115 jours pour l'IgM, de 120 jours pour l'IgG et de 140 jours pour l'IgA. - La plupart des adultes ont produit des anticorps neutralisants (à 99 % d'anticorps neutralisants, 95 % d'IgG et 80 % d'IgM) qui ont persisté plusieurs mois après l'infection. - L'âge, la gravité de la maladie et la présence de symptômes peuvent être associés à des niveaux d'anticorps plus élevés (éléments de preuve de bas niveau). - Certains adultes n'ont pas développé d'anticorps après l'infection par le SRAS-CoV-2, pour des raisons qui ne sont pas claires. - La qualité des éléments de preuve résumés a été jugée être de faible à modérée.
Poland (2020) (1) Examen S.O. Octobre 2020*	Cet examen porte sur ce que l'on savait au sujet des réponses immunitaires humorales et cellulaires humaines au SRAS-CoV-2 à la date de la recherche, soit le 24 septembre 2020.	- L'article examine l'immunité humorale et cellulaire et présente certaines données sur la cinétique et la durabilité de la réponse des anticorps et la corrélation avec la réponse des lymphocytes T. De nombreuses incohérences ont été relevées lors de la recherche initiale. - Les lacunes dans les connaissances incluent des études de grande qualité sur la durée de la protection par les anticorps neutralisants et une bonne compréhension de la façon dont les mesures immunologiques sont utilisées pour établir une corrélation avec la protection.
Post (2020) (63) Revue systématique S.O. Juin 2020	Revue systématique sur la réponse des anticorps au SRAS-CoV-2 à la date de la recherche, soit le 26 juin 2020. 150 documents ont été inclus. Les critères d'inclusion comprenaient un suivi de plus de 28 jours et les titres des anticorps mesurés. L'auteur a indiqué une forte variabilité entre les études et plans d'étude.	- Des incohérences dans les corrélats d'anticorps ont été observées dans l'ensemble de la littérature. - L'IgM (séroconversion de 4 à 14 jours, pic à 2 à 5 semaines et baisse jusqu'à des niveaux indétectables autour de 6 semaines) a été systématiquement détecté avant l'IgG. - L'IgG (séroconversion de 12 à 15 jours, pic à 3 à 7 semaines, plateau jusqu'à au moins 8 semaines avec le suivi le plus long (12 semaines) pendant lequel les anticorps étaient encore détectés). - L'IgA, qui est rarement étudiée, a montré une séroconversion entre 4 et 11 jours, avec des valeurs aberrantes à 24 jours. - Les anticorps neutralisants ont été détectés de 7 à 15 jours après l'apparition des symptômes, ont atteint un sommet entre 14 et 22 jours, avant de diminuer pendant 6 semaines. Au jour 39, 79 % des participants à l'étude avaient un faible taux d'anticorps neutralisants alors que 3 % avaient encore un taux élevé. Les personnes qui avaient été atteintes d'une

	Voir à l'annexe 2 pour un graphique sur la cinétique des anticorps au fil du temps.	forme bénigne présentaient des anticorps moins neutralisants. - Les études sur les animaux montrent des résultats initiaux prometteurs en ce qui concerne l'immunité protectrice; toutefois, les études étaient de petite envergure et de courte durée. Des études ont démontré des corrélations avec la gravité de la maladie. Une relation inverse avec la charge virale n'a pas été déclarée de façon uniforme et aucun lien avec la redétection n'a été signalé. Les études ne peuvent pas parler d'immunité durable.
Shrotri (2021) (74) Revue systématique S.O. Juin 2020	Une revue systématique qui évalue de façon critique et synthétise la documentation publiée et préimprimée de janvier 2020 au 26 juin 2020 sur l'immunité induite par les lymphocytes T après l'infection à SRAS-CoV-2. 61 publications ont été incluses dans cette revue.	- Les cas d'adultes symptomatiques montrent constamment une réduction du nombre de lymphocytes T périphériques pendant la phase d'infection aiguë, ce qui correspond positivement à une augmentation de la gravité de la maladie, de la durée de la positivité de l'ARN et du fait que le virus ne survit pas. Les réductions relatives observées dans les lymphocytes T CD4+ et CD8+ variaient. - Les cas asymptomatiques et pédiatriques affichent des nombres préservés de lymphocytes T. - Les personnes ayant eu des formes graves ou critiques de COVID-19 ont développé des réactions de lymphocytes T spécifiques d'un virus plus robustes. Des concentrations élevées de cytokines pro-inflammatoires, d'interleukine-6 (IL-6), à un degré moindre, d'interleukine-10 (IL-10) et de facteur alpha de nécrose tumorale (TNF-α) ont été identifiées dans les cas graves. - Le suivi longitudinal (14 à 44 jours après l'infection) a suggéré le rétablissement des sous-ensembles de cellules T ainsi que le rétablissement clinique et la clairance virale. - Le lymphocyte T mémoire et son effet sur les personnes qui débutent leur convalescence (jusqu'à environ 3 mois après l'apparition des symptômes) ont été démontrés contre les antigènes viraux S, M et N. La portée et l'ampleur de la réponse des lymphocytes T étaient généralement plus importantes chez les personnes qui se rétablissaient de formes graves de l'infection. L'activité productrice de cytokine des lymphocytes T CD 8+ spécifiques aux protéines M et N affichait de plus vastes fonctions que celles ciblant la protéine S chez les personnes atteintes d'une forme bénigne

		de l'infection. Les lymphocytes T CD3+ étaient moins nombreux dans les formes graves de l'infection. - Les lymphocytes T à réaction croisée chez les personnes n'ayant pas été exposées à d'autres coronavirus ou ayant déjà été exposées à d'autres formes de ce virus (p. ex., souches de coronavirus saisonniers prépandémiques, SRAS-CoV-1) ont souvent été détectés et semblent être présents à long terme puisque dans certains cas, ils sont restés dans le sang jusqu'à 17 ans après l'infection. Les lymphocytes T à réaction croisée ciblant les protéines virales S et N sont ceux qui ont été détectés comme cellules immunitaires à réaction croisée. L'impact de la réactivité croisée sur les infections par le SRAS-CoV-2 demeure en grande partie incertain, mais on suppose qu'il est faible en raison de la variabilité des épitopes du coronavirus.

Méthodologies :

Une analyse quotidienne de la littérature (publiée et prépubliée) est effectuée par le groupe des sciences émergentes de l'ASPC. L'analyse a permis de compiler la littérature sur la COVID-19 depuis le début de l'épidémie et est mise à jour quotidiennement. Les recherches visant à extraire les ouvrages pertinents sur la COVID-19 sont menées dans Pubmed, Scopus, BioRxiv, MedRxiv, ArXiv, SSRN et Research Square, et les résultats sont recoupés avec les ouvrages figurant sur la liste de la documentation sur la COVID de l'Organisation mondiale de la Santé et des centres d'information sur la COVID-19 gérés par Lancet, BMJ, Elsevier, Nature et Wiley. Le résumé quotidien et les résultats complets de l'analyse sont conservés dans une base de données RefWorks et dans une liste Excel consultable. Une recherche ciblée par mot-clé a été effectuée dans ces bases de données pour recenser les citations pertinentes sur la COVID-19 et le SRAS-CoV-2. Trois recherches distinctes ont été effectuées pour déterminer les citations relatives à la réinfection, aux infections ayant percé et à l'immunité. Les termes de recherche utilisés comprenaient : TERMES ASSOCIÉS À LA RÉINFECTION (reinfect* ou re-infect* ou recurren* ou re-positive).
TERMES associés à RÉVOLUTION (efficacy OU effective* OU breakthrough) dans les études qui utilisent la balise Vaccine
TERMES ASSOCIÉS À L'IMMUNITÉ (month* ou longitudinal) dans les études qui utilisent la balise Immunology.
La présente revue contient des recherches publiées jusqu'au 9 avril 2021.
Chaque référence potentiellement pertinente a été examinée pour confirmer qu'elle comportait des données pertinentes, qui ont été extraites dans la revue.

Examen par les pairs

Ce document a fait l'objet d'un examen par les pairs dirigé par un expert en la matière et d'un examen en ce qui concerne la rédaction et la science par le Bureau de la Conseillère scientifique en chef.

Préparée par : Kaitlin Young (CMIAEZ), Chatura Prematunge (LNM), Lisa Waddell (LNM), Kusala Pussegoda (LNM). Groupe des sciences émergentes, ASPC.

Connaissances mobilisées par le Bureau de la Conseillère scientifique en chef phac.ocsoevidence-bcscdonneesprobantes.aspc@canada.ca

Emerging Evidence on COVID-19

Evidence Brief on the Risk of COVID-19 and Non-Professional Sports

Introduction

What evidence is available on the risk of transmission of SARS-CoV-2 from playing non-professional sports and has research been conducted on modified play to mitigate the transmission risk?

Governments and health authorities across the globe implemented lockdown and social distancing practices in an effort to mitigate SARS-CoV-2 spread within populations. These included closing of workplaces, schools, and other public venues, as well as the cancelling of sporting events and games. As public health measures to curb the pandemic are cautiously relaxed, many consider retuning to physical activity and sports. This evidence brief provides an overview of the published literature on SARS-CoV-2 transmission risks associated with playing non-professional sports up to August 18, 2020.

Key Points

- Two published investigations of SARS-CoV-2 outbreaks associated with recreational physical activity appear in the literature (Table 1). These transmission events were linked to indoor fitness facility settings and aerobic activities (one a Zumba class, the other playing squash) and occurred in March 2020.
- An additional 10 transmission events related to sports or exercise were identified in a COVID-19 Superspreading Events database (Swinkles, 2020).
    - Several transmission events have been reported in gyms associated with indoor classes, bonspiels, square dancing, and football. Many of these are considered high contact activities within the reporting news articles.
    - The actual sources of infection and transmission within these clusters arising from team sports events have not been identified. For example, in two curling bonspiels and one road hockey game, social activities also occurred before and/or after the game. Similarly, the source of an outbreak in a soccer team in Japan that is on-going has not been identified.
    - Activities such as running do no appear to be at high risk of transmission, a single cluster between running partners was identified.
- Computer simulations of SARS-CoV-2 aerodynamics concluded that respiratory droplets will ride a runner's slip steam and thus, one should avoid running or walking directly behind another person (Blocken, Malizia, van Druenen, & Marchal, 2020).

- Wong et al., report findings from two independent investigations applicable to participation in sports and SARS-CoV-2 transmission (Wong et al., 2020).
    - Analysis of professional soccer game video footage estimates a semi-professional soccer player spends on average 20% of the game within close contact of another player.
    - Experimental simulations of physical activity among athletes found individuals who wore a face mask recorded higher heartrates and perceived exertion compared to those not wearing a face mask.
- Helpful strategies to reduce the risk of SARS-CoV-2 transmission during sports can be found in World Health Organization (WHO) guidance documents, risk assessment tools, and published commentaries (Table 2).
    - WHO guidance outlines key considerations, risks, and mitigation based on the type of sport (i.e. the level of contact among players), size of the event, indoor/outdoor locations, venue facilities, demographics of competitors and spectators, and risk communication, and provides guidance on managing SARS-CoV-2 cases that may be identified at a sporting event (WHO, 2020a). The document is to be used in conjunction with the Key Planning Recommendations for Mass Gatherings in the Context of the Current COVID-19 Outbreak (WHO, 2020b), and Mass Gathering COVID-19 Risk Assessment Tool – Sports Events (WHO, 2020c).
    - Commentary by Carmody et al. proposes a risk assessment matrix to support decision makers on restarting sports events that is based on WHO guidance and consideration of local community transmission of SARS-CoV-2 (Carmody, Murray, Borodina, Gouttebarge, & Massey, 2020).
    - A technical note by Blocken et al. considers the process of reopening indoor exercise facilities while minimizing SARS-CoV-2 transmission. Based on the application of limited indirect evidence, the authors conclude deep exhalation and inhalation from exercise can increase respiratory aerosol emission and inhalation. As such, they advocate for the use of displacement (vs. mixing) ventilation systems, HEPA filters, and limited occupancy within indoor facilities where physical exercise is frequent (B. Blocken et al., 2020).
    - Guidance for physical educators at Chinese schools reinitiating after the COVID-19 lockdown, proposes various strategies, such as the use of drills and staggered physical activity periods, that can be adopted by non-professional sports teams to mitigate transmission risks.

Overview of the Evidence

Publications that directly report on SARS-CoV-2 and non-professional sports is sparse. As such, we applied the available evidence from indoor sports facility settings (i.e. gyms) and professional sports to deduce transmission risks. Fifteen relevant publications and guidance documents on physical activity and sports informed this review.

Among the included publications are two detailed outbreak investigations and 10 reports of SARS-CoV-2 outbreaks associated with sports or exercise from the COVID-19 Superspreading Events Database (Table 1). Although outbreak investigations can be sensitive to high risk of bias the two published investigations appear to have been carefully conducted, with robust case finding and contact tracing activities that minimize sampling bias. The Superspreading Events Databased includes COVID-19 case clusters (n>5 cases) identified from national COVID-19 dashboards and news articles, none of which provide detailed information about the transmission event. As such the information included in this database is noted to be incomplete and imperfect, and highly sensitive to multiple biases and confounders.

The observational analyses scored video footage of a soccer game and has moderate risk of investigator bias, but the reported physiologic measurements were less sensitive to such bias; it simply compared heart rate and rate of perceived exertion in those who wore masks or not. The computer simulation study to observe air flow dynamics in runners is largely theoretical and would have a low risk of bias.

The literature on strategies to mitigate infection transmission risk in non-professional sports is largely limited to commentaries and expert guidance (Table 3). This literature is grounded in available public health evidence and adopts strategies commonly used to minimize SARS-CoV-2 transmission in public settings.

Overall, there remains considerable knowledge gaps in this literature, as such current guidance largely depends on the general principles of risk assessment and mitigation and COVID-19 public health guidance.

CONTENTS

OUTBREAKS ASSOCIATED WITH PARTICIPATION IN SPORTS/PHYSCIAL ACTIVITY

There are few transmission events associated with sports in the current COVID-19 literature. This may largely be due to the public health measures that stopped most sporting activities since early in the pandemic. With the exception of the Zumba outbreak describe by Jang et al., other outbreaks lack detailed investigation or were also associated with social activities before or after the sports activity that make it difficult to attribute transmission to participation in the sport itself.

The outbreak currently on-going within a Japanese soccer team underscores how SARS-CoV-2 infections can travel within a team, and infection control guidelines and precautions should be part of return to sports plans (Swinkles, 2020).

Table 1. Twelve Outbreaks of COVID-19 Linked to Sports and Exercise

Reference	Publication Title	Key Outcomes
(Jang, Han, & Rhee, 2020)	Cluster of Coronavirus Disease Associated with Fitness Dance Classes, South Korea	Summarizes the investigation of 112 COVID-19 cases associated with Zumba classes at 12 different fitness/sports facility locations in South Korea. The primary attack rate was estimated to be 26.3% (95% CI 20.9%–32.5%) and the secondary attack rate was 4.10% (95% CI 2.95%–5.67%). The initial transmission event is assumed to have occurred among fitness instructors at a workshop, where eight of the twenty seven attendees tested positive for SARS-CoV-2. Over the following weeks the infection transmissions occurred among dance class attendees, household contacts, colleagues and acquaintances of instructors and students. 50.9% (n=63) of cases were the result of transmission from instructors and 52 cases were identified among to dance class attendees. The instructors and students met only during classes, which lasted for 50 minutes 2 times per week, and did not have contact outside of class. No cases were observed among Pilates and yoga class participants, also taught by an infected instructor in the same sports/fitness facility setting. These observations suggest the lower intensity of Pilates and yoga did not lead to the same transmission effects as those that occurred during the dance classes, whether that is due to less respiratory droplets or less air movement was not determined.
(Brlek, Vidovič, Vuzem, Turk, & Simonović, 2020)	Possible Indirect Transmission of COVID-19 at a Squash Court, Slovenia, March 2020: Case Report	A SARS-CoV-2 case cluster (n=6) linked to playing squash at a sports venue in Maribor, Slovenia is described. The index case (person A), assumed to have acquired the infection during travel to Italy developed symptoms (i.e. tiredness and fatigue) during the game of squash. Epidemiological investigations link additional cases (four confirmed and one suspect) to the same squash hall and change rooms. Case B had direct contact with the index case, as they spent time in the change room and played a squash match together. Case C and D do not report direct contact with the index case (or Case B), and are epidemiologically linked through the use of change rooms and playing in the same squash court within 20 minutes of case A and B. The remaining two cases, Case E and Case F, arrived at the sports facility approximately 1.5 hr after index case's departure. This pair of cases spoke with Case C and D outside the squash court, used the same change room and the same squash court.

		None of the cases shared sport equipment or had contact with the facility staff. No additional cases were identified.
(Swinkles, 2020)	SARS-CoV-2 Super Spreading Events Around the World	An additional 10 sports events linked to transmission have been reported in news articles, as listed in the database of COVID-19 Superspreading Events (SSE) from around the world. This information source often lacks details of the outbreak or activities that likely resulted in transmission: - 2 curling bonspiels (multiday tournament and social) in Edmonton, Canada March 14-15. 24/72 attendees developed COVID-19 and in Maryland USA March 27, ~20 cases, - Outdoor ball hockey and they "shared a drink" Racine, QC, Canada, Feb 29. 15/21 were infected with COVID-19 - Running, an infected marathon runner transmitted the virus to his running partner, in Italy, February, - Soccer team, Sagan Tosu J1, outbreak, Japan August. 11 players and coaches infected to date, - Square dancing, Lynnwood, WA, USA, February, there was little testing and no investigation. Only anecdotal information that some who were tested were COVID-19 positive (>15 people), - Two gym and one table tennis school outbreak is recorded in Japan without further details and 1 gym outbreak is recorded in Singapore.

TRANSMISSION RISK WHEN PLAYING SPORTS

Two studies provide evidence applicable to COVID-19 transmission risk during sports. One study was a video analysis of a professional football (soccer) game. It identified there was close player-to-player contact for ~19/90minutes game and approximately 52 episodes of high risk interactions (Wong et al., 2020). The use of face masks during exercise was studied under laboratory conditions and this small study concluded heart rate and perceived exertion were significantly elevated after six minutes of moderate exercise with a mask compared to not wearing a mask (Wong et al., 2020).

The other study examined aerodynamic dispersion of droplets when someone is running to assess the transmission risk if an individual is following an infected runner (Bert Blocken et al., 2020). If the individuals are running or walking fast even at 1.5 meters apart there is some risk of infectious particle exposure if the trailing person is directly behind the leading person (positioned in the slipstream). This exposure can be avoided if two runners are beside each other (1.5 meters apart) or are staggered.

Table 2. COVID-19 Transmission Risk When Playing Sports

Reference	Publication Title	Key Outcomes
(Wong et al., 2020)	Impact of the COVID-19 Pandemic on Sports and Exercise.	Video footage of professional Soccer players in Hong Kong was analysed to track players' time engaged in close body contact and frequency of behaviours that increase infection transmission risk. The analysis finds the average duration of close contact between players to be a mean of 19 minutes (range 5.9-35.5)/ 90 minute game, and each player engaged in an average of 52 episodes of increased infection transmission risk behaviour (touching eyes, mouth or nose), during a 90 minute game. The physiological effects of wearing a mask during play was also examined in laboratory settings. The heart rate and rate of perceived exertion (RPE) of participants wearing a face mask were significantly elevated compared to those without a face mask after 6 minutes of moderate exercise (heart rate of 128 beats per minute and 12.7 RPE when masked, heart rate of 124 beats per minute and a RPE of 10.8 when unmasked). Values were statistically significant, but they may not be biologically significant. The investigation concludes infection transmission risk to be high among players during a game, even without spectators. Donning of face masks during physical exercise increases the physiological burden of the body, with implications for those with multiple underlying comorbidities.
(Bert Blocken et al., 2020)	Towards Aerodynamically Equivalent COVID19 1.5 m Social Distancing for Walking and Running	Computer Fluid Dynamics study informed by previous data on droplet dispersion around a runner takes into account the potential aerodynamic effects introduced by individual movements (e.g., walking fast, running and cycling) on droplet travel distance. The study investigates whether a leading infectious person standing still and moving nearby a second susceptible person at a distance of 1.5 meters or more can pose any infection transmission risk. Although particle exposure is negligible when two people are standing 1.5 meters apart, if the individuals are running or walking fast even at 1.5 meters apart there is some risk of infectious particle exposure. The study results suggest the greatest exposure to the trailing person occurs if they are directly behind the leading person (positioned in the slipstream). Substantial droplet exposure risk reduction can be achieved by 1) avoiding to walk or run in the slipstream of the leading person,

		2) keeping the 1.5 meters distance in staggered or side by side arrangement, or 3) by keeping social distances greater than 1.5 meters when moving fast or running.

STRATEGIES AND GUIDANCE

The literature on strategies to mitigate infection transmission risk in non-professional sports includes two WHO interim guidance documents, two risk assessment tools and several expert commentaries (Table 2). Considerations of local SARS-CoV-2 transmission and case rates, risk assessments to identify potential levels of contact among players, limiting the number of players, prioritizing outdoor play and social distancing, prohibiting the shared use of sports equipment, enhanced cleaning and disinfection practices, and screening of participants to effectively identify and isolate SARS-CoV-2 cases are overarching strategies. The WHO recommends refraining from direct contact sports as they increased risk of direct exposure to infection.

Two tools for assessing COVID-19 risk in sports among spectators and participants were identified. The WHO Mass Gathering COVID-19 Risk Assessment Tool - Sports Events, provides a decision tree, risk evaluation, risk mitigation, decision matrix, and risk communication that mass sports event organizers and host countries can apply to determine infection spread associated with an event. An alternative risk matrix is presented by Carmody et al. This risk assessment tool is based on WHO interim guidance, applies local community transmission rates, and mitigation measures to calculate residual risk associated with various professional sports. The commentary by Timpka note the importance of trust, that if players think that other players are not going to abide by COVID-19 restrictions, they are also unlikely to adhere to them. This points to the importance of an excellent communication plan.

Some indirect evidence predating SARS-CoV-2, as presented in the technical note by Blocken, suggest physical activity can increase the emission and inhalation of respiratory aerosols with the potential to cause infection (B. Blocken et al., 2020). Although much of the evidence on aerosol transmission of SARS-CoV-2 is currently evolving the available evidence and outbreaks do point to elevated risks of infection transmission when performing intense physical activity in crowded indoor settings. This evidence should be weighted appropriately when considering the return to non-professional sports in indoor settings.

Table 3. Strategies to Reduce COVID-19 Transmission During Sports

Reference	Publication Title	Key Statements
(WHO, 2020a)	Considerations for Sports Federations/Sports Event Organizers when Planning Mass Gatherings in the Context of COVID-19	Provides key considerations and risk factor mitigating techniques. Recommendations are based on the consideration of contact and transmission risk within a sport, size of the event (i.e. number of attendees), the location of the event, venue facilities, the demographics of participating players, and the adoption of relevant public health guidance.

		Recommendations include daily health check for competitors, distance (at least 1 meter) separation of competitors, officials, spectators and support staff, thorough disinfection and cleaning, the prohibition of sharing equipment, utilization of outdoor venues where possible, the use of designated and physically separated seating and isolation areas to support potential case management and contact tracing activities and effective risk communication and advising individuals at increased risk of SARS-CoV-2 mortality and morbidity to not attend the sports event. Interim guidance, April 14, 2020
(WHO, 2020c)	WHO Mass Gathering COVID-19 Risk Assessment Tool – Sports Events	A formal risk assessment and risk communication tool to be used in conjunction with the, Considerations for Sports Federations/Sports Event Organizers when Planning Mass Gatherings in the Context of COVID-19, document (above). Updated July 10, 2020
(WHO, 2020b)	Key Planning Recommendations for Mass Gatherings in the Context of COVID-19	Provides guidance to host governments, health authorities and national or international organizers of mass gatherings on containing risks of COVID-19 transmission associated with mass gathering events. Interim guidance, May 29, 2020
(Carmody et al., 2020)	When Can Professional Sport Recommence Safely During the COVID-19 Pandemic? Risk Assessment and Factors to Consider	Presents a risk assessment matrix to support decision makers on restarting professional sports when COVID-19 public health measures begin to relax. In addition to leveraging the considerations outlined by WHO guidance (i.e. WHO Guidelines for Mass Gatherings, Considerations for Sports Events, and WHO Sporting Risk Assessment) the risk assessment takes local community transmission of COVID-19 into account. The basic approach is to assess risk, then consider mitigation measures, and then calculate residual risk. Based on the application of this risk assessment, professional soccer is identified to be of high residual risk, while professional golf is considered low residual risk, if appropriate infection mitigation measures are applied. Based on the application of this risk matrix the authors suggest overall risk of restarting sporting events can be low, if local community transmission is low and adequate risk mitigation

		procedures are in place. Professional soccer is assessed at high residual risk, while professional golf is considered to be of low residual risk.
(Timpka, 2020)	Sports Health During the SARS-Cov-2 Pandemic	Written prior to release of WHO guidelines, this commentary states sports organisations should address the athletes and coaches needs, while complying with social distancing and regional public health guidance on COVID-19, when developing a pandemic response strategy. Highlights the importance of trust: "If sportspeople do not believe that most others are going to play by the temporary restrictive rules, they are unlikely to adhere to them. The authors suggest sports activities should be performed outdoors in small groups and physical contact among players avoided as much as possible. Virtual competitions encouraged among athletes of individual sports.
(B. Blocken et al., 2020)	Can Indoor Sports Centers be Allowed to Re-open During the COVID-19 Pandemic based on a Certificate of Equivalence?	Identifies evidence (predating the emergence of COVID-19) that found deep exhalation (as with physical exercise) produces higher concentrations of aerosols and deep inhalation increases exposure to aerosols. Based on this the authors identify the need for good ventilation (displacement of air from floor to ceiling better than mixing), HEPA filters, applying public health measures to visitors and staff, cleansing surfaces for fomites and ensuring no contact activities. The authors also proposed the idea of a Certificate for indoor sports centers prior to reopening.
(Chen et al., 2020)	Returning Chinese School-Aged Children and Adolescents to Physical Activity in the Wake of COVID-19: Actions and Precautions	Summarizes precautions that can be taken by school administrators, physical educators and parents for physical activity as schools in China begin to come back post COVID-19 lockdown that include: - Encouraging proper social distancing (at least 1 meter), - Staggering time tables to avoid crowding, - Making hand-washing or hand sanitizer stations readily accessible, - Sanitizing all surfaces and equipment regularly, - Restricting physical activities that involve body contact and the sharing of sports equipment and water bottles.
(Peter, 2020)	Return to Play After COVID-19: A Sport Cardiologist's View	The article outlines the need for a cardiac assessment prior to a return to sports for adult COVID-19 cases noting sub-clinical cardiac injuries can occur following SARS-CoV-2 infection.

(Dores & Cardim, 2020)	Returning to Play After Coronavirus Infection: A Perspective From Pediatric Cardiologists	The article outlines the need for a cardiac assessment prior to a return to sports for pediatric COVID-19 cases following SARS-CoV-2 infection, as sub-clinical cardiac injury may be present post infection.

Methods

All of the literature on COVID-19 has been compiled and organized by the Emerging Science Group of the Public Health Agency of Canada since the beginning of the outbreak. This involves a daily scan of the literature for all published and pre-published articles. Searches to retrieve relevant COVID-19 literature are conducted in PubMed, Scopus, BioRxiv, MedRxiv, ArXiv, SSRN, and Research Square. These are cross-referenced with the literature on the World Health Organization COVID literature list, and COVID-19 information centers run by Lancet, BMJ, Elsevier, and Wiley. The daily summary and full scan results are maintained in a RefWorks database and a searchable Excel file. Each article is tagged using various foci to identify the focus of the article (e.g., epidemiology, clinical data, therapeutics etc.). Targeted keyword searching is conducted within these databases to identify relevant citations on COVID-19 and SARS-CoV-2. The search terms included in this review were sports, exercise and physical fitness/activity. Each potentially relevant reference was analyzed to confirm its relevance and data was extracted into the review. This review contains research published up until August 18, 2020.

Emerging Evidence on COVID-19

Rapid Review on the Risk of COVID-19 Outbreaks in the Workplace

Introduction

What is the evidence on COVID-19 clusters associated with the workplace, characteristics of workplace settings and factors that may increase the risk of SARS-CoV-2 transmission, and evidence of successful infection prevention and control measures in the workplace?

Sub-Questions:

Is there evidence that employer provided accommodations result in clusters of COVID-19 cases?
Is there evidence that transportation or commuting to the workplace results in clusters of COVID-19 cases?
Is there evidence of work-related travel resulting in clusters of COVID-19 cases?
Is there evidence that social gatherings of co-workers have resulted in COVID-19 clusters?

Mitigation of the current pandemic has involved social-distancing policies that have had an important impact on workplaces (Corrin, 2020). This includes closing workplaces, encouraging telework, changing business flow to minimize individual employee contacts with others and developing enhanced infection prevention and control procedures to reduce the risk of SARS-CoV-2 transmission. The definition of workplace in this review is meant to be all encompassing, thus workplace ranges from, but may not be limited to office, production, retail, service, and public services. Transmissions within healthcare workplaces were not included in this review. In addition to transmission occurring directly at a workplace, evidence was sought for work-related transmission situations including employer provided accommodation or transportation, commuting, work-related travel, and social gatherings of co-workers. This evidence brief identifies and summarizes literature until August 21, 2020.

Key Points

- Outbreaks have been associated with many types of workplaces and occupations (Table 1).
    - In addition to the known risk to healthcare professionals, the occupations most at risk of SARS-CoV-2 infection include drivers and transport workers, service and sales workers, food industry, personal care occupations, food production workers, preschool occupations, community and social services occupations (e.g. social workers, counselors), construction and related trades occupations, and public safety workers (e.g. correction officers, police, firefighters).

  - The majority of these require workers to have frequent contact with clients, work on customers' premises, or in public spaces. Many of these occupations do not allow employees to work from home.

- Workplace clusters have occurred across a wide range of workplaces and circumstances that resulted in transmission (Table 2).
  - Most of the workplace clusters were traced to an asymptomatic or very mild symptomatic index case.
  - Thirty-seven publications describe one or more transmission events considered to have occurred in a workplace involving workers broadly captured under the categories: office environment, meat processing facilities, other factories, migrant work, fitness centers, ships, other service related occupation, and transportation (Table 2).
  - Eight COVID-19 clusters in workplaces with employer-provided accommodations were identified (Table 3). Shared accommodation results in close contact of workers for long durations of time.
  - There is limited evidence on COVID-19 clusters resulting from transportation or commuting to the workplace (Table 4). Shared transportation to and from the workplace was determined as a risk factor for exposure to SARS-CoV-2 in outbreaks at meat processing facilities.
  - COVID-19 clusters resulting from work-related travel were identified in five publications (Table 5). Risk factors identified related to the proximity and length of time secondary cases spent with the primary cases (e.g. sitting at the same table during a meal or meeting).
  - Three COVID-19 clusters resulting from social gatherings of co-workers outside of the workplace were identified (Table 6). In all three scenarios, the infections acquired during the social gathering of co-workers resulted in additional infections in the workplace.
- Risk factors for SARS-CoV-2 infection identified in the workplace include difficulties adhering to physical distancing, lack of hand hygiene, poor ventilation/air circulation design, and crowded working, transportation and/or accommodation conditions (Tables 1-6).
  - The main facilitators for SARS-CoV-2 transmission in an office setting include close contact, duration of interaction, shared common areas, and work-related travel.
  - Socio-demographic factors and occupation were examined to explore determinants of SARS-CoV-2 exposure (Table 1). Being female, a visible minority, and being in a low-income bracket were associated with employment in occupations associated with significantly higher risk of exposure to COVID-19 which typically do not allow working from home and involves working in close proximity to other people. Conversely, increasing age and higher education was associated with lower risk of exposure occupations.

- The risk factors for infection in meat processing facilities were identified as difficulties with physical distancing, prolonged close contact with coworkers for long periods of time, hand hygiene, shared accommodation, shared transportation to and from work, and frequent community contact with fellow workers. These risk factors were also identified for outbreaks on ships.
- In addition to SARS-CoV-2 activity in the community, the activities a worker engages in outside of the workplace will determine the individual risk that a person brings to the organization.
- Several studies report increased risk of exposure to SARS-CoV-2 proportional to the number of contacts related to the workers job. For example grocery store employees with direct customer exposure were five times more likely to test positive for SARS-CoV-2 (OR 4.7; 95% CI: 1.2-32.0). A similar finding was reported for firefighters and paramedics in a second study.
- Shared accommodation or facilities (e.g. bathroom) and a lack of preventative measures (e.g. face mask) have been suggested to contribute to several outbreaks in shopping malls, retail stores, bars, nightclubs, restaurants, concerts, and overnight camps.
- Outbreaks are more likely to occur in an indoor environment OR 18.7 (95%CI 6.0-57.9).

- Two risk assessments explored the attributes of workplaces and potential for SARS-CoV-2 transmission.
  - In a risk assessment a 1% increase in the density of super spreading businesses (SSB - based on the frequency, duration, and square footage of businesses pre-pandemic) equated to a 5% increase in cases. The most common SSBs were full service restaurants, limited service restaurants, and hotels/motels.
  - The potential health risks of SARS-CoV-2 in sewage to wastewater treatment plant workers (WWTPs) was investigated using a quantitative microbial risk assessment (QMRA). Duties close to sewage tanks were considered high risk of exposure and protection such as face mask, eye protection, and/or face shields were recommended.
- Strategies to reduce the risk of SARS-CoV-2 transmission in the workplace were identified in 21 publications (Table 7).
  - Successful prevention strategies included limiting social contact (restricting activities in the workplace, cohorting or staggering employees, and telework), policies on exclusion of sick workers from the work environment, providing workplace guidelines, and provision of personal protective equipment.
  - Monitoring strategies explored the mode (worker or environmental sampling) and frequency of sampling for effective identification of transmission or circulating SARS-CoV-2 in the workplace and how the level of SARS-CoV-2 in the community impact sampling strategies.

- Lifting public health measures were explored to minimize a resurgence, while allowing the economy to slowly re-open.
- Management of migrant workers, particularly their movement from place to place was discussed in three publications from China and India. Strategies included screening and quarantine protocols to limit the importation of SARS-CoV-2 into an unaffected area.

Overview of the Evidence

Seventy-seven publications pertaining to the risk of COVID-19 outbreaks in the workplace and risk reduction in the workplace were identified and included in this review. Of these, 33 are preprints and have not completed the peer-review process. Observational study designs can be affected by several categories of biases including reporting, information, and selection bias which can bias the data and conclusions of a study (Murad, Asi, Alsawas, & Alahdab, 2016). A formal risk of bias assessment is outside of the scope of this rapid review. Bias ratings are based on the study design where observational studies are considered to have moderate to high risk of bias depending on the design. For observational study designs, this places large prospective cohorts at the top as the design has the potential to have a low risk of bias and high confidence in the results and case reports are considered very weak confidence in the results.

The largest proportion of research underpinning this review consists mainly of small epidemiological outbreak and cluster investigations, which generally have a high risk of bias due to their retrospective nature. Although there is a lot of variability in the completeness of the investigations and reporting, there is good consistency across these investigations which improves our confidence in the evidence.

Several ecological studies were captured; these studies are susceptible to a range of biases and ecological fallacy due to their inability to characterize within-group variability in exposures and confounders. Cross-sectional studies were used to provide a snap shot of individual risk factors and exposure to SARS-CoV-2, but cannot make inferences about causality. Prospective cohort design was used in two studies evaluating mitigation strategies in the workplace. The prospective cohort has a lower risk of bias than other observational study designs, although the two captured in this review had small sample sizes.

Predictive models and risk assessments do not predict a future reality, but rather present a range of plausible outcomes within the scenarios being studied. Their results are useful to compare different options as part of a decision-making process, however the results should be interpreted with caution as the models will vary on their assumptions and input values based on the epidemic period and region specific parameters used.

Due to the nature of the evidence in this review (observational studies and predictive models) and their associated biases, this rapid review provides weak evidence on the workplace conditions that lead to higher risk of SARS-CoV-2 transmission and risk reduction strategies. Based on the study designs of included studies there is low confidence that additional research will not change the conclusions of this review. The COVID-19 literature is evolving rapidly and this review should be periodically updated with new research.

CONTENTS

OCCUPATIONAL RISKS

Occupational risks associated with COVID-19 infection were identified in 20 publications (Table 1). These included two reviews and three risk assessments. The publications in this section focused on both occupations and attributes of those occupations that lead to higher or lower risk of transmission in the workplace.

- Across publications occupations identified as most at risk of SARS-CoV-2 exposure aside from healthcare professionals are listed below (Table 1). Healthcare workers (HCWs) are considered outside the scope of this review, however in papers looking at occupational risk factors, HCWs are frequently included in the analysis and results.
    - Transportation: drivers and transport workers, couriers, bus drivers
    - Retail/Service: service and sales workers, hotel/resort staff
    - Food Industry: restaurant, food processing, abattoirs and meat processing plants
    - Office Administration and Sales: occupations with a high client contact rate.
    - Personal care: working in nursing homes, daycares, preschool, religious professionals, personal care workers, associated health professionals (e.g. dentist), salon staff
    - Community and social services: social workers and counselors, community health workers, daycare providers
    - Construction, extraction and related trades: plumbers, septic tank installers, elevator repair, grounds and facility maintenance
    - Public Safety workers: fire, police, correctional officers
    - Wastewater workers
- Occupations at lower risk of SARS-CoV-2 exposure included occupations that could telework and/or socially distance from others (Table 1). Examples of the latter were farmers, machine operators, business that have minimal interaction with the public or clients (Sierpiński et al., 2020).
- Essential workers (includes many of the categories listed as high risk above) are at an increased risk of COVID-19 infection compared to the general population (Table 1). This risk is increased with increasing interaction with co-workers, clients or the public.
- Socio-demographic factors and their association with high risk of SARS-CoV-2 exposure were examined in several studies (Table 1). Being female, a visible minority, and being in a low-income bracket are more likely to be employed in occupations associated with significantly

higher risk of exposure to COVID-19 as their occupation does not allow them to work at home and involves working closely with people. Conversely, increasing age and higher education was associated with lower risk of exposure occupations.

- Staff in pre-school, primary school, and high school do not have a higher relative prevalence of COVID-19 compared to other professions (Swedish Public Health Agency, 2020).
- One study indicated commuting to work on public transport was positively associated with risk of SARS-CoV-2 infection. A result that was considerably stronger in the U.S. then the UK sample, which the authors hypothesize may be related to the uniformity and stringency of the UK lockdown (Anand et al., 2020).
- Two risk assessments explored the attributes of workplaces and mobility for their potential for SARS-CoV-2 transmission.
    - A risk assessment scored businesses for their potential to be super-spreading business (SSBs) based on the frequency, duration, and square footage of businesses pre-pandemic across 8 U.S. states. A positive association between SSBs (the top 5% of scores were considered SSBs) and the cumulative weekly cases of COVID-19 was reported where a 1% increase in the number of SSBs in an area equated to a 5% increase in cases. The most common SSBs were full service restaurants, limited service restaurants, and hotels/motels (Donoghue et al., 2020).
    - The potential health risks of SARS-CoV-2 in sewage to wastewater treatment plant workers (WWTPs) was investigated using a quantitative microbial risk assessment (QMRA). The estimated viral loads in sewage at the entrance of WWTPs was higher than the safe cut-off values suggested by the World Health Organization (WHO) (Zaneti et al., 2020).

Table 1. Twenty Publications on Occupational Risks for COVID-19 Infection.

Reference	Publication Title	Study Details	Key Outcomes
Observational Studies			
(Lan, Wei, & Hsu, 2020)	Work-related COVID-19 transmission in six Asian countries/areas: a follow-up study	• This retrospective observational study which identified possible work-related cases from government investigation reports in Hong Kong, Japan, Singapore, Taiwan, Thailand and Vietnam that were reported between January 23 – March 14, 2020. • The authors have declared that no competing interests exist.	• After excluding all imported cases, 103 possible work-related transmissions were identified from 690 local transmission events investigated. • Apart from HCW, the occupational groups most commonly implicated were: drivers and transport workers (18%), services and sales workers (18%), cleaning and domestic workers 22 (9%) and public safety workers (7%) and religious professionals (6%).

			• A shift in occupations implicated in clusters during the initial phase of the outbreaks (predominantly services and sales workers, and construction laborers) to later in the outbreak (predominantly HCWs, cleaning and domestic workers and police officers).
(Sierpiński et al., 2020)	Occupational risks for SARS-CoV-2 infection: the Polish experience	• This cross-sectional study analyzed the sources and occupational risk factors for SARS-CoV-2 infections on 2122 patients infected with SARS-CoV-2 who remained in home isolation in Poland. • The survey was conducted on April 17–18, 2020 using a structured interview. • No conflict of interest statement available.	• Among the 2,122 participants with SARS-CoV-2 infection, 75% became infected at work and 70% were currently employed (occupationally active). • Of the occupationally active cases, 48% worked in healthcare, 3% worked in public administration or defense, 3% worked in transportation, and 2% worked in education. • 65% of the occupationally active cases worked in companies with >100 employees.
(Torres Martínez, Diaque García, Rubio Salas, & et al., 2020) *preprint*	IgG seroprevalence against SARS-CoV-2 in a cohort of 449 non-hospitalized, high-risk exposure individuals	• This cross-sectional study estimated the seroprevalence on 449 individuals in Madrid, Spain with one of the inclusion criteria: having symptoms of COVID-19, being in contact with a COVID-19 case, or belonging to essential occupations including healthcare workers, firefighters or public safety personnel such as police. • Study conducted April 15 – June 15, 2020. • Authors declare that 3 of their authors are founders, board members and shareholders of EMPIREO Diagnóstico Molecular.	• The overall seroprevalence was 33.69% (95% CI: 29.27-38.21). • Of the 449 individuals tested, 9.58% were healthcare workers, 4.01% were firefighters, and 6.46% worked preserving public safety. The remainder did not belong to these professions. • With respect to these high risk of exposure occupations, there was no significant difference in seroprevalence. Nor was there a difference in IgG seroprevalence between groups of suspected, exposed or high risk occupation groups suggesting a high level of exposure in high risk of exposure occupations.

(Koh, 2020b)	Occupational risks for COVID-19	• This retrospective observational study describes 17 cases that were likely due to occupational exposure in Singapore during the period of February 4-11, 2020 prior to any public health measures. • No conflict of interest statement available.	• Occupational exposures included retail personnel primarily selling to tourists and company staff attending an international business meeting in Singapore. • Transportation drivers, construction workers, and people that work in tourism were implicated (e.g. casino worker, resort employee).
(Anand et al., 2020) *preprint*	Work-related and personal predictors of COVID-19 transmission	• This cross-sectional study analyzes work and personal predictors of COVID-19 transmission experience in the U.S. and UK. • An online survey of 2,000 participants was conducted the first week of June, 2020. • No conflict of interest statement available.	• The findings for the U.S. were different from the UK, the authors theorize this has to do with the stringency of the public health measures. The results indicate occupation, personal traits, circumstance and behaviours all impact risk of COVID-19 exposure and ability to physically distance. • The UK analysis indicated higher risk of having had a COVID-19 diagnosis for those who had no income, lower-middle income status, shared a kitchen and occupations where interactions with customers and staff were on-going. • The U.S. analysis indicated higher risk of having had COVID-19 was related to low income (OR=5.8-6.3), shared kitchen (3.6), having a university degree (2.7), working in a transport related occupation (8.5), belonging to a trade union (4.8), having had a consultation on COVID-19 transmission at work (2.5) and having to take public transportation to work (3.2).

(Swedish Public Health Agency, 2020) *preprint*	Prevalence of COVID-19 in different occupational groups	• Article in Swedish.
		• This cross-sectional study analyzes prevalence of COVID-19 between different occupational groups using data on occupational classification from Statistics Sweden and cases
			• Compared to other occupational groups, taxi drivers were ~5 times more likely to become infected with SARS-CoV-2 (RR: 4.8, 95% CI: 3.9-6).
			• Other high risk occupational groups include:
			  • Pizza bakers – RR 4.5, 95% CI: 3.2-6.3
			  • Bus and tram drivers – RR 4.3, 95% CI: 3.6-5.1
			  • Translators and linguists – RR 2.9, 95% CI: 1.8 - 4.7

		diagnosed during the period of March 13 – May 27, 2020. • Healthcare professionals were excluded from the analysis. • No conflict of interest statement available.	• Restaurant and kitchen managers – RR 2.5, 95% CI: 1.7-3.8 • Other services workers (e.g. workers who refill vending machines, read electrical and gas metres etc.) – RR 2.3, 95% CI: 2.1-3 • Firefighters – RR 2.2, 95% CI: 1.4-3.5 • Cleaning professionals (e.g. car cleaner, window cleaner) – RR 1.7, 95% CI: 1.1-2.7 • Property manager - RR 1.6, 95% CI: 1.3-2 • Restaurant and kitchen assistants – RR 1.4, 95% CI: 1.2-1.7 • Staff in pre-school, primary school, and high school do not have a higher relative prevalence of COVID-19 compared to other professions. • High school teacher – RR 0.7, 95% CI: 0.5-1 • Primary school teacher – RR 1.1, 95% CI: 0.9-1.3 • Leisure educators – RR 0.8, 95% CI: 0.5-1.3 • Pre-school teacher – RR 0.7, 95% CI: 0.6-0.9 • Other educators with specialist competence – RR 1.0, 95% CI: 0.7-1.5 • Nanny – RR 1.0, 95% CI: 0.8-1.2 • Student assistants – RR 1.1, 95% CI: 0.8-1.4 •
Ecological Studies			
(Lewandowski, 2020) *preprint*	Occupational exposure to contagion and the spread of COVID-19 in Europe	• This ecological study measured country-specific levels of occupational exposure to contagion index derived from a combination of data in O*NET (exposure to disease or infection and physical proximity at work) and the European Working Condition Survey (dealing with people, work in public, work at client's premises and no ability	• In countries with higher proportions of highly exposed workers, these workers tended to be older was the reason for a strong correlation between age 45-64 and the occupational exposure to contagion index. • 20-25% of the cross-country variance in numbers of COVID-19 cases and deaths can be attributed to cross-country differences in levels of occupational exposure to contagion in European countries.

		to work at home). HCWs were excluded from the analysis. • No conflict of interest statement available.	• The occupations most at risk include personal service workers, protective service workers, sales workers, and building and related trade workers. • The occupations with the least amount of risk include farm and agriculture workers, plant and machine operators who do not have close proximity to each other, and businesses that do not interact with the public or clients and have the capacity to allow employees to work from home.
(Baker, Peckham, & Seixas, 2020)	Estimating the burden of United States workers exposed to infection or disease: a key factor in containing risk of COVID-19 infection	• This pre-COVID-19 analysis aimed to quantify the number of workers who are frequently exposed to infection and disease in the workplace in the U.S., and understand which occupational groups they represent by combining data on occupational work activities from the Occupation Information Network (O*Net) (from partial update in 2018) with data from the Bureau of Labor Statistics (BLS) Occupational Employment Statistics database (from May 2018). • No conflict of interest statement available.	• Based on self-reported estimates from O*Net in 2018 and extrapolated based on data from BLS, ~10% (14.4 million) workers in the U.S. are employed in occupations where exposure to disease or infection occurs at least once per week. Additionally, 18.4% (26.7 million) are employed in occupations where exposure to disease or infection occurs at least once per month. • Occupations with a higher risk of exposure include those in the healthcare sectors, protective service occupations (e.g. police officers, correctional officers, firefighters), office and administrative support occupations (e.g. couriers and messengers, patient service representatives), education occupations (e.g. preschool and daycare teachers), community and social services occupations (community health workers, social workers, counselors), and construction and extraction occupations (e.g. plumbers, septic tank installers, elevator repair).
(St-Denis, 2020)	Sociodemographic determinants of occupational risks of exposure to COVID-19 in Canada	• This pre-COVID-19 analysis identified which groups of the labor force are at greater risk of exposure to COVID-19 based on the characteristics of their occupation and assessed them against sociodemographic data.	• The results highlight the association between socioeconomic status and occupational-level work activities that may increase the risk of exposure among women, immigrants, and members of visible minority groups.

		• Data on occupational work activities was derived from the O*Net database (level of physical proximity to other people, and the frequency of exposure to diseases and infections) Canadian 2016 census data. • No conflict of interest statement available.	• ~45% of Canadian workers are in occupations that require working in relatively close physical proximity to others (at arm's length or closer). • Women work in occupations associated with significantly higher average risks of exposure to COVID-19 than men. • Those with a Bachelor's degree or higher tend to face significantly lower occupational risks of exposure. • Workers in low-income occupations are more likely to be employed in occupations with high exposure risk scores. • Occupations held by older workers (65+) were characterized by a lower level of physical proximity to others than their younger colleagues.
(Barbieri, Basso, & Scicchitano, 2020) *preprint*	Italian workers at risk during the COVID-19 epidemic	• This ecological study uses synthetic indexes that proxy for physical proximity in the workplace, exposure to diseases and infections, and the possibility to work remotely at the occupational level were created using data from the Italian Sample Survey on Professions (ICP) and the ISTAT Italian labour force survey (LFS). • Authors state that the views expressed in the paper are those of the authors and do not necessarily reflect those of the Bank of Italy nor those of INAPP.	• Several sectors require physical proximity to operate: the workers employed in Italy in sectors whose physical proximity index is above the national average are more than 6.5 million (most of them in retail trade). • Groups at risk of contagion and complications from COVID-19 (mainly male above the age of 50) work in sectors that have little exposure to other people, are currently under lockdown, or can work remotely. • The sectors with the highest physical index are hotel and restaurants, education, healthcare and trade (mainly retail).
(Lewandowski, Lipowska, & Magda, 2020)	The gender dimension of occupational exposure to contagion in Europe	• This ecological study aimed to measure the occupational exposure to contagious diseases using data from O*Net 2018 and the European Working Conditions Survey ('EWCS' 2015).	• Women are 26% more likely to work in highly exposed occupations that require contact with diseases, frequent contact with clients, and high levels of physical proximity at work. • Women are more likely than men to be unable to work from home due to their occupation. Older women and

		• Authors specifically analyze the gender dimension of occupational exposure. • No conflict of interest statement available.	women with higher education were less likely to be in a high exposure occupation. • Occupations with a high exposure to contagions were personal care workers, HCWs, associate health professionals, personal service workers and protective service workers. With the exception of the last category the former categories are female dominated. Accounting for the economic sector of work sex is not a significant predictor of exposure to contagions. However within some sectors younger women were significantly more likely to be in high exposure occupations.
(Hawkins, 2020)	Differential occupational risk for COVID-19 and other infection exposure according to race and ethnicity	• This ecological study aimed to assess how occupational segregation according to race and ethnicity contributes to the risk of COVID-19. • Data from the Bureau of Labor Statistics Current Population Survey was used for the analysis. • The authors have declared that no competing interests exist.	• This article identifies that some high risk of exposure occupations are disproportionately occupied by certain ethnic groups. • Black workers were more likely to be employed in essential industries and in occupations frequently requiring close proximity to others (HCWs, social assistance, hospital, bus drivers, personal care aids, food industry). • Black and Hispanic workers were more than twice as likely to be employed in the animal slaughtering and processing industry, where there have been many outbreaks of COVID-19.
(Rogers et al., 2020)	Racial disparities in COVID-19 mortality among essential workers in the United States	• This ecological study analyses used data from the American Community Survey and Current Population Survey to examine the correlation between COVID-19 deaths and occupational differences across racial/ethnic groups across U.S. states. • COVID-19 death data up to April 24, 2020 was included.	• Non-Hispanic (NH) Black individuals disproportionately occupy the top 9 essential occupations, which increases their risk of exposure to COVID-19 including the 3 highest disparities: transportation and material moving, healthcare support, food preparation and serving. • Hispanic ethnicity was disproportionately more likely to work in food preparation and serving, building and grounds cleaning and maintenance and production.

		• Authors acknowledge an individual, who provided editorial assistance, and Data for Black Lives (http://d4bl.org/) who indirectly supported the investigation as one of the first organizations to compile a list of states that publicly shared COVID-19 incidence and mortality data. The research was partially supported by a grant from the National Institutes of Health.	• Asian ethnicity was disproportionately more likely to work in personal care and service, HCW and in food preparation and service.
(Peters, 2020)	Community susceptibility and resiliency to COVID-19 across the rural-urban continuum in the United States	• In this ecological study, a COVID-19 susceptibility scale is generated at the country level using data from the U.S. Census Bureau and CDC. Authors then assess the health and socioeconomic resiliency of susceptible places across the rural-urban continuum in the U.S. • The study was supported by USDA Agricultural Experiment Station Multistate Research Project W4001. Authors declare there are no conflicts of interest.	• Based on employment data, meat-processing facilities drive risk of infection in rural areas. • Outbreaks of COVID-19 in rural meat packing communities disproportionally impact Hispanic and other minority workers.
Predictive Models			
(Milligan et al., 2020) *preprint*	Impact of essential workers in the context of social distancing for epidemic control	• This SEIR model examined scenarios with 3 different groups of essential workers to determine their risk of contracting COVID-19: 1) public-facing essential workers (cashiers, retail, transportation), 2) non-public facing essential workers (factory, warehouse,	• Essential workers are at an increased risk of COVID-19 infection compared to the general population. • Non-public-facing essential workers are susceptible to outbreaks in the workplace even after social distancing practices, while public-facing essential workers have a high contact rate with people and thus a higher risk of being exposed to an infected person compared to those who stay at home.

		and agriculture employees), and 3) healthcare workers. • No conflict of interest statement available.	• It was found that different types of essential workers (cashiers, factory employees, and HCWs) had different impacts on transmission scenarios. Similarly, mitigation efforts (e.g. masks, physical distancing etc.) had an impact on transmission.
Reviews			
(Rafeeman esh, Ahmadi, & Memarzad eh, 2020)	A Review of the strategies and studies on the prevention and control of the new Coronavirus in workplaces	• Literature Review published in April, 2020, no search date or methods section. • Authors aimed to review the required strategies to prevent and control COVID-19 in the workplace. • Search strategy and dates of the search not reported. • The authors have declared that no competing interests exist.	• High Risk of exposure occupations: o CDC has identified occupations that are more exposed to COVID-19: 1) health care workers (HCWs), 2) staff of the cemeteries and the funeral houses, 3) officials and staff of airports, airlines, railways, subways and all public transport (buses, taxis, etc.), 4) border guards, 5) solid waste and wastewater workers, and 6) employees who travel regularly, especially to contaminated areas o Dentists and makeup artists are also at high risk due to face-to-face communication with clients and exposure to saliva, blood, and exhaled breath o Flight and ship crews are at risk of contact with infected passengers • Control solutions: o Engineering controls (isolation of symptomatics, ventilation, barriers between people, disposable tools) o Administrative controls (exclusion of sick workers, hygiene training, reduced staff hours, teleworking, cohorting, continuous cleaning and disinfection, restrict staff gatherings) o Personal Protective Equipment (proper face mask, eye protection, gloves and special clothing – as needed) • Key Barriers:

			○ Continuing to work despite being sick (presenteeism) is a major issue. Extended sick leave policies will help
(Peng et al., 2020)	Transmission routes of 2019-nCov and controls in dental practice	• Literature review published in April, 2020, no search date or methods section • Authors aim to provide an overview of the transmission routes and risk of exposure to those working in the dental industry. • The authors have declared that no competing interests exist.	• Routes of transmission ○ There is a high risk of direct transmission in dental practice due to working directly with the mouth and contact with the oral/nasal mucous membranes, as well as exposure to saliva, blood, and other respiratory fluids ○ Airborne transmission to susceptible people in the clinic ○ Indirect transmission via fomites may also be a risk as handling of sharp instruments that are in direct contact with potentially virus laden bodily fluids could occur • Infection control measures ○ Patient evaluation, temperature check ○ Hand hygiene ○ Barrier protection including face mask, eye protection, face shield, work clothes (e.g. lab coat) ○ Antimicrobial mouth rinse before dental procedure, rubber dam may minimize blood and saliva spatter. ○ Use of anti-retraction high-speed hand pieces may reduce the risk of cross contamination. ○ Strict and continuous disinfection
Risk Assessments			
(Donoghue et al., 2020) *preprint*	Super-spreader businesses and risk of COVID-19 transmission	• This risk assessment explores the attributes of super-spreading businesses (SSBs). SSBs were those businesses within the top 5% of the COVID-19 Business Transmission Risk Index which is based on the frequency,	• The negative binomial analysis found a positive association between SSBs and the cumulative weekly cases of COVID-19 where a 1% increase in SSB equated to a 5% increase in cases.

		duration and square footage of businesses pre-pandemic across 8 U.S. states. • No conflict of interest statement available.	• Common business types classified as SSBs included full service restaurants, limited service restaurants and hotels/motels. • SSB attributes in this study were typically businesses where visitors stay for longer and are more densely packed.
(Zaneti et al., 2020) *preprint*	QMRA of SARS-CoV-2 for workers in wastewater treatment plants	• A quantitative microbial risk assessment (QMRA) was used to investigate the potential health risks of SARS-CoV-2 in sewage to wastewater treatment plants (WWTPs) workers. • QMRA was applied for 3 COVID-19 scenarios (moderate, aggressive and extreme) to study the risk during different stages of the pandemic. • No conflict of interest statement available.	• Estimated viral loads in sewage at the entrance of WWTPs ranged from $1.03x10^2$ to $1.31x10^4$ GC/mL (GC= genome copies) assumed to equate to 0.1 to 13.06 PFU/mL (PFU= plaque forming units). • The exposure dosage was assumed to be 1mL that were contaminated at concentrations ranging from 1.03×10^2 GC/mL to 1.31×10^4 GC/mL across moderate to extreme scenarios. • The outcome was estimated risk for which WHO suggests a cut-off of 1 x 10-3 (based in the tolerable risk for rotavirus infection from drinking water): The extreme 3.1 x 10-2. Aggressive 6.5 x 10-3 and moderate 3.0 x 10-4 scenarios report risk 31, 6.5 and 0.3 time higher than the WHO cut-off. • WWTP workers exposed to bioaerosols and airborne particles are an occupational risk, few studies have examined this risk. • Infection control could include use of face mask and face shield when performing manual cleaning work and minimizing the time spent in treatment tank areas • Viral loads in sewage could be used as an early-warning tool for the community and aid in prioritizing enhanced infection control strategies in the sanitation sector.
(Zachreson, Mitchell, Lydeamor	Risk mapping for COVID-19 outbreaks using mobility data	• A heuristic approach to estimating transmission risk based only on qualitative information about epidemiological factors and informed	• Workplace (context) specific factors: o Common location (travel into/out of an outbreak area)

e, & et al., 2020) *preprint*		by near-real-time estimates of mobility patterns. • Gathering related outbreaks are particularly well suited to this method. • They validate their estimates using 3 well documented COVID-19 outbreak scenarios in Australia. These include an outbreak at an abattoir, a hotel, and within a community. • Mobility data was used from Facebook and case data was obtained through the Australian state health authorities. • No conflict of interest statement available.	○ Was in the outbreak location prior to identification of the outbreak ○ Occupation statistics for the area or location being studied (aids in identification of a common type of business in the outbreak area) Note: the above method could be applied to anywhere with habitual travel patterns. • Example: Cedar Meats outbreak April, 2020, Australia ○ A mobility risk map and Spearman's correlation coefficient indicates that with limited case data and mobility data, the location of the outbreak associated with Cedar meats in Brimbank could have been identified very early on. This result was further improved with the addition of occupation data for the area. ○ These results also demonstrate how mobility data can be a useful tool in the estimation of COVID-19 transmission risk diffusion from epidemic locations early in an outbreak. This can be used to intensify public health measures early and aid in containment of an outbreak or community transmission (as demonstrated in the other examples) particularly when we have few cases and are working on preventing a resurgence of cases. • 2 other examples are presented related to a social gathering and community transmission. These are not summarized here.

TRANSMISSION IN THE WORKPLACE

A wide range of workplaces have been implicated in transmission events for SARS-CoV-2 and many transmission events despite being identified have not been fully investigated or published. An ongoing publicly available project to compile COVID-19 super spreading events (>5 cases) was identified and the 1500 events reported in this list underscores the magnitude of under-reporting on transmission events (Swinkels, 2020). Transmission events omitted from the published and preprint literature were recorded on country dashboards and by the media. The latter was excluded from this review as they are often not reported with sufficient details to assess the transmission event or investigation.

- Table 2 lists 37 publications that describe one or more transmission events considered to have occurred in a workplace involving workers broadly captured under the categories: office environment, meat processing facilities, other factories, migrant work, fitness centers, ships, other service related occupation, transportation, and studies with multiple clusters.
- Four outbreaks in office settings (call center, administrative office, meetings) were identified. The main facilitators for SARS-CoV-2 transmission in an office setting include activity (e.g. talking), proximity to an infected person (e.g. sitting next to each other) and duration of being in close proximity to an infected person.
- Outbreaks in meat processing facilities in Germany and across the U.S. are described in five publications. The risk factors for infection were identified as: difficulties with physical distancing, prolonged close contact with coworkers, environmental factors such as cooled re-circulated air, hand hygiene, shared accommodation, shared transportation to and from work, and frequent community contact with fellow workers.
    - The cluster investigation on the largest meat processing complex in Germany reports a high attack rate for workers within eight meters of the index cases fixed work station (Guenther et al., 2020).
- A seroprevalence study of a factory in Croatia reported antibodies were detected in 1.27% of participants (95% CI: 0.77–1.98%, n=1,494). However, no outbreak had been detected in the plant, and none of the workers from employer provided accommodations had antibodies. The employer had adopted enhanced protective measures (e.g. hand disinfection stations, regular workstation cleaning, closed communal coffee and food vending stations, temperature checks, self-isolation for those returning from abroad, and work from home for part of the business and administrative staff) (Jerkovic et al., 2020).
- Migrant workers housed in shared accommodations were associated with a large outbreak in Singapore (Koh, 2020a).

- In three outbreaks that occurred on boats (Diamond Princess cruise ship, a fishing vessel and U.S. naval ship), shared accommodation and working in close proximity were identified as risk factors for acquisition of SARS-CoV-2.
- A large multi-center gym related outbreak was traced to a workshop where several instructors were infected and proceeded to transmit SARS-CoV-2 to other employees and clients at centers where they were employed (Jang, Han, & Rhee, 2020).
- A cross-sectional study estimated the seroprevalence of 104 individuals employed at one grocery retail store in Massachusetts, U.S. Results from multivariate analysis reveal that employees with direct customer exposure were five times more likely to test positive for SARS-CoV-2 (OR 4.7; 95% CI: 1.2-32.0) (Lan, Suharlim, Kales, & Yang, 2020). A similar finding was reported for firefighters and paramedics in a second study (Caban-Martinez et al., 2020).
- Employment in transportation was shown to be a risk factor for taxi drivers and bus drivers in three studies, however a transmission event to a flight attendant has not been documented to date.
- Shared accommodation or facilities (e.g. bathroom) and a lack of preventative measures (e.g. face mask) have been suggested to contribute to several outbreaks in shopping malls, retail stores, bars, nightclubs, restaurants, concerts and overnight camps.
- Outbreaks are more likely to occur in an indoor environment OR 18.7 (95%CI 6.0-57.9) (Nishiura et al., 2020).
- Key protective measures identified include practicing exemplary infection control within closed environments, policies on exclusion of ill workers from the work environment, and adherence to personal infection control precautions when working.

Table 2. Thirty-Seven Publications on Transmission Events in the Workplace.

Reference	Publication Title	Study Details	Key Outcomes
Office Environment			
(Park et al., 2020)	Coronavirus Disease Outbreak in Call Center, South Korea	• Aggregated data from retrospective epidemiological investigations. • Conducted on an outbreak of COVID-19 at a call center in Seoul, South Korea in March, 2020. • No conflict of interest statement available.	• The first confirmed case was identified at the call center on March 8, 2020. The call center is located on floors 7-9 and 11 of a 19 storey building. In general, employees do not travel between floors, and they do not have an in-house restaurant for meals. Both residents and employees in in the building had frequent contact in the lobby or elevators. • The building was closed on March 9, 2020 and testing was offered to all occupants of the building.

			• Of 1,143 individuals tested for COVID-19, 97 (8.5%) were positive. The majority of these (94/97) were working on the 11th floor at the call center with 216 employees. This translates to an attack rate of 43.5% (95% CI: 36.9-50.4%). In addition, most of the cases on the 11th floor were on the same side of the building. • The household secondary attack rate among symptomatic cases was 16.2% (95% CI: 11.6-22%). • Duration of interaction (or contact) was most likely the main facilitator for transmission.
(Zhang et al., 2020)	Epidemiological survey of a new coronavirus pneumonia cluster epidemic in collective units in Tianjin	• Article in Chinese. • Retrospective epidemiological investigation conducted in January, 2020. • The outbreak occurred in the administrative office of a plant that has 906 employees in Tianjin, China. • Authors declare there is no conflict of interest.	• The first case was identified on January 15, 2020 and spread to 10 other coworkers before control measures were put in place on January 24, 2020. • The index case and initial case exposures are linked to work related travel to Wuhan. • Secondary and tertiary cases either travelled with, participated in meetings, or sat close to infected cases.
(Böhmer et al., 2020; Rothe et al., 2020)	Transmission of 2019-nCoV infection from an asymptomatic contact in Germany Investigation of a COVID-19 outbreak in Germany resulting from a single travel-associated	• Retrospective epidemiological investigation • 2 studies describing the transmission of SARS-CoV-2 from a Chinese resident who visited Germany for professional reasons to her colleagues in January, 2020. • Böhmer et al. provide detailed outbreak investigation. • Authors declare there is no conflict of interest.	• Patient 0 was an employee of the Chinese branch of a German company based in Munich. She travelled from Shanghai to Munich by airplane on January 19, 2020 to facilitate workshops and attend meetings in the company building. She returned on an overnight flight back to Shanghai on January 22, 2020 and tested positive for SARS-CoV-2 infection on January 26, 2020. • The German company was informed of the infection on January 27, 2020. Initial testing of high-risk contacts identified patients 1-4 as first generation cases. The company site was closed on February 11, 2020. By February 19, 2020, 16 subsequent cases were identified. • The median serial interval was 4.0 days (IQR 3.0–5.0).

	primary case: a case series		• Ten patients in addition to patient 0 were employees of the company. The other 5 were household contacts. Investigation revealed that transmission from patient 0 to the 10 others likely occurred during the following scenarios: ○ Accompanying patient 0 in multiple activities in Germany traveling back on the same plane ○ In business meetings (60-90 minutes) where colleagues sat close together ○ Colleagues worked simultaneously on the same computer for a short period of time ○ After sitting closely for a 90 minute meeting during the day, 2 colleagues also spent the evening together one of their homes. However, the partner of the colleague hosting who was also there that evening did not test positive ○ 2colleagues met during a canteen visit where they sat back to back. One of them turned to the other to borrow the salt shaker
(Hall, Bui, Rowe, & Do, 2020)	COVID-19 case and contact Investigation in an office workspace	• Retrospective epidemiological investigation conducted in March, 2020, • The outbreak occurred in a combined military and civilian office workspace in the U.S. • No conflict of interest statement available	• The index case unintentionally exposed 150 coworkers to SARS-CoV-2 through participation in carpools, conferences, and small meetings over a period of 3 days. • Of the 150 exposures, 37 were considered medium risk and 113 were considered low risk. 5 people reported COVID-19 like symptoms and 5 developed symptoms during the 14 day quarantine. None of the contacts tested positive for SARS-CoV-2 infection. • None of the coworkers who were exposed during the carpool developed symptoms and despite the close contact were believed to not have been infected. • The rapid identification of those at risk of infection and subsequent implementation of mitigation and control

			efforts was successful in controlling the spread of SARS-CoV-2.
Meat Processing Facilities			
(Dyal et al., 2020)	COVID-19 among workers in meat and poultry processing facilities — 19 states, April 2020	• Aggregated data from retrospective epidemiological investigations. • The report provides aggregate data of positive COVID-19 cases among 115 meat and poultry processing facilities across 19 U.S. states through April 27, 2020. • No potential conflicts of interest were disclosed.	• Among approximately 130,000 workers at these facilities, 4,913 cases (~3.0%) and 20 deaths occurred. • These numbers reflect inadequate infection control practices followed within these facilities including poor social distancing, source control measures (e.g., the use of cloth face covers), and increased workload. • The risk factors for infection were identified as difficulties with physical distancing, hygiene, and crowded living and transportation conditions (many workers live in crowded, multigenerational settings and sometimes share transportation to and from work).
(Waltenburg et al., 2020)	Update: COVID-19 among workers in meat and poultry processing facilities — 19 states, April-May 2020	• Aggregated data from retrospective epidemiological investigations. • This is an update to the report above. • The report provides aggregate data of positive COVID-19 cases among 239 meat and poultry processing facilities across 23 US states through May 31, 2020. • No potential conflicts of interest were disclosed.	• Within 239 facilities, there has been 16,233 COVID-19 cases and 86 COVID-19 related deaths among workers (264 facilities / 17,358 cases/ 91 deaths across both publications (Dyal et al., 2020; Waltenburg et al., 2020)). • Among 14 states reporting the total number of workers in affected meat and poultry processing facilities (112,616), COVID-19 was diagnosed in 9.1% of workers. • Of 9,919 (61%) cases with reported race/ethnicity, 87% were among racial and ethnic minority workers. • Factors that increase risk of exposure for these workers include prolonged close workplace contact with coworkers (within 6 feet for ≥15 minutes) for long time periods (8–12 hour shifts), shared work spaces, shared transportation to and from the workplace, congregate housing, and frequent community contact with fellow workers. • Data from 111 facilities across 14 states reveals the implementation of the following prevention and

			control strategies: screening workers on entry (89/111), required all workers to wear face coverings (86/111), increased the availability of hand hygiene stations (72/111), educated workers on community spread (70/111), installed physical barriers between workers (69/111), offered testing to employees (41/111, and closing temporarily (24/111). • Using data from 7 facilities that implemented facility-wide testing, the crude prevalence of asymptomatic or presymptomatic infections among 5,572 workers who tested positive for SARS-CoV-2 infection was 14.4%.
(Steinberg et al., 2020)	COVID-19 Outbreak among employees at a meat processing facility – South Dakota, March – April 2020	• Retrospective epidemiological investigation • Conducted between March 16 - April 25, 2020 in a meat processing facility (facility A). • No potential conflicts of interest were disclosed.	• A total of 929/3,635 (25.6%) COVID-19 cases were diagnosed among facility A employees, of which 39 were hospitalized and 2 died. • An additional 210/2,408 (8.7%) cases were identified among contacts of employees with diagnosed COVID-19. 9 of these were hospitalized. • The attack rate at facility A during March 16 – April 25, 2020 was 25.6%. Department-groups where employees worked in close proximity (i.e., <6 feet) to one another on the production line had the highest attack rates (department groups: cut – 30.2%, conversion – 30.1%, and harvest – 29.4%). • The attack rate was higher among non-salaried employees (26.8%) compared to salaried employees (14.8%). • The attack rate increased ~fivefold during the first 3 weeks of the outbreak. On average 67 employee COVID-19 cases were occurring per day during the fourth week. Cases among employees declined to ~ 10 per day within 7 days of facility closure.
(Richmond, Sabin,	Interregional SARS-CoV-2	• Molecular epidemiology study.	• Results from phylogenetic analysis reveal a large cluster from a single SARS-CoV-2 strain among

Jobe, Lovrich, & Kenny, 2020) *preprint*	spread from a single introduction outbreak in a meat-packing plant in northeast Iowa	• This study describes a phylogenetic analysis of COVID-19 cases identified in 3 neighbouring states in the U.S. (Wisconsin, Iowa, and Minnesota). • No conflict of interest statement available.	individuals associated with a meatpacking plant in Postville, Iowa. • Since April 6, 2020, 27 viral cases attributed to this sub-strain have been identified. Authors believe this only represents a sample of the cases arising from this outbreak. • Cases traceable to this outbreak have been detected in 7 counties in 3 states, affecting a total of 13 municipalities. This region spans 185 square miles.
(Guenther et al., 2020) *preprint*	Investigation of a superspreading event preceding the largest meat processing plant-related SARS-Coronavirus 2 outbreak in Germany	• Retrospective epidemiological investigation. • Conducted March 16 - April 25, 2020 the largest meat processing complex in Germany. • There are 2 facilities MPP-R and MPP-D. MPP-R performs slaughter and fine processing as well as packaging of beef and pork and MPP-D is a processing plant specialized on sow deboning which is located 30 km away from MPP-R.	• Serial testing by health authorities performed a month after the initial encounter identified more than 1,400 positive cases. • Assessment of viral sequences shows that all cases share a set of 8 single nucleotide mutations representing a novel sub-branch in the SARS-CoV-2 C20 clade. • Initial transmission occurred in a confined area of a beef processing plant in which air is constantly recirculated and cooled to 10°C. The index case transmitted the virus to more than 60% (17/26) of their co-workers in a radius of more than 8 meters during work-shifts on 3 consecutive days. • Statistical relationships were also identified for a single shared apartment, bedroom and carpool groups. Correlations between working within 8 meters of the index case and the infection rate in the apartment, bedroom or carpool groups indicate the majority of transmission events are thought to have occurred within the beef processing facility. • Findings indicate that a physical distance of 2 meters is not sufficient to prevent transmission in this environment of low fresh air exchange and continuous cooling, which may favour transmission. Authors

			recommend additional measures such as improved ventilation and airflow, installation of filtering devices, and the use of high-quality face masks to reduce the infection risk in these environments.
Other Factory			
(Jerkovic et al., 2020) *preprint*	SARS-CoV-2 antibody seroprevalance in industry workers in Split-Dalmatia and Šibenik-Knin County, Croatia	• This cross-sectional study estimated the seroprevalence on 1,494 factory employees living in the Split-Dalmatia and Šibenik-Knin County (Croatia) and was conducted between April 23 - 28, 2020. • The factory (DIV Group) specializes in the production and trade of screws and other mechanical parts and metal with 2 major production sites located in Split (Split-Dalmatia County), and Knin (Šibenik-Knin County) employing around 2,200 people and around 400 people, respectively, • Authors declare there is no conflict of interest.	• As of February 25, 2020 the DIV group implemented protective measures such as providing hand disinfection stations in all rooms, regular workstation cleaning protocols, closing communal coffee and food vending stations, temperature checks, self-isolation for those returning from abroad, and work from home for part of the business and administrative staff. The total number of employees working at the facilities was reduced to around 1,300 and 300, respectively, • In a total sample of tested employees (n=1,494), antibodies were detected in 1.27% of participants (95% CI: 0.77–1.98%). • At the facility in Split, some of the employees live at the facility premises. • In the Split facility 13/1,316 (0.99%, 95% CI: 0.53–1.68%) of participants tested positive, of which 13/1,079 (1.20%, 95% CI: 0.64–2.05%) of those were living outside the facility and 0/237 (0%, 95% CI: 0–1.26%) of those were living inside the facility. In the Knin facility, 6/178 (3.37%, 95% CI: 1.25–7.19%) participants tested positive for antibodies. • All participants living inside facility premises, and with limited mobility during the lockdown measures, tested negative for antibodies. Therefore exposure was likely not related to workplace accommodation in this outbreak.
Migrant Work			

(Koh, 2020a)	Migrant workers and COVID-19	• Retrospective epidemiological investigation. • The daily numbers of COVID-19 cases in Singapore from March to May 2020 were analyzed to determine the cause of a surge in cases in April, 2020. Regulations on migrant worker accommodation were studied. • Authors declare there is no conflict of interest.	• The majority of cases associated with a peak in April, 2020 occurred among low-skilled migrant workers living in foreign worker dormitories. As of May 6, 2020 there were 17,758 confirmed COVID-19 cases among dormitory workers (88% of 20,198 nationally confirmed cases). • One dormitory housing with ~ 13,000 workers had 2,526 confirmed cases, which accounted for 12.5% of all cases in the country. • The national response included extensive testing of workers in dormitories, segregation of healthy and infected workers, and daily observation for fever and symptoms. In addition, 24 dormitories were declared as 'isolation areas' for residents to quarantine for 14 days. Vacant public housing flats, military camps, exhibition centres, and floating hotels have been provided to workers that will allow for appropriate social distancing.
Fitness Center			
(Jang et al., 2020)	Cluster of Coronavirus Disease associated with fitness dance classes, South Korea	• Retrospective epidemiological investigation. • An outbreak associated with a nationwide fitness dance instructor workshop held on February 15, 2020 in Cheonan, South Korea. • No conflict of interest statement available.	• At the nationwide fitness dance instructor workshop, instructors trained intensely for 4 hours. Of the 27 instructors who participated, 8 had positive RT-PCR) results for SARS-CoV-2 infection. All were asymptomatic on the day of the workshop. • On March 9, 2020, 112 COVID-19 cases associated with fitness dance classes in 12 different sports facilities were identified. Of these, 82 (73.2%) were symptomatic and 30 (26.8%) were asymptomatic. • Transmission from instructors to fitness class participants accounted for 57 (50.9%) cases. In-family transmission from instructors and students resulted in 38 cases (33.9%) and 17 cases (15.2%) were from

			transmission during meetings with coworkers or acquaintances. • Prior to closing the sports facilities, 217 students were exposed in 12 facilities, an attack rate of 26.3% (95% CI: 20.9-32.5%). • Close contacts of fitness instructors and students were followed up on (n=830) and 34 cases of COVID-19 were identified, translating to a secondary attack rate of 4.10% (95% CI: 2.95-5.67%). From these 34 cases, 418 close contacts were followed and 10 quaternary cases were identified, resulting in a tertiary attack rate of 2.39% (95% CI: 1.30-4.35%). • Fitness classes from which secondary COVID-19 cases were identified included 5–22 students in a room ≈60 m2 during 50 minutes of intense exercise. Cases among classes with <5 participants were not identified. • One of the infected instructors taught Pilates and yoga for classes of 7–8 students in the same facility at the same time as another infected instructor, but none of her students tested positive for the virus. • Authors speculate that the lower intensity of Pilates and yoga did not cause the same transmission effects as the more intense fitness dance classes.
Ships			
(Kakimoto et al., 2020)	Initial investigation of transmission of COVID-19 among crew members during quarantine of a cruise ship — Yokohama, Japan, February 2020	• Retrospective epidemiological investigation of an outbreak on a the Diamond Princess cruise ship of 3,700 passengers and crew that began on February 3, 2020. • Authors declare there is no conflict of interest.	• The investigation of SARS-CoV-2 spread among staff concluded that infection had apparently spread among persons whose cabins were on the same deck (deck 3) and who worked in the same occupational group (food service), probably through contact or droplet spread, which is consistent with current understanding of COVID-19 transmission. • 8 of 20 positive crew members had cabin mates, of which 5/8 became COVID-19 positive.

(Addetia et al., 2020)	Neutralizing antibodies correlate with protection from SARS-CoV-2 in humans during a fishery vessel outbreak with high attack rate	• Retrospective epidemiological investigation. • This study describes an outbreak of SARS-CoV-2 on a fishing vessel that departed from Seattle, Washington in May, 2020. • Prior to the ship's departure, crew members were screened for active SARS-CoV-2 infection by RT-PCR and for serological evidence of prior or ongoing infection. • Authors declare there is no conflict of interest.	• The attack rate on board was 85.2% (104/122 individuals). • 3 crew members tested positive prior to the boat's departure in initial serological screening and had neutralizing and spike-reactive antibodies in follow-up assays. None of these crew members showed evidence of viral infection or experienced any symptoms during the outbreak. • The crew members with neutralizing antibodies from prior infection were protected against re-infection.

(Payne et al., 2020)	SARS-CoV-2 infections and serologic responses from a sample of U.S. Navy service members - USS Theodore Roosevelt, April 2020	• Retrospective epidemiological investigation of an outbreak that occurred on the USS Theodore Roosevelt in March/April 2020 with approximately 1,000 service men onboard.
		• The investigation occurred April 20-24, 2020 once the ship docked in Guam.
		• A convenience sample of 382 (27% of the total service members on the ship or at the Guam naval base).
		• Questionnaires, serology and RT-PCR tests were done to develop the dataset.
			• Previous or current infection was higher among participants who reported contact with someone known to have COVID-19 (64.2%), compared with those who did not (41.7%) (OR = 2.5; 95% CI = 1.1–5.8).
			• Prevalence was also higher among persons who reported sharing the same sleeping berth with a crewmember who had positive test results (65.6%), compared with those who did not (36.4%) (OR = 3.3; 95% CI = 1.8–6.1).
			• Taking protective measures was associated with lower risk of being COVID-19 positive:
			  • Face covering (55.8% versus 80.8%; OR = 0.3; 95% CI = 0.2–0.5)
			  • Avoiding common areas (53.8% versus 67.5%; OR = 0.6; 95% CI = 0.4–0.9)
			  • Social distancing (54.7% versus 70.0%; OR=0.5; 95% CI = 0.3-0.8)

Other Service-Related Occupations			
(Liu et al., 2020)	Analysis on cluster cases of	• Aggregated data from retrospective epidemiological investigations.	• There were family clusters (28 cases, 71 cases), unit clusters (1 case, 10 cases), transportation clusters (3

	COVID-19 in Tianjin	• This study describes all clusters of confirmed COVID-19 cases Tianjin as of February 22, 2020. • Authors declare there is no conflict of interest.	cases, 8 cases), and a public place cluster (1 case, 26 cases). • A cluster in the passenger section of a train involved 10 cases. After epidemiological investigations, it was finally determined that 2 employees with a history of going out in Wuhan were first-generation cases. • The department store outbreak was an infected sales person that infected 26 customers and coworkers.
(Wu et al., 2020)	Investigation and analysis on characteristics of a cluster of COVID-19 associated with exposure in a department store in Tianjin	• Article in Chinese. • Retrospective epidemiological investigation • An outbreak associated with exposure in a department store. • Authors declare there is no conflict of interest.	• The first confirmed case of department employee was on January 31, 2020. • There are 40 cases associated with a department store, which accounted for 75.47% of the number of confirmed cases (53 cases) in the jurisdiction. • The analysis revealed that 6 cases (15%) involved department store employees, 19 cases (47.5%) were customers of the department store, and 15 cases (37.5%) were close contacts.
(Leffler & Hogan, 2020) *preprint*	Age-dependence of mortality from novel coronavirus disease (COVID-19) in highly exposed populations: New York transit workers and residents and Diamond Princess passengers	• Cross-sectional data from several sources and settings were obtained and mortality data was compared. • Authors used publicly available sources to estimate COVID-19 mortality for each age group on the Diamond Princess cruise ship, in the U.S., in New York City and state, and among New York Metropolitan Transit Authority (MTA) workers. • Authors declare there is no conflict of interest.	• In New York transit workers, mortality was estimated to be 1 in 7,329 for those ages 30-39 years, 1 in 1,075 for ages 40-49 yrs, 1 in 343 for ages 50-59 yrs, and 1 in 178 for ages 60-69 yrs. • Of the MTA workers who had died of COVID-19 (106/109 individuals) as of May 6, 2020 were in the subways and buses division, which has 55,000 employees. • Unclear if transmission of these workers occurred at the workplace or outside of the workplace. • Among New York MTA workers, over 6,000 workers (8%) have either tested positive (over 2,000), or entered quarantine (4,000 workers).

(Lan et al., 2020b) *preprint*	Association between SARS-CoV-2 infection, exposure risk and mental health among a cohort of essential retail workers in the United States	• This cross-sectional study estimated the seroprevalence of 104 individuals employed at one grocery retail store in the greater Boston area in Massachusetts, U.S. and was conducted on 3 consecutive days in early May 2020. • No conflict of interest statement available.	• Of the workers tested, 21/104 (20%) had positive viral assays. Among these, 76% of the cases were asymptomatic. • Results from multivariate analysis reveal that employees with direct customer exposure were 5 times more likely to test positive for SARS-CoV-2 (OR 4.7; 95% CI: 1.2-32.0). Smokers were 90% less likely to test positive (OR 0.1; 95% CI: 0.01-0.8).
(Yang et al., 2020)	The preliminary analysis on the characteristics of the cluster for the COVID-19	• Article in Chinese. • Aggregated data from retrospective epidemiological investigations. • This study describes 377 retrospective cluster investigations of SARS-CoV-2 infections involving 1,719 cases in non-medical institutions from January 1-February 20, 2020. • Authors declare there is no conflict of interest.	• Of the 377 clusters the likely setting where SARS-CoV-2 was acquired was attributed to: family clusters accounted for 79%, meals together accounted for 10%, shopping malls or supermarkets accounted for 6%, workplaces accounted for 3%, and transportation vehicles accounted for 2%. • Details of workplace transmission clusters were not presented.
(Hendrix, Walde, Findley, & Trotman, 2020)	Absence of apparent transmission of SARS-CoV-2 from two Stylists after exposure at a hair salon with a universal face covering policy – Springfield, Missouri, May 2020	• Retrospective epidemiological investigation. • 2 hair stylists as a single salon in Missouri, U.S. interacted with approximately 139 clients while they were infected with SARS-CoV-2 in May, 2020. • Both clients and hair stylists were wearing face masks. • Authors declare there is no conflict of interest.	• Of the 139 clients who were exposed, 67 were tested. • There were no symptomatic secondary cases reported, which was most likely due to the use of face masks. • Attack rate: 0/139

(Cai et al., 2020)	Indirect virus transmission in cluster of COVID-19 cases, Wenzhou, China, 2020	• Retrospective epidemiological investigation of an outbreak associated with a shopping mall in Wenzhou, China. • Authors declare there is no conflict of interest.	• After identifying a positive case, the mall was shut down on January 22, 2020. • During January 19 – February 9, 2020, COVID-19 was diagnosed for 7 mall employees and 10 mall customers. • Close contacts associated with the mall were traced, and COVID-19 was confirmed for 11 persons. • A sole common source was not identified, some common spaces were used by infected employees, thus exposure to aerosolized virus or fomite transmission is suspected, possibly from using a common bathroom or elevator.
(Szablewski et al., 2020)	SARS-CoV-2 transmission and infection among attendees of an overnight camp - Georgia, June 2020	• Retrospective epidemiological investigation of an outbreak associated with an overnight camp in Georgia, U.S.. • There was an overnight camp (camp A) for orientation for 138 trainees and 120 staff members during June 17-20, 2020 • The staff members remained for the first camp session, scheduled during June 21–27, 2020, and were joined by 363 campers and 3 senior staff members on June 21, 2020. • Authors declare there is no conflict of interest.	• 597 Georgia residents attended camp A. Of those tested, 260/344 (76%) tested positive for SARS-CoV-2 infection. • The overall attack rate was 44% (260/597), with staff members having the highest attack rate (56%). Attack rates increased with increasing length of time spent at the camp. • The occupancy of the 31 cabins averaged 15 persons per cabin (range = 1–26). The median cabin attack rate was 50% (range = 22–70%) among 28 cabins that had 1 or more cases. • The camp followed all CDC recommendations except opening windows and doors for increased ventilation in buildings and campers wearing cloth masks (but staff wore masks).
(Caban-Martinez et al., 2020)	Epidemiology of SARS-CoV-2 antibodies among firefighters/paramedics of a US fire department: a	• This cross-sectional study estimated seroprevalence of SARS-CoV-2 antibodies among 203 frontline firefighters/paramedics in Florida, U.S. collected on April 16 - 17, 2020.	• Of the 203 firefighters/paramedics tested, 18 were positive for SARS-CoV-2 (8.9%). • The average number of COVID-19 case contacts (i.e. within 6 feet of an infected person ≥15min) was significantly higher (13.3 ± 4.8 case contacts vs 7.31 ± 4.8 contacts; p=0.022) among firefighters/paramedics

	cross-sectional study	• Research was funded in part by the State of Florida, the Federal Emergency Management Administration, and the National Cancer Institute of the National Institutes of Health. • Authors declare there are no conflicts of interest.	who were SARS-CoV-2 antibody positive compared with firefighters who tested negative for antibodies. • Of the firefighters/paramedics who tested positive, none reported receipt of the annual influenza vaccine compared with firefighters/paramedics who tested negative for SARSCoV-2 antibodies (0.0% vs 21.0%; p=0.027).
(Valencia et al., 2020) *preprint*	Asymptomatic and presymptomatic transmission of 2019 novel Coronavirus (COVID-19) infection: an estimation from a cluster of confirmed cases in Ho Chi Minh City, Vietnam	• Retrospective epidemiological investigation from a bar gathering in Ho Chi Minh City, Vietnam. • Demographic, clinical, and laboratory information of all COVID-19 confirmed cases and contacts from a bar gathering on March 14, 2020 were collected. • Authors declare there are no conflicts of interest.	• Of the 298 individuals who attended a bar gathering in Ho Chi Minh City, 13 tested positive for SARS-CoV-2. • Contact tracing of 4,466 individuals identified another 6 cases. • The cluster specific R0 was 2.64 (90% CI: 1.41−3.68). • 3 contexts of transmission coming from field investigations were identified (bar, household, workplace). The bar constituted 68%, workplace 21%, and household 11% of transmissions. • Within the second generation, 3 (50%) of the transmissions were workplace-related, of which 2 (67%) reported symptoms after being exposed to a case that did not report symptoms.
(Bao et al., 2020)	COVID-19 outbreak following a single patient exposure at an entertainment site: An epidemiological study	• Retrospective epidemiological investigation of an outbreak associated with a bathing pool at an entertainment venue in Wuhan, China. • Demographic, clinical, and laboratory information of all COVID-19 confirmed cases and contacts were collected during January-February, 2020. • Authors declare there are no conflicts of interest.	• A COVID-19-infected worker who returned home from Wuhan caused an outbreak by visiting a bathing pool on January 20 where he infected some workers and customers. • The infection was then spread by a pool worker who continued to work and by a customer who attended a family party and dinner with colleagues. • The pool worker who continued to work until January 26 caused SARS-CoV-2 infections in 12 customers. • The dinner party with colleagues was comprised of 36 colleagues on January 22. The infected individual sang together in a closed space with 7 colleagues. All 7 colleagues were later confirmed to be infected

			• The secondary attack rate for the dinner party with colleagues was 20.5 (95% CI: 7.8–33.2). • Overall, 56 cases were confirmed across 8 districts with a resident population of 3.9 million.
Transportation			
(Yang et al., 2020)	In-flight transmission cluster of COVID-19: a retrospective case series	• Retrospective epidemiological investigation. • This study describes an in-flight transmission cluster of COVID-19. • Data was collected from January 25 – February 28, 2020. • Face mask policies were not implemented at the time of this cluster. • Authors declare there is no conflict of interest.	• After a flight, 12 COVID-19 cases were identified and associated with the flight. • No flight attendants were infected, thus demonstrating a lack of transmission to the flight attendants.
(Pongpirul , Pongpirul, Ratnarathon, & Prasithsirikul, 2020)	Journey of a Thai taxi driver and novel Coronavirus	• This case report describes a SARS-CoV-2 infection in a taxi driver in Thailand in January 2020. • No conflict of interest statement available.	• The taxi driver became ill on January 20, 2020 and went to a primary care clinic on January 23, 2020. • He reported contact with Chinese tourist passengers in his taxi who had had frequent coughing but who wore masks. He had no history of travel to China.
Other or Combined			
(Qian et al., 2020) *preprint*	Indoor transmission of SARS-CoV-2	• Aggregated data from retrospective epidemiological investigations. • This study analyzed all outbreaks involving 3 or more cases reported to the municipal health commissions in China during the January 4 – February 11, 2020. • The work was funded by the Research Grants Council of Hong and the National	• 318 indoor outbreaks are described across 120 cities. • 80% of the outbreaks involved <5 people. • The venues in which the outbreaks occurred were divided into 6 categories: 79.9% occurred within a home, followed by 34.0% transportation, 4.4% at restaurant, 2.2% shopping venue, and 9.7% at other venues. Many outbreaks involved more than one venue category.

		Natural Science Foundation of China. The authors declare no conflict of interest.	
(Nishiura et al., 2020) *preprint*	Closed environments facilitate secondary transmission of Coronavirus Disease 2019 (COVID-19)	• Aggregated data from retrospective epidemiological investigations. • This study reports the epidemiological data on 11 clusters of 110 cases total that occurred in Japan as of February 26, 2020: 4 in Tokyo and 1 each in Aichi, Fukuoka, Hokkaido, Ishikawa, Kanagawa and Wakayama prefectures. • Authors declare there is no conflict of interest.	• All clusters were associated with indoor environments: gym, restaurant, hospital, and a festival where eating occurred in tents. • Details on whether the cases were employees or customers was not provided. • This study estimated the odds of transmitting in a closed environment vs. open air environment OR 18.7 (95%CI 6.0-57.9). • There was no control for confounders or potential interaction with other predictors in this analysis. The definition of "open-air environment" was not described
(Pung et al., 2020)	Investigation of three clusters of COVID-19 in Singapore: implications for surveillance and response measures	• Retrospective epidemiological investigation of 3 clusters linked to a tour group from China, a company conference, and a church in Singapore in February, 2020. • Authors declare there is no conflict of interest.	• The analysis revealed that 36 individuals with confirmed COVID-19 were linked to 3 local clusters, consisting of 11, 20, and 5 individuals. • The first outbreak involved 11 individuals in a tour group from China. 5 shop assistants from one of the tour stops tested positive for SARS-CoV-2. The assistants reported that they would assist customers to apply samples of medicinal oil on their bodies, and handwashing was not usually done between customers. • The second cluster was a conference attended by at least 111 participants from 19 different countries on January 20–22, 2020. Twenty individuals were infected. 5 of the cases were seated at the same table for a 3hr banquet-style dinner and another 4 cases attended a 4hr breakout session.
(Furuse et al., 2020)	Clusters of Coronavirus Disease in	• Retrospective epidemiological investigation of 3,184 cases in Japan reported during January 15 – April 4, 2020.	• During the time period, 61 case-clusters were identified in healthcare facilities (18 clusters), other care facilities such as nursing homes and day care centers (10),

	communities, Japan, January-April 2020	• Authors declare there is no conflict of interest.	restaurants and bars (10), workplaces (8), music events (7), gymnasiums (5); ceremonial functions (2), and a transportation-related incident in an airplane (1). • The largest non–healthcare-related cluster observed involved >30 persons who attended a live music concert, including performers, audience members, and event staff. • Authors identify 22 probable primary-case patients responsible for the clusters. Most were 20-39 years of age and were pre-symptomatic or asymptomatic at the time of transmission.
(Ministry of Health Manatū Hauora, 2020)	COVID-19 – significant clusters	• The government of New Zealand compiled a list of significant clusters in New Zealand as of August 17, 2020. • No epidemiological details on the clusters provided.	• Clusters reported in potential workplace settings include: wedding, hospitality venue, conference, and cruise ship.
(Colorado Department of Public Health & Environment, 2020)	Outbreak data	• List of all confirmed outbreaks of COVID-19 reported in Colorado, U.S. as of August 12, 2020. • No epidemiological details on the clusters provided.	• Clusters reported in multiple potential workplace settings in Colorado, U.S. A few examples include construction sites, prison, distribution center, laundry services, potato warehouse, meat processing plant, dog food plant, grocery store etc.
(Kim, 2020)	Social distancing and public health guidelines at workplaces in Korea: responses to Coronavirus Disease-19	• Aggregated data from retrospective epidemiological investigations. • This study summarizes public and workplace policies in response to COVID-19 in Korea. • An overview of workplace outbreaks during the period of January 20 - May 15, 2020 are described using data from the Korean	Workplace Transmission in Korea: • Of the 11,018 COVID-19 cases identified as of May 15, 2020, 15.7% occurred in workplaces including such as health-care facilities, call centers, sports clubs, coin karaoke, and nightlife destinations • 111 cases were associated with fitness clubs after instructors were infected at a workshop (Jang et al., 2020) • 192 cases were associated with the call center outbreak

		Center for Disease Control and the Central Disaster Management Headquarters.
		• Authors declare there is no conflict of interest.
			• 95 cases are related to public service (e.g. health department, correctional officers, fire department and police). However, the reason for their exposure has not been identified.
			• Guidelines were developed by February 29, 2020 and are considered to have been effective at limiting workplace transmission after implementation. The Ministry of Employment and Labor workplace guidelines for COVID-19 included:
			  • Social distancing, flexible working schedules, early identification of workers with suspected infections, and disinfection of workplaces
			  • To prevent the spread of workplace infection, the guidelines suggest avoiding face-to-face meetings, business trips, and education and training

Review			

(Prakash, 2020) *preprint*	Eat, pray, work: a meta-analysis of COVID-19 transmission risk in common activities of work and leisure	• Literature review.
		• The author aggregated data from case studies (20 situations and 425 cases) captured through a literature review to identify transmission patterns and estimate attack rates.
		• Author aimed to investigate the social activities that may carry a risk of COVID-19 transmission after the government's ease of the lockdown measures.
		• Methods of literature review and analysis are lacking detail and clarity. No conflict of interest statement available.
			• Events such as family dinners and work meetings, have higher attack rates and, hence, carry significant risks.
			• Overall, 20 situations that resulted in 418 infections across 32 instances from 44 individuals are described below.
			• Situation (transmission rate):
			  ○ Meals/ family events (15.7% to 66.7%)
			  ○ Meetings – 1 hour private meeting (72.7%, 95% CI: 43.6-98.0%)
			  ○ Open work space with people movement (78.7%, 95% CI: 70.3-85.3%)
			  ○ Singing – 2 hour practice (86.7%, 95% CI: 76.2-93.2%)
			  ○ Prayer service (resulted in 1-7 secondary infections per infected individual)
			  ○ Travelling in a car (closed environment) and talking had a higher risk (100%, 95% CI: 20-100%)

			○ Public transportation, wearing a mask with no talking (0%) ○ Hotels (53.3%, 95% CI: 30.1-75.2%)/Cruise ships (28.1%, 95% CI: 27.3-29.0%) where space is shared for days ○ Direct interaction with an infected sales agent (25%, 95% CI: 10.2-49.5%) ○ Nightclub, attack rate among direct contacts >50%, among patrons of the nightclub (6.27%, 95% CI: 5.15-7.61%) ○ Restaurant overall attack rate (9.9%, 95% CI: 5.3-17.7% vs those down wind of the infected individual (45%, 95% CI: 25.8-65.8%) • Across all these super spreading events, the number of infections caused depends on the number of close contacts and in most cases the index case had no symptoms of COVID-19 at the time of transmission.

EVIDENCE OF COVID-19 CLUSTERS FROM EMPLOYER PROVIDED ACCOMMODATIONS

In some occupations, accommodations are provided to workers. In general, shared accommodation results in close contact of workers for long durations of time. Eight COVID-19 publications of workplaces with employer provided accommodations were identified (Table 3). In most of these investigations it is not possible to separate the risk of transmission due to congregate living from activities in the workplace, however the high attack rates among workers in congregate living facilities underscores that transmission occurs in situations where people spend time together and the number of contacts (or density of people) is associated with the number of transmission events that may occur in a given setting.

- Two sequential outbreak summaries of 264 outbreaks in meat processing facilities that have occurred up to May 31, 2020 in the U.S. indicated shared accommodation was a risk factor for the transmission of SARS-CoV-2, however specific data on the number of outbreaks where shared accommodation was a potential factor or the resulting investigations is not provided in these summaries (Dyal et al., 2020; Waltenburg et al., 2020).
- An outbreak associated with shared accommodation of employees on a cruise ship (Diamond Princess cruise ship) where roommates and people that worked with infected cases were more likely to become infected. Another outbreak on a fishing vessel had an attack rate of 85% (N=122) on the small vessel during its 16 days at sea despite pre-screening for SARS-CoV-2 infection. The third outbreak was on a U.S. naval ship, the investigation reported a higher odds of testing positive among persons who reported sharing the same sleeping berth with a crewmember who had positive test results OR = 3.3; 95% CI = 1.8–6.1 (Payne et al., 2020).
- During the initial outbreak peak of COVID-19 cases in Singapore, 88% (17,758/20,198 as of May 6, 2020) of the national cases were attributed to low-skilled migrant workers living in foreign worker dormitories.
- In an outbreak at an overnight summer camp with shared accommodations, staff member attack rates increased with increasing length of time spent at the camp. People stayed in cabins; there was an average of 15 people per cabin (range = 1–26). The median cabin attack rate was 50% (range = 22–70%) among 28 cabins that had one or more cases suggesting an association between transmission risk and staying in a cabin.
- A seroprevalence study in a facility that specializes in the production of mechanical parts and has 237/1,316 employees living at the facility determined that none of the 13 workers with IgG antibodies (history of SARS-CoV-2 infection) were among those living at the facility.

Table 3. Eight COVID-19 publications of Workplaces with Employer Provided Accommodations.

Reference	Publication Title	Study Details	Key Outcomes
(Jerkovic et al., 2020) *preprint*	SARS-CoV-2 antibody seroprevalance in industry workers in Split-Dalmatia and Šibenik-Knin County, Croatia	• This cross-sectional study estimated the seroprevalence on 1494 factory employees living in the Split-Dalmatia and Šibenik-Knin County (Croatia) and was conducted between April 23-28, 2020. • The factory (DIV Group) specializes in the production and trade of screws and other mechanical parts and metal with 2 major production sites located in Split (Split-Dalmatia County), and Knin (Šibenik-Knin County) employing around 2200 people and around 400 people, respectively. • Authors declare there is no conflict of interest.	• As of February 25, 2020 the DIV group implemented protective measures such as providing hand disinfection stations in all rooms, regular workstation cleaning protocols, closing communal coffee and food vending stations, temperature checks, self-isolation for those returning from abroad, and work from home for part of the business and administrative staff. The total number of employees working at the facilities was reduced to around 1,300 and 300, respectively. • In a total sample of tested employees (n=1,494), antibodies were detected in 1.27% of participants (95% CI: 0.77–1.98%). • At the facility in Split, some of the employees live at the facility premises. • In the Split facility 13/1316 (0.99%, 95% CI: 0.53–1.68%) of participants tested positive, of which 13/1079 (1.20%, 95% CI: 0.64–2.05%) of those were living outside the facility and 0/237 (0%, 95% CI: 0–1.26%) of those were living inside the facility. In the Knin facility, 6/178 (3.37%, 95% CI: 1.25–7.19%) participants tested positive for antibodies. All participants living inside facility premises, and with limited mobility during the lockdown measures, tested negative for antibodies. Therefore exposure was likely not related to workplace accommodation in this outbreak,
(Koh, 2020a)	Migrant workers and COVID-19	• Retrospective epidemiological investigation.	• The majority of cases associated with a peak in April occurred among low-skilled migrant workers living in foreign worker dormitories. As of May 6, 2020 there

		• The daily numbers of COVID-19 cases in Singapore from March to May 2020 were analyzed to determine the cause of a surge in cases in April. Regulations on migrant worker accommodation were studied. • Authors declare there is no conflict of interest.	were 17,758 confirmed COVID-19 cases among dormitory workers (88% of 20,198 nationally confirmed cases). • One dormitory housing with ~ 13,000 workers had 2,526 confirmed cases, which accounted for 12.5% of all cases in the country. • The national response included extensive testing of workers in dormitories, segregation of healthy and infected workers, and daily observation for fever and symptoms. In addition 24 dormitories were declared as 'isolation areas' for residents to quarantine for 14 days. Vacant public housing flats, military camps, exhibition centres, and floating hotels have been provided to workers that will allow for appropriate social distancing.
(Dyal et al., 2020)	COVID-19 among workers in meat and poultry processing facilities — 19 States, April 2020	• Aggregated data from retrospective epidemiological investigations. • The report provides aggregate data of positive COVID-19 cases among 115 meat and poultry processing facilities across 19 US states through April 27, 2020. • No potential conflicts of interest were disclosed.	• Among approximately 130,000 workers at these facilities, 4,913 cases (~3.0%) and 20 deaths occurred. • These numbers reflect inadequate infection control practices followed within these facilities including poor social distancing, source control measures (e.g. the use of cloth face covers), and increased workload. • The risk factors for infection were identified as difficulties with physical distancing, hygiene, and crowded living and transportation conditions (many workers live in crowded, multigenerational settings and sometimes share transportation to and from work).
(Waltenburg et al., 2020)	Update: COVID-19 Among Workers in Meat and Poultry Processing Facilities — 19	• Aggregated data from retrospective epidemiological investigations. • This is an update to the report above. • The report provides aggregate data of positive COVID-19 cases among 239 meat and poultry processing facilities across 23 US states through May 31, 2020.	• Within 239 facilities there has been 16,233 COVID-19 cases and 86 COVID-19 related deaths among workers (264 facilities/17,358 cases/91 deaths across both publications (Dyal et al., 2020; Waltenburg et al., 2020)). • Among 14 states reporting the total number of workers in affected meat and poultry processing facilities (112,616), COVID-19 was diagnosed in 9.1% of workers.

	States, April-May 2020	• No potential conflicts of interest were disclosed.	• Of 9,919 (61%) cases with reported race/ethnicity, 87% were among racial and ethnic minority workers. • Factors that increase risk of exposure for these workers include prolonged close workplace contact with coworkers (within 6 feet for ≥15 minutes) for long time periods (8–12 hour shifts), shared work spaces, shared transportation to and from the workplace, congregate housing, and frequent community contact with fellow workers. • Data from 111 facilities across 14 states reveals the implementation of the following prevention and control strategies: screening workers on entry (89/111), required all workers to wear face coverings (86/111), increased the availability of hand hygiene stations (72/111), educated workers on community spread (70/111), installed physical barriers between workers (69/111), offered testing to employees (41/111, and closing temporarily (24/111). • Using data from 7 facilities that implemented facility-wide testing, the crude prevalence of asymptomatic or presymptomatic infections among 5,572 workers who tested positive for SARS-CoV-2 infection was 14.4%.
(Kakimoto et al., 2020)	Initial investigation of transmission of COVID-19 among crew members during quarantine of a cruise ship — Yokohama, Japan, February 2020	• Retrospective epidemiological investigation of an outbreak on a the Diamond Princess cruise ship of 3,700 passengers and crew that began on February 3, 2020. • Authors declare there is no conflict of interest.	• The investigation of SARS-CoV-2 spread among staff concluded that infection had apparently spread among persons whose cabins were on the same deck (deck 3) and who worked in the same occupational group (food service), probably through contact or droplet spread, which is consistent with current understanding of COVID-19 transmission. • 8 of 20 positive crew members had cabin mates, of which 5/8 became COVID-19 positive.

(Addetia et al., 2020)	Neutralizing antibodies correlate with protection from SARS-CoV-2 in humans during a fishery vessel outbreak with high attack rate	• Retrospective epidemiological investigation. • This study describes an outbreak of SARS-CoV-2 on a fishing vessel that departed from Seattle, Washington in May, 2020. • Prior to the ship's departure, crew members were screened for active SARS-CoV-2 infection by RT-PCR and for serological evidence of prior infection. • Authors declare there is no conflict of interest.	• The attack rate on board was 85.2% (104/122 individuals) and metagenomics suggests the outbreak originated from a single source. • The outbreak reports minimal information of the likely transmission dynamics on the boat, but the high attack rate indicates most people were likely exposed. • 3 individuals with neutralizing antibodies prior to departure of the ship did not get re-infected based on the evidence presented, indicating they likely had some protection.

(Payne et al., 2020)	SARS-CoV-2 infections and serologic responses from a sample of U.S. Navy service members - USS Theodore Roosevelt, April 2020	• Retrospective epidemiological investigation of an outbreak that occurred on the USS Theodore Roosevelt in March/April 2020 with approximately 1,000 service men onboard.
		• The investigation occurred April 20-24, 2020 once the ship docked in Guam.
		• A convenience sample of 382 (27% of the total service members on the ship or at the Guam naval base).
		• Questionnaires, serology and RT-PCR tests were done to develop the dataset.
		• Authors declare there is no conflict of interest.
			• Previous or current infection was higher among participants who reported contact with someone known to have COVID-19 (64.2%), compared with those who did not (41.7%) (OR = 2.5; 95% CI = 1.1–5.8).
			• Prevalence was also higher among persons who reported sharing the same sleeping berth with a crewmember who had positive test results (65.6%), compared with those who did not (36.4%) (OR = 3.3; 95% CI = 1.8–6.1).
			• Taking protective measures was associated with lower risk of being COVID-19 positive:
			  • Face covering (55.8% versus 80.8%; OR = 0.3; 95% CI = 0.2–0.5)
			  • Avoiding common areas (53.8% versus 67.5%; OR = 0.6; 95% CI = 0.4–0.9)
			  • Social distancing (54.7% versus 70.0%; OR = 0.5; 95% CI = 0.3–0.8)

(Szablewski et al., 2020)	SARS-CoV-2 transmission and infection among attendees of an overnight camp -	• Retrospective epidemiological investigation of an outbreak associated with an overnight camp in Georgia, U.S.	• 597 Georgia residents attended camp A. Of those tested, 260/344 (76%) tested positive for SARS-CoV-2 infection. • The overall attack rate was 44% (260/597), with staff members having the highest attack rate (56%). Attack

	Georgia, June 2020	• There was an overnight camp (camp A) for orientation for 138 trainees and 120 staff members during June 17-20, 2020. • The staff members remained for the first camp session, scheduled during June 21–27, 2020, and were joined by 363 campers and 3 senior staff members on June 21, 2020. • Authors declare there is no conflict of interest.	rates increased with increasing length of time spent at the camp. • The occupancy of the 31 cabins averaged 15 persons per cabin (range = 1–26). The median cabin attack rate was 50% (range = 22–70%) among 28 cabins that had one or more cases. • The camp followed all CDC recommendations except opening windows and doors for increased ventilation in buildings and campers wearing cloth masks. Staff were supposed to use cloth masks and campers were cohorted, however adherence to these prevention measures could not be assessed.

EVIDENCE OF COVID-19 CLUSTERS FROM TRANSPORTATION OR COMMUTING TO THE WORKPLACE

There is limited evidence on COVID-19 clusters resulting from transportation or commuting to the workplace. Five COVID-19 publications were identified on this topic (Table 4).

- Two publications summarize 264 outbreaks associated with meat processing facilities in the U.S. up to May 31, 2020, shared transportation to and from the workplace was determined as a risk factor for exposure to SARS-CoV-2 (Dyal et al., 2020; Waltenburg et al., 2020). However no specific data is presented.
- In an outbreak in a combined military and civilian office workspace, none of the 150 coworkers who were exposed over three days during carpooling developed symptoms or were considered to have been infected (Hall et al., 2020).
- A study of risk factors for becoming infected with COVID-19 in the UK and U.S. reported a significant higher odds of infection among U.S. workers who use public transportation to get to work. This finding was in the same direction but not significant for UK respondents. Reasons for this difference may be related to difference in public health measures implemented in the study areas (Anand et al., 2020).

Table 4. Five COVID-19 Publications Related to Transportation or Commuting to the Workplace.

Reference	Publication Title	Study Details	Key Outcomes
(Hall et al., 2020)	COVID-19 case and contact investigation in an office workspace	• Retrospective epidemiological investigation conducted in March, 2020. • The outbreak occurred in a combined military and civilian office workspace in the U.S. • No conflict of interest statement available.	• The index case unintentionally exposed 150 coworkers to SARS-CoV-2 through participation in carpools, conferences, and small meetings over a period of 3 days. • Of the 150 exposures, 37 were considered medium risk and 113 were considered low risk. 5 people reported COVID-19 like symptoms and 5 developed symptoms during the 14 day quarantine. None of the contacts tested positive for SARS-CoV-2 infection. • None of the coworkers who were exposed during the carpool developed symptoms and were not believed to have been infected. • The rapid identification of those at risk of infection and subsequent implementation of mitigation and control

			efforts was successful in controlling the spread of SARS-CoV-2.
(Dyal et al., 2020)	COVID-19 among workers in meat and poultry processing facilities — 19 states, April 2020	• Aggregated data from retrospective epidemiological investigations. • The report provides aggregate data of positive COVID-19 cases among 115 meat and poultry processing facilities across 19 US states through April 27, 2020. • No potential conflicts of interest were disclosed.	• Among approximately 130,000 workers at these facilities, 4,913 cases (~3.0%) and 20 deaths occurred. • These numbers reflect inadequate infection control practices followed within these facilities including poor social distancing, source control measures (e.g., the use of cloth face covers), and increased workload. • The risk factors for infection were identified as difficulties with physical distancing, hygiene, and crowded living and transportation conditions (many workers live in crowded, multigenerational settings and sometimes share transportation to and from work).
(Waltenburg et al., 2020)	Update: COVID-19 among workers in meat and poultry processing facilities — 19 states, April - May 2020	• Aggregated data from retrospective epidemiological investigations. • This is an update to the report above. • The report provides aggregate data of positive COVID-19 cases among 239 meat and poultry processing facilities across 23 US states through May 31, 2020. • No potential conflicts of interest were disclosed.	• Within 239 facilities, there has been 16,233 COVID-19 cases and 86 COVID-19 related deaths among workers (264 facilities/17,358 cases/91 deaths across both publications (Dyal et al., 2020; Waltenburg et al., 2020)). • Among 14 states reporting the total number of workers in affected meat and poultry processing facilities (112,616), COVID-19 was diagnosed in 9.1% of workers. • Of 9,919 (61%) cases with reported race/ethnicity, 87% were among racial and ethnic minority workers. • Factors that increase risk of exposure for these workers in include prolonged close workplace contact with coworkers (within 6 feet for ≥15 minutes) for long time periods (8–12 hour shifts), shared work spaces, shared transportation to and from the workplace, congregate housing, and frequent community contact with fellow workers. • Data from 111 facilities across 14 states reveals the implementation of the following prevention and control strategies: screening workers on entry (89/111), required all workers to wear face coverings (86/111),

			increased the availability of hand hygiene stations (72/111), educated workers on community spread (70/111), installed physical barriers between workers (69/111), offered testing to employees (41/111, and closing temporarily (24/111.) • Using data from 7 facilities that implemented facility-wide testing, the crude prevalence of asymptomatic or presymptomatic infections among 5,572 workers who tested positive for SARS-CoV-2 infection was 14.4%.
(Anand et al., 2020) *preprint*	Work-related and personal predictors of COVID-19 transmission	• This cross-sectional study analyzes work and personal predictors of COVID-19. transmission experience in the U.S. and UK • An online survey of 2,000 participants was conducted the first week of June, 2020. • No conflict of interest statement available.	• The findings for the U.S. were different from the UK, the authors theorize this has to do with the stringency of the public health measures. The results indicate occupation, personal traits, circumstance and behaviours all impact risk of COVID-19 exposure and ability to physically distance. • The UK analysis indicated higher risk of having had a COVID-19 diagnosis for those who had no income, lower-middle income status, shared a kitchen and occupations where interactions with customers and staff were on-going. • The U.S. analysis indicated higher risk of having had COVID-19 was related to low income (OR=5.8-6.3), shared kitchen (3.6), having a university degree (2.7), working in a transport related occupation (8.5), belonging to a trade union (4.8), having had a consultation on COVID-19 transmission at work (2.5) and having to take public transportation to work (3.2).
(Leffler & Hogan, 2020) *preprint*	Age-dependence of mortality from novel coronavirus disease (COVID-19) in highly exposed	• Cross-sectional data from several sources and settings were obtained and mortality data was compared. • Authors used publicly available sources to estimate COVID-19 mortality for each age group on the Diamond Princess cruise ship,	• In New York transit workers, mortality was estimated to be 1 in 7,329 for those ages 30-39 years, 1 in 1,075 for ages 40-49 yrs, 1 in 343 for ages 50-59 yrs, and 1 in 178 for ages 60-69 yrs. • Of the MTA workers who had died of COVID-19 (106/109 individuals) as of May 6, 2020 were in the

	populations: New York transit workers and residents and Diamond Princess passengers	in the U.S., in New York City and state, and among New York Metropolitan Transit Authority (MTA) workers. • Authors declare there is no conflict of interest.	subways and buses division, which has 55,000 employees. • Unclear if transmission of these workers occurred at the workplace or outside of the workplace. • Among New York MTA workers, over 6,000 workers (8%) have either tested positive (over 2,000), or entered quarantine (4,000 workers).

EVIDENCE OF COVID-19 CLUSTERS FROM WORK RELATED TRAVEL

Five COVID-19 publications resulting from work related travel were identified (Table 5).

- The first published cluster started with an infected employee who travelled between the China and Germany branches of an organization to facilitate workshops and attend meetings.
- In the second outbreak, the index case and initial case exposures were linked to work related travel to Wuhan, China. Employees infected while on business travel sparked an outbreak in their workplace.
- The last two studies report on clusters of cases that have been linked to conferences, which are often social and networking events (Ministry of Health Manatū Hauora, 2020; Pung et al., 2020). Risk factors identified related to the proximity and length of time secondary cases spent with the primary cases (e.g. sitting at the same table during a meal).

Table 5. Five COVID-19 Publications with Documented Clusters Associated with Work Related Travel.

Reference	Publication Title	Study Details	Key Outcomes
(Böhmer et al., 2020; Rothe et al., 2020)	Transmission of 2019-nCoV infection from an asymptomatic contact in Germany Investigation of a COVID-19 outbreak in Germany resulting from a single travel-associated primary case: a case series	• Retrospective epidemiological investigation. • 2 studies describing the transmission of SARS-CoV-2 from a Chinese resident who visited Germany for professional reasons to her colleagues in January, 2020. • Böhmer et al provide detailed outbreak investigation. • Authors declare there is no conflict of interest.	• Patient 0 was an employee of the Chinese branch of a German company based in Munich. She travelled from Shanghai to Munich by airplane on January 19, 2020 to facilitate workshops and attend meetings in the company building. She returned on an overnight flight back to Shanghai on January 22, 2020 and tested positive for SARS-CoV-2 infection on January 26, 2020. • The German company was informed of the infection on January 27, 2020. Initial testing of high-risk contacts identified patients 1-4 as first generation cases. The company site was closed on February 11, 2020. By February 19, 2020, 16 subsequent cases were identified. • The median serial interval was 4.0 days (IQR 3.0–5.0). • 10 patients in addition to patient 0 were employees of the company. The other 5 were household contacts. Investigation revealed that transmission from patient 0

			to the 10 others likely occurred during the following scenarios: ○ Accompanying patient 0 in multiple activities in Germany traveling back on the same plane ○ In business meetings (60-90 minutes) where colleagues sat close together ○ Colleagues worked simultaneously on the same computer for a short period of time ○ After sitting closely for a 90-minute meeting during the day, 2 colleagues also spent the evening together at one of their homes. However, the partner of the colleague hosting who was also there that evening did not test positive ○ 2 colleagues met during a canteen visit where they sat back-to-back. One of them turned to the other to borrow the salt shaker
(Zhang et al., 2020)	Epidemiological survey of a new coronavirus pneumonia cluster epidemic in collective units in Tianjin	• Article in Chinese. • Retrospective epidemiological investigation conducted in January, 2020. • The outbreak occurred in the administrative office of a plant that has 906 employees in Tianjin, China. • Authors declare there is no conflict of interest.	• The first case was identified on January 15 and spread to 10 other coworkers before control measures were put in place on January 24, 2020. • The index case and initial case exposures are linked to work related travel to Wuhan. • Secondary and tertiary cases either travelled with, participated in meetings, or sat close to infected cases.
(Pung et al., 2020)	Investigation of three clusters of COVID-19 in Singapore: implications for surveillance and response measures	• Retrospective epidemiological investigation of 3 clusters linked to a tour group from China, a company conference, and a church in Singapore in February, 2020. • Authors declare there is no conflict of interest.	• The analysis revealed that 36 individuals with confirmed COVID-19 were linked to 3 local clusters, consisting of 11, 20, and 5 individuals. • The first outbreak involved 11 individuals in a tour group from China. 5 shop assistants from one of the tour stops tested positive for SARS-CoV-2. The assistants reported that they would assist customers to apply samples of medicinal oil on their bodies, and

			handwashing was not usually done between customers. • The second cluster was a conference attended by at least 111 participants from 19 different countries on January 20–22, 2020. 20 individuals were infected. 5 of the cases were seated at the same table for a 3hr banquet-style dinner and another 4 cases attended a 4hr breakout session.
(Ministry of Health Manatū Hauora, 2020)	COVID-19 – significant clusters	• The government of New Zealand compiled a list of significant clusters in New Zealand as of August 17, 2020. • No epidemiological details on the clusters provided.	• Clusters reported in potential workplace settings include: wedding, hospitality venue, conference, and cruise ship.

EVIDENCE OF COVID-19 CLUSTERS RESULTING FROM SOCIAL GATHERINGS OF CO-WORKERS

In addition to SARS-CoV-2 activity in the community, the activities a worker engages in outside of the workplace will determine the individual risk that person brings to the organization. Three COVID-19 clusters resulting from social gatherings of co-workers outside of the workplace were identified (Table 6). All three clusters involved a group of colleagues socializing outside of the workplace and becoming infected. One group socialized in a bar, the other a dinner party which involved singing in an enclosed space, and the third group had "a history of going out in Wuhan". In all three scenarios, the infections acquired through social gatherings of co-workers resulted in additional infections in the workplace.

Table 6. Three COVID-19 Clusters Associated with Social Gatherings of Co-Workers Outside of the Workplace.

Reference	Publication Title	Study Details	Key Outcomes
(Valencia et al., 2020) *preprint*	Asymptomatic and presymptomatic transmission of 2019 Novel Coronavirus (COVID-19) infection: an estimation from a cluster of confirmed cases in Ho Chi Minh City, Vietnam	• Retrospective epidemiological investigation from a bar gathering in Ho Chi Minh City, Vietnam. • Demographic, clinical, and laboratory information of all COVID-19 confirmed cases and contacts from a bar gathering on March 14, 2020 were collected. • Authors declare there are no conflicts of interest.	• Of the 298 individuals who attended a bar gathering in Ho Chi Minh City, 13 tested positive for SARS-CoV-2. • Contact tracing of 4,466 individuals identified another 6 cases. • The cluster specific R0 was 2.64 (90% CI: 1.41−3.68). • 3 contexts of transmission coming from field investigations were identified (bar, household, workplace). The bar constituted 68%, workplace 21%, and household 11% of transmissions. o Within the second generation, 3 (50%) of the transmissions were workplace-related, of which 2 (67%) reported symptoms after being exposed to a case that did not report symptoms
(Bao et al., 2020)	COVID-19 outbreak following a single patient exposure at an entertainment	• Retrospective epidemiological investigation of an outbreak associated with a bathing pool at an entertainment venue in Wuhan, China. • Demographic, clinical, and laboratory information of all COVID-19 confirmed	• A COVID-19-infected worker who returned home from Wuhan caused an outbreak by visiting a bathing pool on January 20, 2020 where he infected workers and patrons of the facility.

	site: An epidemiological study	cases and contacts were collected during January-February, 2020. • Authors declare there are no conflicts of interest.	• The infection was then spread by a pool worker who continued to work and by a customer who attended a family party and dinner with colleagues. • The pool worker who continued to work until January 26, 2020 caused SARS-CoV-2 infections in 12 customers. • The dinner party with colleagues was comprised of 36 colleagues on January 22, 2020. The infected individual sang together in a closed space with 7 colleagues. All 7 colleagues were later confirmed to be infected. • The secondary attack rate for the dinner party with colleagues was 20.5% (95% CI: 7.8–33.2).
(Liu et al., 2020)	Analysis on cluster cases of COVID-19 in Tianjin	• Aggregated data from retrospective epidemiological investigations. • This study describes all clusters of confirmed COVID-19 cases Tianjin as of February 22, 2020. • Authors declare there is no conflict of interest.	• There were family clusters (28 cases, 71 cases), unit clusters (1 case, 10 cases), transportation clusters (3 cases, 8 cases), and a public place cluster (1 case, 26 cases). • A cluster in the passenger section of a train involved 10 cases. After epidemiological investigations, it was finally determined that 2 employees with a history of going out in Wuhan were first-generation cases. • The department store outbreak was an infected sales person that infected 26 customers and coworkers.

EVIDENCE OF SUCCESSFUL RISK REDUCTION STRATEGIES IN THE WORKPLACE

There were 21 publications on strategies to reduce the risk of SARS-CoV-2 infection in the workplace (Table 7). The majority (75%) of these are mathematical models. These studies covered prevention strategies, impact and lifting of public health measures, and management of migrant workers (Table 7).

- Encouraging individuals not to go to work while sick was demonstrated to be effective in five studies through the implementation of an income support program (ISP), furlough policies, and quarantine policies (Brotherhood & Jerbashian, 2020; Coleman, 2020).
- Limiting social contact through a gradual reintroduction of people to the workplace, and reduced people and time in the workplace overall are effective in slowing the spread of SARS-CoV-2 infections (Kim, 2020; Koralnik & Tyler, 2020; Shaw et al., 2020; Yilmazkuday, 2020).
- Availability of guidelines and measures for personal protection at work improved individual personal protective behaviour (Wang, Yi Wong, & Ho, 2020).
- The effectiveness of workplace testing strategies was examined as a way to identify an outbreak. The strategies explored included environmental testing and worker testing.
    - Environmental testing was explored in a study of workplaces in the UK and U.S., findings from environmental testing concluded that workplaces with positive environmental samples were 10 times more likely to have an infected person within the workplace (Marshall et al., 2020).
    - Testing workers was explored across different R0: if R0=2.4, workers would have to be tested at least every 3-4 days to prevent an outbreak in the workplace whereas if R0=3.0, testing would have to take place every 2 days (Chin, Lo, Huynh, Murrill, & Basu, 2020). Less frequent strategies such as once per week or upon return to work were less likely to prevent an outbreak.

Table 7. Twenty-one Publications on Strategies for Risk Reduction in the Workplace.

Reference	Publication Title	Study Details	Key Outcomes
Limiting Social Contact			
(Shaw et al., 2020) *preprint*	Lessons from movement ecology for the	• 2 SEIR models are used: 1) a movement model to explore movement between home and work environments, and 2) a	• Results from the models show that limiting social contact, via reduced people or reduced time in the

	return to work: modeling contacts and the spread of COVID-19	network model to explore contact patterns within the work environment. • A network case study of 1 academic laboratory and office building to explore trade-offs between limiting contact, people, or time on campus. • No conflict of interest statement available.	workplace are equivalent strategies to slow pathogen spread • Restricting on-campus activities to labs (rather than labs and offices) could dramatically alter (modularize) contact network structure and thus, potentially reduce relative risk of pathogen spread. • If commuting specifically increase transmission risk (i.e., shared transport), reducing the number of people on campus is the most effective strategy to reduce the infection spread rate.
(Brotherhood & Jerbashian, 2020) *preprint*	Firm behavior during an epidemic	• Authors derive a mathematical model in which a representative firm operates in an epidemic environment. • The strategies of the firm for reducing the infections and the associated costs include allocation of employees into teleworking and leave, and their rotation between on-site work, teleworking, and leave. • No conflict of interest statement available.	• Simulation results show that the fight against infections in firms has significant effect on the dynamics of the epidemic. Strategies that are successful include increasing teleworking, rotating/cohorting on-site employees and having appropriate leave options. • A 3% subsidy to teleworking reduces the peak of the epidemic by ~ 3% and the total number of symptomatic infections and death rate by nearly 9%. • Furlough policies are successful in reducing infections and death. • When compared to a hypothetical situation where a firm does not fight against infections, the choices of employee allocations and rotation in firms reduce the peak number of sick employees with symptoms by 5%. These choices also flatten the infections curve by reducing the total number of symptomatic infections by 18%. As a consequence, the death rate also declines by 18%.
(Gallardo, de Arroyabe, & Arranz, 2020)	Preventing internal COVID-19 outbreaks within businesses and	• This study applies Social Networks Analysis (SNA) techniques to support Occupational Health and Safety Services in the design and selection of	• The methodology was demonstrated in a real case, a Spanish Research Center, providing promising results. • Authors use the concept of a network of employees whose interaction is caused by triggers, which are defined as common circumstances between 2 workers

	institutions: a methodology based on social networks analysis for supporting occupational health and safety services decision making	preventive measures to reduce the risk of outbreaks among employees. • Authors declare there is no conflict of interest.	that may result in contagion, like sharing an office or participating in the same management board. • As an example, a shared location with enlarged space between people, which is disinfected daily, is less likely to be a contagion trigger than the same location crowded and without regular disinfection.
(Kim, 2020)	Social distancing and public health guidelines at workplaces in Korea: responses to Coronavirus Disease-19	• Aggregated data from retrospective epidemiological investigations. • This study summarizes public and workplace policies in response to COVID-19 in Korea. • An overview of workplace outbreaks during the period of January 20 - May 15, 2020 are described using data from the Korean Center for Disease Control and the Central Disaster Management Headquarters. • Authors declare there is no conflict of interest.	• Workplace Transmission in Korea: o Of the 11,018 COVID-19 cases identified as of May 15, 2020, 15.7% occurred in workplaces including such as health-care facilities, call centers, sports clubs, coin karaoke, and nightlife destinations. o 111 cases were associated with fitness clubs after instructors were infected at a workshop (Jang et al., 2020). o 192 cases were associated with the call center outbreak. o 95 cases are related to public service (e.g. health department, correctional officers, fire department and police). However, the reason for their exposure has not been identified. • Guidelines were developed by February 29, 2020 and are considered to have been effective at limiting workplace transmission after implementation. The Ministry of Employment and Labor workplace guidelines for COVID-19 included: o Social distancing, flexible working schedules, early identification of workers with suspected infections, and disinfection of workplaces

			○ To prevent the spread of workplace infection, the guidelines suggest avoiding face-to-face meetings, business trips, and education and training ○ Small group gatherings, club activities, and social dinner at workplaces were restricted and a culture of returning home right after work was encouraged
Stay-at-Home/Quarantine Policies			
(Coleman, 2020) *preprint*	Economically-motivated interactions and disease spread	• This SIR model analyzed the movement of people throughout the day to match data on the distribution of households by size and age of occupants, the distribution of K-12 schools and colleges by size and staff-student ratios, and office and retail establishments by number of employees. The model was then used to assess large-scale compliance to a mitigation policy directing symptomatic individuals to stay at home. • No conflict of interest statement available.	• Simulations reveal that a mitigation policy where all symptomatic people stay home is sufficient to control the spread of COVID-19 without any noticeable employment effects. • This holds true even if up to 60% of the population is asymptomatic.
(Yilmazkuday, 2020) *preprint*	Stay-at-home works to fight against COVID-19: international evidence from Google mobility Data	• Ecological study. • Used daily Google mobility data covering 130 countries over the period between February 15 – May 2, 2020. • No conflict of interest statement available.	• A 1% weekly reduction in visits to workplaces was equated to about (SE 6.3, $p<0.01$) less COVID-19 cases and 2.0 (0.5, $P<0.01$) less COVID-19 deaths.
(Koo et al., 2020)	Interventions to mitigate early spread of SARS-CoV-2 in	• This influenza epidemic simulation model published in March 2020 investigated options for early	• Modelling in the early days of the pandemic suggested that if community transmission occurred, implementing the combined intervention of quarantining infected individuals and their family members, workplace

	Singapore: a modelling study	intervention in Singapore should local containment be unsuccessful. • Authors declare there is no conflict of interest.	distancing, and school closure could substantially reduce the number of SARS-CoV-2 infections.
Testing and Contact Tracing			
(Chin et al., 2020) *preprint*	Frequency of routine testing for SARS-CoV-2 to reduce transmission among workers	• This SEIR model simulated different testing frequencies required in the workforce to control the epidemic after shelter-in-place policies are lifted. • No conflict of interest statement available.	• If R0=2.4, workers would have to be tested at least every 3-4 days to reduce R0<1 and prevent an outbreak in the workforce. • With a higher R0 (3.0), testing would have to take place every 2 days. Since this is likely unrealistic, other strategies such as social distancing and contact tracing should also be implemented.
(Foncea, Mondschein, & Massouh, 2020) *preprint*	Safer working spaces at Coronavirus time: a novel use of antibody tests	• A Monte Carlo simulation model was used to analyze the efficacy of periodic SARS-CoV-2 antibody testing to reduce the risk of infection in the workplace. • No conflict of interest statement available.	• This preliminary simulation model suggests that with antibody testing twice a week and quarantine of workers suspected of SARS-CoV-2 infection can reduce the number of infections while improving the productivity of the company. • Authors are currently in the process of applying some combinations of the protocols within the model with specific firms and government agencies and will report on these when results become available.
(Bicher, Rippinger, Urach, Brunmeir, & Popper, 2020) *preprint*	Agent-based simulation for evaluation of contact-tracing policies against the spread of SARS-CoV-2	• This agent-based model quantifies the impact of contact tracing and relaxing lockdown measures on the spread of the disease. The impact of the location tracing for households and for workplaces were evaluated separately and in combination with different compliance levels. • No conflict of interest statement available.	• In workplace tracing, the workplace of a confirmed COVID-19 patient is temporarily closed and all the coworkers are put into quarantine. • Location tracing based on shared workspaces reduces the peak by 30% regardless of compliance level, whereas household tracing performs better as compliance increases. • These measures combined achieves the greatest peak reduction and performs best with a high level of compliance. Additional individual tracing would result in a higher reduction.

(Meng et al., 2020) *preprint*	The effect of control measures on COVID-19 transmission and work resumption: international evidence	• Ecological study, the causal effect of different control measures on COVID-19 transmission and work resumption in 5 countries: China, Italy, Germany, the United Kingdom, and the United States was quantified. • Authors acknowledge financial supports from the National Natural Science Foundation of China, Chinese National Social Science Foundation, and the Humanities and Social Sciences grant of the Chinese Ministry of Education. No conflict of interest statement available.	• The 2 most effective policy measures for disease containment and work resumption are digital contact tracing and delegating clear responsibility to the local community. • Population-wide contact tracing contributes to the largest effect on work resumption, encouraging work resumption by 2.4%. • A 1% increase in the strictness of social distancing encouraged work resumption by 1.2%. • Public information campaigns, delegating clear responsibility to the local community encouraged work resumption of approximately 0.9-1.0%. • Fiscal measures such as loans, tax deduction, and factor price deduction contribute less to work resumption (~0.5%) while the strictness of health care does not directly help at all.
(Way, Champneys, Dyson, & et al., 2020) *preprint*	The benefits of peer transparency in safe workplace operation post pandemic lockdown	• An SEIR model was used to investigate workplace transmission in 2 different groups of workers under the assumption that all workers are regularly tested for SARS-CoV-2 infection: 1) those that are transparent about testing, share their results with colleagues, and isolate as soon as a contact tests positive for the disease, 2) opaques who do none of these. • The workplaces considered in the analysis were back offices, or factory settings where employees are assumed to have a static network of coworkers they regularly interact with and all other interactions in the workplace would be socially distanced.	• The greater the connectivity among coworkers, the smaller the opacity must be among employees to reduce transmission. • There is a double benefit of transparency among employees in maximising productivity and minimizing overall infection rates.

		• No conflict of interest statement available.	
De-Escalation of Public Health Measures			
(Asfaw, 2020) *preprint*	The effect of Income support program on workplace mobility, COVID-19 case and mortality growth	• Ecological study on the income support program (ISP) aims to mitigate the economic consequences of the pandemic while increasing compliance with social distancing measures. This study analyzes the effect of ISP on workplace mobility, and COVID-19 case and mortality growth using a multi-event analysis model. • No conflict of interest statement available.	• Workplace mobility was reduced in the range of 4.4-8.29% 1 week after the introduction of ISP and 21.8-47.7% after 3 weeks. • 5 weeks after the implementation of the program, there was a 21.8-47.0% and 17.1-29.7% reduction on COVID-19 case growth and mortality growth, respectively. • In the absence of ISP programs, authors estimate the global cumulative number of COVID-19 cases and mortality would have been 3.69 million and 160, 000 more than the observed COVID-19 cases and deaths registered by May 15, 2020.
(Koralnik & Tyler, 2020) *preprint*	COVID-19 epidemic study II: phased emergence from the lockdown in Mumbai	• An agent-based city-scale simulator was used to model scenarios for phased emergence from lockdown in Mumbai, India starting on June 1, 2020. • Study was funded by IISc-Cisco Centre for Networked Intelligence, the Robert Bosch Centre for CyberPhysical Systems, the Indian Institute of Science, and the Department of Atomic Energy, Government of India. • No conflict of interest statement available.	• Results demonstrate that a phased opening of workplaces, at a conservative attendance level of 20-33% is a good way to restart economic activity while ensuring that the city's medical care capacity remains adequate to handle the possible rise in the number of COVID-19 patients in June and July 2020. • This will keep the occupancy on the suburban trains and buses at a similar low level, thereby reducing infection spread in crowded public transit systems. • For trains, occupancy should be restricted to about 20% for the first few weeks with enforcement of strict physical distancing and compulsory wearing of face covers.
(López & Rodó, 2020)	The end of the social confinement in Spain and the COVID-19 re-emergence risk	• This SEIR model simulates various potential post-confinement strategies in Spain such as instant massive liberation of different populations and a gradual incorporation of people to work.	• Results show that the current lockdown should be extended at least 2 more weeks to prevent a new escalation in cases and deaths, as well as a second wave in a few months. • Of all the scenarios modeled, the best case involves gradually incorporating workers back into society in a

		• Authors declare there is no conflict of interest.	daily proportion of at most 30% higher than that of previous confinement. This will lower incidence and casualties. To maximize the positive impacts, this strategy should not begin earlier than the end of April 2020.
Surveillance and Environmental Monitoring			
(Marshall et al., 2020) *preprint*	Sentinel Coronavirus environmental monitoring can contribute to detecting asymptomatic SARS-CoV-2 virus spreaders and can verify effectiveness of workplace COVID-19 Controls	• Prospective cohort study aimed to assess the efficacy of using SARS-CoV-2 environmental monitoring as a tool to detect asymptomatic and pre-symptomatic spreaders and conducting clinical and environmental surface testing at work locations to minimize infections. • 9 workplaces in Europe and the U.S. were enrolled in the study. Of these, 3 locations had 1 or more employees infected with SARS-CoV-2. • Authors state that funding for the study was provided by the participating locations and laboratories.	• The locations which had surfaces contaminated with SARS-CoV-2 were 10 times more likely to have employees who tested positive for SARS-CoV-2 infection compared to locations with no or very few positive surfaces. • The most frequently contaminated surfaces were break room chairs, work benches, and door handles. • Since locations with numerous environmental positive detections had an infected employee during the study period, environmental monitoring appears to be a useful tool to inform clinical testing required to detect asymptomatic or pre-symptomatic virus spreaders and implement appropriate control measures.
(Gunawardana et al., 2020) *preprint*	Longitudinal COVID-19 surveillance and characterization in the workplace with public health and diagnostic endpoints	• Prospective cohort was conducted to assess if longitudinal workplace disease surveillance would be an effective approach to controlling SARS-CoV-2 among employees and their household members. Results between March 23-June 22, 2020 are presented. • From a small Southern California organization (Oak Crest), 54 volunteers (27 employees and 27 household members) provided frequent samples	• Using the current prevalence in Los Angeles County, the model predicted without surveillance intervention, up to 7 employees (95% CI: 3-10) would have become infected with at most 1 of them requiring hospitalizations and 0 deaths. • During the study period, 2 study participants were found to be infected with SARS-CoV-2. 1 was an employee and the other a household member. • The employee was not allowed entry to the safe zone workplace until testing negative 3 consecutive times over a period of 7 days. No other employee or

		for SARS-CoV-2 testing. Only participants with a negative test result were able to enter the "safe zone" workplace facility. • A combination of an SEIR model and Bayesian non-linear mixed model were used to predict the number of employees and household members that would have been infected in the absence of the surveillance program. • Authors state that the study was funded entirely through discretional, institutional funds.	household member contracted SARS-CoV-2 over the course of the study.
Workplace Guidance			
(Wang et al., 2020) *preprint*	Availability of workplace policy for prevention of coronavirus disease 2019 and its relationship with personal protective behaviors: a survey of employees	• Cross-sectional study using an online questionnaire assessing the workplace guidelines and personal protection behavior of employed Hong Kong residents (n=1,048) was conducted between February 17-27, 2020. • Authors declare there is no conflict of interest.	• 1,048 questionnaires across 5 occupational groups were analyzed. • In most occupations, the availability of workplace guidelines and measures for the prevention of COVID-19 improved personal protection behaviors such as hand hygiene, wearing a face mask, and social distancing.
Management of Migrant Workers			
(Maji, Choudhari, & Sushma, 2020)	Implications of repatriating migrant workers on	• This SEIR model investigated the potential surge in confirmed and active cases of COVID-19 infection in India and assessed the train and bus fleet size	• Results indicate that reducing the daily arrival rate of migrant workers for states with a very high out flux of migrants (i.e., Uttar Pradesh and Bihar) can help to lower the surge in confirmed and active cases.

	COVID-19 spread and transportation requirements	required for the repatriating migrant workers. • By forecasting the 2011 census data and comparing it with the information reported in the media, the expected repatriate migrant worker population was obtained. • No conflict of interest statement available.	• However, it could create a disparity in the number of days needed to transport all repatriating migrant workers to the home states. Travel arrangements for about 100,000 migrant workers per day to Uttar Pradesh and Bihar, about 50,000 per day to Rajas-than and Madhya Pradesh, 20,000 per day to Maharashtra and less than 20,000 per day to other states of India was recommended. • Authors suggest that stringent measures in screening migrant workers before boarding and strict isolation policy after arrival might control the surge in confirmed and active cases.
(Han & Jia, 2020) *preprint*	Reductions of migrant population reduces the number of COVID-19 epidemic: a case study in China	• A generalized additive model (GAM) was utilized to model the relationship between migrant population and the number of confirmed cases of COVID-19 in China. • The study was funded by the Peking University Start-up Grant. Authors declare there is no conflict of interest.	• Using China as a case study, results show that the number of confirmed COVID-19 cases were correlated with the population migration and regional population density (R2adj = 0.873, deviance explained = 89.6%). The number of confirmed cases will increase with the growth of these variables. • Therefore, restricting population travel can greatly reduce the number of confirmed cases and limit the expansion of the disease. • Once the migrant population returns to work increasing population movement, the number of confirmed cases will reach 27,483 (95% CI: 16,074-48,097). The average increase in 73 cities was 85.53% (95% CI: 19.53-189.81%).
(Maji, Sushma, & Choudhari, 2020) *preprint*	Implication of inter-state movement of migrant workers during COVID-19 lockdown using	• This SEIR model evaluates the effect of inter-state migrant worker transportation during the lockdown in India. Starting on May 5, 2020 it is assumed that migrant workers will start arriving at their respective destinations and the model analyzed the daily arrival	• The states with significant migrant workers are estimated to have a rise in confirmed and active cases • Authors suggest that stringent measures in screening migrant workers prior to boarding and strict isolation after arrival can help to keep the rise in confirmed and active cases under control.

	modified SEIR model	rate of 20,000-100,000 migrant workers per state. • No conflict of interest statement available.	

Methods

All of the literature on COVID-19 has been compiled and organized by the Emerging Science Group of the Public Health Agency of Canada since the beginning of the outbreak. This involves a daily scan of the literature for all published and pre-published articles. Searches to retrieve relevant COVID-19 literature are conducted in PubMed, Scopus, BioRxiv, MedRxiv, ArXiv, SSRN, and Research Square. These are cross-referenced with the literature on the World Health Organization COVID literature list, and COVID-19 information centers run by Lancet, BMJ, Elsevier, and Wiley. The daily summary and full scan results are maintained in a RefWorks database and a searchable Excel file. Each article is tagged using various foci to identify the focus of the article (e.g. epidemiology, clinical data, therapeutics etc.). Targeted keyword searching is conducted within these databases to identify relevant citations on COVID-19 and SARS-CoV-2. The search terms included in this review were workplace, work*, occupation, colleague, manufacturing, factory, and employee, gathering, and super spread*. There were no language restrictions. Each potentially relevant reference was analyzed to confirm its relevance and data was extracted into the review. Additional articles and grey literature reports were added to the database as they were identified. Grey literature was limited to government and public health institution reports. Media sources and news briefs were not considered reliable or detailed enough for inclusion. A snowball search was conducted which included cross-checking the reference lists of published reviews and relevant articles for relevant research omitted by the search. As this is a rapid review, double screening or extraction from articles and a formal quality (risk of bias) assessment was not conducted on the included studies. This review contains research published up until August 21, 2020.

Nouveaux éléments de preuve sur la COVID-19

Revue rapide du risque d'éclosion de la COVID-19 sur le lieu de travail

Introduction

Quels sont les éléments de preuve de l'existence de grappes de COVID-19 associées au lieu de travail, les caractéristiques des lieux de travail et les facteurs susceptibles d'augmenter le risque de transmission du SRAS-CoV-2, et les preuves de la réussite des mesures de prévention et de contrôle de l'infection sur le lieu de travail?

Sous-questions :

Existe-t-il des éléments de preuve que les aménagements fournis par l'employeur entraînent des grappes de cas de COVID-19?
Existe-t-il des éléments de preuve que le transport ou les déplacements vers le lieu de travail entraînent des grappes de cas de COVID-19?
Existe-t-il des éléments de preuve de voyages liés au travail entraînant des grappes de cas de COVID-19?
Existe-t-il des éléments de preuve que les rassemblements sociaux de collègues ont donné lieu à des grappes de COVID-19?

L'atténuation de la pandémie actuelle a impliqué des politiques de distanciation sociale qui ont eu un impact important sur les lieux de travail (Corrin, 2020). Il s'agit notamment de fermer des lieux de travail, d'encourager le télétravail, de modifier le flux des activités pour réduire au minimum les contacts entre les employés avec d'autres personnes et de mettre au point des procédures améliorées de prévention et de contrôle des infections pour réduire le risque de transmission du SRAS-CoV-2. La définition du lieu de travail dans cette étude est censée être globale, c'est-à-dire que le lieu de travail comprend, sans s'y limiter, les bureaux, la zone de production, les commerces de détail, les services et les services publics. Les transmissions sur les lieux de travail des soins de santé n'ont pas été incluses dans cette revue. En plus de la transmission se produisant directement sur les lieux de travail, des éléments de preuve ont été recherchés pour les situations de transmission liées au travail, notamment le logement ou le transport fourni par l'employeur, les trajets domicile-travail, les déplacements liés au travail et les réunions sociales de collègues. Cette synthèse en bref identifie et résume la littérature jusqu'au 21 août 2020.

Points clés

- Les éclosions ont été associées à de nombreux types de lieux de travail et de professions (tableau 1).
    - Outre le risque connu des professionnels de la santé, les professions les plus exposées au risque d'infection par le SRAS-CoV-2 sont les suivantes : les conducteurs et les travailleurs du transport, les travailleurs des services et de la vente, l'industrie alimentaire, les professions des

soins personnels, les travailleurs de la production alimentaire, les professions du secteur préscolaire, les professions des services communautaires et sociaux (par exemple, les travailleurs sociaux, les conseillers), les professions du bâtiment et des métiers connexes, et les travailleurs de la sécurité publique (par exemple, les agents correctionnels, la police, les pompiers).

- La majorité d'entre eux exige que les travailleurs aient des contacts fréquents avec les clients, travaillent dans les locaux des clients ou dans les espaces publics. Nombre de ces professions ne permettent pas aux employés de travailler à domicile.

- Des grappes sur le lieu de travail se sont produites dans un large éventail de lieux et de circonstances qui ont entraîné une transmission (tableau 2).
    - La plupart des grappes sur le lieu de travail ont été attribuées à un cas index asymptomatique ou très légèrement symptomatique.
    - Trente-sept publications décrivent un ou plusieurs événements de transmission considérés comme s'étant produits sur un lieu de travail impliquant des travailleurs, classés en gros dans les catégories suivantes : environnement de bureau, usines de transformation de la viande, autres usines, travail des migrants, centres de remise en forme, navires, autres professions liées aux services et transports (tableau 2).
    - Huit grappes de COVID-19 ont été identifiées dans les lieux de travail où l'employeur fournit le logement (tableau 3). Le partage du logement entraîne un contact étroit entre les travailleurs pendant de longues périodes.
    - Il existe peu de données sur les grappes de COVID-19 résultant du transport ou du déplacement vers le lieu de travail (tableau 4). Le transport partagé vers et depuis le lieu de travail a été déterminé comme un facteur de risque d'exposition au SRAS-CoV-2 dans les éclosions des usines de transformation de la viande.
    - Les grappes de COVID-19 résultant de déplacements liés au travail ont été identifiées dans cinq publications (tableau 5). Les facteurs de risque identifiés sont liés à la proximité et à la durée de la période passée avec les cas primaires (par exemple, s'asseoir à la même table pendant un repas ou une réunion).
    - Trois grappes de COVID-19 résultant de rassemblements sociaux de collègues en dehors du lieu de travail ont été identifiées (tableau 6). Dans les trois scénarios, les infections transmises lors des réunions sociales des collègues ont entraîné des infections supplémentaires sur le lieu de travail.
- Les facteurs de risque d'infection par le SRAS-CoV-2 identifiés sur le lieu de travail comprennent les difficultés à respecter les distances physiques, le manque d'hygiène des mains, une mauvaise conception de la ventilation/circulation de l'air et des conditions de travail, de transport et/ou de logement surpeuplées (tableaux 1-6).

- Les principaux facteurs facilitant la transmission du SRAS-CoV-2 dans un bureau sont les contacts étroits, la durée des interactions, les zones communes partagées et les déplacements professionnels.
- Les facteurs sociodémographiques et la profession ont été examinés pour étudier les facteurs communs de l'exposition au SRAS-CoV-2 (tableau 1). Le fait d'être une femme, d'appartenir à une minorité visible et d'avoir un faible revenu était lié aux professions associées à un risque considérablement plus élevé d'exposition à la COVID-19 qui ne permettent généralement pas de travailler à domicile et qui impliquent de travailler à proximité d'autres personnes. À l'inverse, l'augmentation de l'âge et une éducation supérieure étaient associées à un risque plus faible d'exposition liée à la profession.
- Les facteurs de risque d'infection dans les usines de transformation de la viande ont été identifiés comme étant les difficultés de distanciation physique, le contact étroit prolongé avec les collègues de travail pendant de longues périodes, l'hygiène des mains, le partage du logement, le transport partagé pour se rendre au travail et en revenir, et les contacts fréquents communautaires avec les collègues de travail. Ces facteurs de risque ont également été identifiés dans les éclosions sur les navires.
- En plus de l'activité liée au SRAS-CoV-2 dans la communauté, les activités qu'un travailleur exerce en dehors du lieu de travail détermineront le risque individuel qu'une personne apporte à son entreprise.
- Plusieurs études font état d'un risque accru d'exposition au SRAS-CoV-2 proportionnel au nombre de contacts liés à l'emploi des travailleurs. Par exemple, les employés d'une épicerie directement exposés aux clients avaient cinq fois plus de chances d'obtenir un résultat positif au test de dépistage du SRAS-CoV-2 (RC de 4,7; IC de 95 % : de 1,2 à 32,0). Une deuxième étude a fait état d'un résultat similaire pour les pompiers et les ambulanciers.
- Le partage des logements ou des installations (par exemple, les toilettes) et l'absence de mesures préventives (par exemple, un masque facial) ont été suggérés comme contribuant à plusieurs éclosions dans les centres commerciaux, les magasins de détail, les bars, les boîtes de nuit, les restaurants, les concerts et les camps de nuit.
- Les éclosions sont plus susceptibles de se produire dans un environnement intérieur (RC de 18,7; IC de 95 % : de 6,0 à 57,9).

- Deux évaluations des risques ont examiné les caractéristiques des lieux de travail et le potentiel de transmission du SRAS-CoV-2.
  - Dans une évaluation des risques, une augmentation de 1 % de la densité des entreprises à super-propagation (ESP – basée sur la fréquence, la durée et la superficie des entreprises avant la pandémie) équivaut à une augmentation de 5 % des cas. Les ESP les plus courantes sont les restaurants à service complet, les restaurants à service limité et les hôtels/motels.

  - Les risques sanitaires potentiels du SRAS-CoV-2 dans les eaux usées pour les travailleurs des stations d'épuration ont été étudiés à l'aide d'une évaluation quantitative des risques microbiens (EQRM). Les tâches à proximité des réservoirs d'eaux usées ont été considérées comme présentant un risque élevé d'exposition et une protection telle qu'un masque facial, une protection oculaire et/ou des écrans faciaux ont été recommandés.

- Des stratégies visant à réduire le risque de transmission du SRAS-CoV-2 sur le lieu de travail ont été identifiées dans 21 publications (tableau 7).
  - Parmi les stratégies de prévention réussies, citons la limitation des contacts sociaux (limitation des activités sur le lieu de travail, cohorte ou échelonnement des employés et télétravail), les politiques d'exclusion des travailleurs malades du milieu de travail, la fourniture de directives sur le lieu de travail et la mise à disposition d'équipements de protection individuelle.
  - Les stratégies de surveillance ont exploré le mode (échantillonnage des travailleurs ou de l'environnement) et la fréquence d'échantillonnage permettant une identification efficace de la transmission ou de la circulation du SRAS-CoV-2 sur le lieu de travail et la manière dont le niveau de SRAS-CoV-2 dans la communauté a un impact sur les stratégies d'échantillonnage.
  - La levée des mesures de santé publique a été envisagée pour minimiser une résurgence, tout en permettant une lente réouverture de l'économie.
  - La gestion des travailleurs migrants, en particulier leur déplacement d'un endroit à l'autre, a été abordée dans trois publications de Chine et d'Inde. Les stratégies comprenaient des protocoles de dépistage et de quarantaine pour limiter l'importation du SRAS-CoV-2 dans une zone non touchée.

Vue d'ensemble des éléments de preuves

Soixante-dix-sept publications relatives au risque d'éclosions de la COVID-19 sur le lieu de travail et à la réduction des risques sur le lieu de travail ont été identifiées et incluses dans cette revue. Parmi celles-ci, 33 sont des prépublications et n'ont pas encore été soumis à l'examen des pairs. Les plans d'étude par observation peuvent être affectés par plusieurs catégories de biais, notamment les biais de déclaration, d'information et de sélection, qui peuvent biaiser les données et les conclusions d'une étude (Murad, Asi, Alsawas et Alahdab, 2016). Un risque formel d'évaluation de la partialité est hors du champ de cette revue rapide. Les cotes de biais sont fondées sur le plan d'étude, les études par observation étant considérées comme présentant un risque de biais de modéré à élevé selon le plan. Dans le cas des plans d'étude par observation, cela place les grandes cohortes prospectives en tête, car le plan d'étude peut présenter un faible risque de biais et une grande confiance dans les résultats et les rapports de cas sont considérés comme ayant une très faible confiance dans les résultats.

La plus grande partie des recherches qui sous-tendent cette revue consiste principalement d'investigations épidémiologiques de petite envergure sur les grappes et les éclosions, qui présentent généralement un risque

élevé de biais en raison de leur nature rétrospective. Bien que l'exhaustivité des investigations et des rapports varie beaucoup, il existe une bonne cohérence entre ces investigations, ce qui contribue à notre confiance dans les éléments de preuve.

Plusieurs études écologiques ont été saisies; ces études sont susceptibles d'une série de biais et d'erreurs écologiques en raison de leur incapacité à caractériser la variabilité des expositions et des facteurs de confusion au sein d'un groupe. Des études transversales ont été utilisées pour fournir un aperçu des facteurs de risque individuels et de l'exposition au SRAS-CoV-2, mais ne permettent pas de tirer des conclusions sur la causalité. Le plan de cohortes prospectives a été utilisé dans deux études évaluant les stratégies d'atténuation sur le lieu de travail. La cohorte prospective présente un risque de biais plus faible que les autres plans d'étude par observation, bien que les deux études retenues dans cette revue aient des échantillons de petite taille.

Les modèles prédictifs et les évaluations des risques ne prédisent pas une réalité future, mais présentent plutôt une série de résultats plausibles dans les scénarios étudiés. Leurs résultats sont utiles pour comparer différentes options dans le cadre d'un processus décisionnel, mais ils doivent être interprétés avec prudence, car les modèles varient en fonction de leurs hypothèses et de leurs valeurs d'entrée selon la période épidémique et les paramètres spécifiques à la région utilisés.

En raison de la nature des éléments de preuve présentés dans cette étude (études d'observation et modèles prédictifs) et des biais qui y sont associés, cette revue rapide fournit peu d'éléments sur les conditions de travail qui entraînent un risque plus élevé de transmission du SRAS-CoV-2, et sur les stratégies de réduction des risques. Sur la base des plans d'étude portant sur les études incluses, il est peu probable que des recherches supplémentaires ne modifient pas les conclusions de cette revue. La littérature existante sur la COVID-19 évolue rapidement et cette revue devrait être périodiquement mise à jour afin d'intégrer les nouvelles recherches.

TABLE DES MATIÈRES

RISQUES PROFESSIONNELS

Les risques professionnels associés à l'infection par la COVID-19 ont été identifiés dans 20 publications (tableau 1). Il s'agissait notamment de deux revues et de trois évaluations des risques. Les publications de cette section ont porté sur les professions et les caractéristiques des professions qui entraînent un risque plus ou moins élevé de transmission sur le lieu de travail.

- Dans les publications, les professions identifiées comme les plus exposées au risque d'exposition au SRAS-CoV-2, en dehors des professionnels de la santé, sont énumérées ci-dessous (tableau 1). Les travailleurs de la santé (TS) sont considérés comme n'entrant pas dans le cadre de cette revue, mais dans les documents portant sur les facteurs de risques professionnels, les TS sont fréquemment inclus dans l'analyse et les résultats.
    - Transport : conducteurs et travailleurs du transport, coursiers, chauffeurs de bus
    - Commerce de détail/services : travailleurs des services et de la vente, personnel des hôtels et des centres de villégiature
    - Industrie alimentaire : restaurant, transformation des aliments, abattoirs et usines de transformation de la viande
    - Administration de bureau et vente : professions avec un taux élevé de contacts avec la clientèle.
    - Soins personnels : travail dans les maisons de soins infirmiers, les garderies, les établissements préscolaires; professionnels religieux; travailleurs de soins personnels; professionnels de la santé associés (par exemple, les dentistes), le personnel des instituts et salons
    - Services sociaux et communautaires : travailleurs sociaux et conseillers, agents de santé communautaires, prestataires de services de garde
    - Construction, extraction et métiers connexes : plombiers, installateurs de fosses septiques, réparation d'ascenseurs, entretien des terrains et des installations
    - Travailleurs de la sécurité publique : pompiers, policiers, agents pénitentiaires
    - Travailleurs des eaux usées
- Les professions à faible risque d'exposition au SRAS-CoV-2 comprenaient les professions qui pouvaient faire du télétravail et/ou s'éloigner socialement des autres (tableau 1). Parmi ces derniers, on peut citer les agriculteurs, les opérateurs de machines, les entreprises qui ont une interaction minimale avec le public ou les clients (Sierpiński et coll., 2020).

- Les travailleurs essentiels (qui comprennent un grand nombre des catégories à haut risque énumérées ci-dessus) sont plus exposés au risque d'infection par la COVID-19 que la population générale (tableau 1). Ce risque est accru par l'interaction croissante avec les collègues, les clients ou le public.
- Les facteurs sociodémographiques et leur association avec un risque élevé d'exposition au SRAS-CoV-2 ont été examinés dans plusieurs études (tableau 1). Les femmes, les minorités visibles et les personnes à faible revenu sont plus susceptibles d'occuper des emplois associés à un risque considérablement plus élevé d'exposition à la COVID-19, car leur profession ne leur permet pas de travailler à domicile et implique de travailler de façon très rapprochée d'autres personnes. À l'inverse, l'augmentation de l'âge et une éducation supérieure étaient associées à un risque plus faible d'exposition liée à la profession.
- Le personnel des écoles maternelles, primaires et secondaires n'a pas une prévalence relative de COVID-19 plus élevée que les autres professions (Agence suédoise de santé publique, 2020).
- Une étude a indiqué que les trajets entre le domicile et le lieu de travail dans les transports publics étaient positivement associés au risque d'infection par le SRAS-CoV-2. Un résultat qui était considérablement plus évident dans l'échantillon américain que dans l'échantillon britannique, ce qui, selon les auteurs, pourrait être lié à l'uniformité et à la rigueur du confinement britannique (Anand et coll., 2020).
- Deux évaluations des risques ont exploré les attributs des lieux de travail et de la mobilité quant à leur potentiel de transmission du SRAS-CoV-2.
    - Une évaluation des risques a évalué les entreprises en fonction de leur potentiel de super-propagation (ESP) sur la base de la fréquence, de la durée et de la superficie des entreprises avant la pandémie dans 8 États américains. Une association positive entre les ESP (5 % des entreprises avec les taux les plus élevés étaient considérées comme des ESP) et les cas hebdomadaires cumulés de COVID-19 a été signalée, montrant qu'une augmentation de 1 % du nombre d'ESP dans une zone équivalait à une augmentation de 5 % des cas. Les ESP les plus courantes étaient les restaurants à service complet, les restaurants à service limité et les hôtels/motels (Donoghue et coll., 2020).
    - Les risques sanitaires potentiels du SRAS-CoV-2 dans les eaux usées pour les travailleurs des stations d'épuration ont été étudiés à l'aide d'une évaluation quantitative des risques microbiens (EQRM). Les charges virales estimées dans les eaux usées à l'entrée des stations d'épuration étaient supérieures aux valeurs seuils de sécurité suggérées par l'Organisation mondiale de la santé (OMS) (Zaneti et coll., 2020).

Tableau 1. Vingt publications sur les risques professionnels liés à l'infection par la COVID-19.

Référence	Titre de la publication	Détails de l'étude	Résultats pertinents
Études d'observation			
(Lan, Wei et Hsu, 2020)	Transmission de la COVID-19 liée au travail dans six pays/régions d'Asie : une étude de suivi	• Cette étude d'observation rétrospective a identifié des cas possibles liés au travail à partir de rapports d'investigation gouvernementaux à Hong Kong, au Japon, à Singapour, à Taiwan, en Thaïlande et au Vietnam qui ont été signalés entre le 23 janvier et le 14 mars 2020. • Les auteurs ont déclaré qu'ils n'avaient pas d'intérêts concurrents.	• Après exclusion de tous les cas importés, 103 transmissions possibles liées au travail ont été identifiées à partir des 690 transmissions locales ayant fait l'objet d'une investigation. • En dehors des travailleurs de la santé, les groupes professionnels les plus souvent impliqués sont les suivants : conducteurs et travailleurs du transport (18 %), travailleurs des services et de la vente (18 %), agents d'entretien et femmes de ménage – 22 (9 %), travailleurs de la sécurité publique (7 %) et professionnels du secteur religieux (6 %). • Un changement entre les professions trouvées dans les grappes pendant la phase initiale de l'éclosion (principalement les travailleurs des services et de la vente, et les ouvriers de la construction) et celles trouvées à la phase ultérieure de l'éclosion (principalement les travailleurs de la santé, les agents d'entretien et femmes de ménage et les agents de police).
(Sierpiński et coll., 2020)	Risques professionnels liés à l'infection par le SRAS-CoV-2 : l'expérience polonaise	• Cette étude transversale a analysé les sources et les facteurs de risque professionnels des infections par le SRAS-CoV-2 sur 2122 patients infectés par le SRAS-CoV-2 qui sont restés isolés chez eux en Pologne. • L'investigation a été menée les 17 et 18 avril 2020 au moyen d'une interview structurée.	• Parmi les 2122 participants atteints du SRAS-CoV-2, 75 % ont été infectés au travail et 70 % avaient un emploi (activité professionnelle). • Parmi les cas d'activité professionnelle, 48 % travaillaient dans le secteur des soins de santé, 3 % dans l'administration publique ou la défense, 3 % dans les transports et 2 % dans l'éducation. • 65 % des cas ayant une activité professionnelle travaillaient dans des entreprises de plus de 100 salariés.

		• Aucune déclaration de conflit d'intérêts n'est disponible.	
(Torres Martínez, Diaque García, Rubio Salas et coll., 2020) *prépublication*	Séroprévalence des IgG contre le SRAS-CoV-2 dans une cohorte de 449 personnes non hospitalisées et exposées à un risque élevé	• Cette étude transversale a estimé la séroprévalence sur 449 personnes à Madrid, en Espagne, avec l'un des critères d'inclusion suivants : avoir des symptômes de la COVID-19, être en contact avec un cas de COVID-19, ou appartenir à des professions essentielles, notamment les travailleurs de la santé, les pompiers ou le personnel de sécurité publique comme la police. • Étude réalisée du 15 avril au 15 juin 2020. • Les auteurs déclarent que 3 de leurs auteurs sont fondateurs, membres du conseil d'administration et actionnaires de EMPIREO Diagnóstico Molecular.	• La séroprévalence globale était de 33,69 % (IC de 95 % : de 29,27 à 38,21). • Sur les 449 personnes testées, 9,58 % étaient des travailleurs de la santé, 4,01 % des pompiers et 6,46 % travaillaient dans la sécurité publique. Les autres n'appartenaient pas à ces professions. • En ce qui concerne ces professions à haut risque d'exposition, il n'y a pas eu de différence significative dans la séroprévalence. Il n'y avait pas non plus de différence dans la séroprévalence des IgG entre les groupes de professions suspectes, exposées ou à haut risque, ce qui suggère un niveau élevé d'exposition dans les professions à haut risque d'exposition.
(Koh, 2020b)	Risques professionnels liés à la COVID-19	• Cette étude d'observation rétrospective décrit 17 cas qui étaient probablement dus à une exposition professionnelle à Singapour pendant la période du 4 au 11 février 2020, avant toute mesure de santé publique. • Aucune déclaration de conflit d'intérêts n'est disponible.	• Les expositions professionnelles comprenaient du personnel du commerce de détail vendant principalement aux touristes et du personnel d'entreprises qui participait à une réunion d'affaires internationale à Singapour. • Des chauffeurs de transport, des ouvriers du bâtiment et des personnes travaillant dans le secteur du tourisme ont été impliqués (par exemple, un employé de casino ou de station balnéaire).
(Anand et coll., 2020) *prépublication*	Prédicteurs professionnels et personnels de la	• Cette étude transversale analyse les prédicteurs professionnels et personnels de l'expérience de	• Les résultats aux États-Unis étaient différents de ceux au Royaume-Uni, les auteurs théorisent que cela est dû à la rigueur des mesures de santé publique. Les résultats indiquent que la profession, les traits personnels, les

	transmission de la COVID-19	transmission de la COVID-19 aux États-Unis et au Royaume-Uni. • Une enquête en ligne a été menée auprès de 2000 participants la première semaine de juin 2020. • Aucune déclaration de conflit d'intérêts n'est disponible.	circonstances et les comportements ont tous une incidence sur le risque d'exposition à la COVID-19 et sur la capacité à s'éloigner physiquement. • L'analyse britannique a indiqué un risque plus élevé d'être testé positif à la COVID-19 pour les personnes sans revenu, à revenu moyen inférieur, qui partageaient une cuisine et avaient un emploi où les interactions avec les clients et le personnel étaient permanentes. • L'analyse américaine a indiqué que le risque plus élevé d'être infecté par la COVID-19 était lié à un faible revenu (CR entre 5,8 et 6,3), à une cuisine partagée (3,6), à un diplôme universitaire (2,7), à une profession liée au transport (8,5), à l'appartenance à un syndicat (4,8), à une consultation sur la transmission de la COVID-19 au travail (2,5) et au fait d'avoir dû prendre les transports publics pour se rendre au travail (3,2).

(Agence suédoise de la santé publique, 2020) *prépublication*	Prévalence de la COVID-19 dans différents groupes professionnels	• Article en suédois.
		• Cette étude transversale analyse la prévalence de la COVID-19 entre différents groupes professionnels en utilisant les données sur la classification des professions de Statistics Sweden et les cas diagnostiqués pendant la période du 13 mars au 27 mai 2020.
		• Les professionnels de la santé ont été exclus de l'analyse.
		• Aucune déclaration de conflit d'intérêts n'est disponible.
			• Par rapport aux autres groupes professionnels, les chauffeurs de taxi avaient environ 5 fois plus de risques d'être infectés par le SRAS-CoV-2 (RR : 4,8, IC de 95 % : de 3,9 à 6).
			• Parmi les autres groupes professionnels à haut risque, on peut citer :
			  • Les préparateurs de pizzas – RR 4,5, IC de 95 % : de 3,2 à 6,3
			  • Les conducteurs d'autobus et de tramways – RR 4,3, IC de 95 % : de 3,6 à 5,1
			  • Les traducteurs et linguistes – RR 2,9, IC de 95 % : de 1,8 à 4,7
			  • Les responsables de restaurant et de cuisine – RR 2,5, IC de 95 % : de 1,7 à 3,8
			  • Les autres travailleurs des services (par exemple, les travailleurs qui remplissent les distributeurs

			automatiques, qui lisent les compteurs électriques et de gaz, etc.) – RR 2,3, IC de 95 % : de 2,1 à 3 • Les pompiers – RR 2,2, IC de 95 % : de 1,4 à 3,5 • Les professionnels du nettoyage (par exemple, nettoyeurs de voitures, laveurs de vitres) – RR 1,7, IC de 95 % : de 1,1 à 2,7 • Les gestionnaires immobiliers – RR 1,6, IC de 95 % : de 1,3 à 2 • Les assistants de restaurant et de cuisine – RR 1,4, IC de 95 % : de 1,2 à 1,7 • Le personnel des écoles maternelles, primaires et secondaires n'a pas une prévalence relative de COVID-19 plus élevée que les autres professions. • Les professeurs de lycée – RR 0,7, IC de 95 % : de 0,5 à 1 • Les enseignants du primaire – RR 1,1, IC de 95 % : de 0,9 à 1,3 • Les éducateurs en loisirs – RR 0,8, IC de 95 % : de 0,5 à 1,3 • Les enseignants de maternelle – RR 0,7, IC de 95 % : de 0,6 à 0,9 • Les autres éducateurs ayant des compétences spécialisées – RR 1,0, IC de 95 % : de 0,7 à 1,5 • Les gardes d'enfants – RR 1,0, IC de 95 % : de 0,8 à 1,2 • Les assistants d'élèves – RR 1,1, IC de 95 % : de 0,8 à 1,4 •
Études écologiques			
(Lewandowski, 2020)	Exposition professionnelle à la contagion et à la	• Cette étude écologique a mesuré les niveaux d'exposition professionnelle à l'indice de contagion spécifique à chaque pays, dérivé d'une combinaison	• Dans les pays où la proportion de travailleurs fortement exposés est plus élevée, le fait que ces travailleurs aient tendance à être plus âgés explique la forte corrélation

prépublication	propagation de la COVID-19 en Europe	de données d'O*NET (exposition à la maladie ou à l'infection et proximité physique au travail) et de l'Enquête européenne sur les conditions de travail (traiter avec les gens, travailler en public, travailler dans les locaux du client et ne pas pouvoir travailler à domicile). Les travailleurs de la santé ont été exclus de l'analyse. • Aucune déclaration de conflit d'intérêts n'est disponible.	entre l'âge de 45 à 64 ans et l'indice d'exposition professionnelle à la contagion. • Dans les pays européens, de 20 à 25 % de la variance entre ces pays dans le nombre de cas et de décès liés à la COVID-19 peuvent être attribués aux différences entre pays dans les niveaux d'exposition professionnelle à la contagion. • Les professions les plus à risque sont les travailleurs des services personnels, les travailleurs des services de protection, les travailleurs de la vente et les travailleurs du bâtiment et des métiers connexes. • Les professions qui présentent le moins de risques sont notamment les ouvriers agricoles et les travailleurs agricoles, les opérateurs d'usines et de machines qui ne sont pas à proximité les uns des autres, et les entreprises qui n'ont pas d'interaction avec le public ou les clients et qui ont la capacité de permettre à leurs employés de travailler à domicile.
(Baker, Peckham et Seixas, 2020)	Estimation de la charge de travail des travailleurs américains exposés à une infection ou à une maladie : un facteur clé pour contenir le risque d'infection par la COVID-19	• Cette analyse préalable à l'épidémie de COVID-19 visait à quantifier le nombre de travailleurs qui sont fréquemment exposés à des infections et des maladies sur leur lieu de travail aux États-Unis, et à comprendre quels groupes professionnels ils représentent en combinant les données sur leurs activités professionnelles du réseau Occupation Information Network(O*Net) (à partir d'une mise à jour partielle en 2018) avec les données de la base de données Occupational Employment Statistics du	• Selon les estimations autodéclarées par O*Net en 2018 et extrapolées à partir des données du BLS, environ 10 % (14,4 millions) des travailleurs aux États-Unis exercent des professions où l'exposition à la maladie ou à l'infection se produit au moins une fois par semaine. En outre, 18,4 % (26,7 millions) sont employés dans des professions où l'exposition à la maladie ou à l'infection se produit au moins une fois par mois. • Les professions présentant un risque d'exposition plus élevé sont celles du secteur des soins de santé, des services de protection (par exemple, policiers, agents correctionnels, pompiers), des bureaux et du soutien administratif (par exemple, messagers et coursiers, représentants des services aux patients), de l'éducation (par exemple, éducateurs préscolaires et de garderie),

		Bureau of Labor Statistics (BLS) (à partir de mai 2018). • Aucune déclaration de conflit d'intérêts n'est disponible.	des services sociaux et de proximité (agents de santé communautaires, travailleurs sociaux, conseillers), et de la construction et de l'extraction (par exemple, plombiers, installateurs de fosses septiques, réparateurs d'ascenseurs).
(St-Denis, 2020)	Facteurs sociodémographiques des risques professionnels d'exposition à la COVID-19 au Canada	• Cette analyse préalable à l'épidémie de COVID-19 a permis d'identifier les groupes de la population active les plus exposés à la COVID-19 en fonction des caractéristiques de leur profession et de les évaluer par rapport aux données sociodémographiques. • Les données sur les activités professionnelles ont été extraites de la base de données O*Net (niveau de proximité physique avec d'autres personnes, et fréquence d'exposition aux maladies et aux infections) du recensement canadien de 2016. • Aucune déclaration de conflit d'intérêts n'est disponible.	• Les résultats mettent en évidence l'association entre le statut socioéconomique et les activités professionnelles qui peut augmenter le risque d'exposition chez les femmes, les immigrants et les membres des minorités visibles. • Environ 45 % des travailleurs canadiens exercent des professions qui exigent de travailler à proximité physique relativement étroite d'autres personnes (à distance d'un bras ou moins). • Les femmes travaillent dans des professions où les risques moyens d'exposition à la COVID-19 sont considérablement plus élevés que chez les hommes. • Les personnes titulaires d'une licence ou d'un diplôme supérieur sont généralement confrontées à des risques d'exposition professionnelle considérablement plus faibles. • Les travailleurs exerçant des professions à faible revenu sont plus susceptibles d'exercer des professions présentant des risques d'exposition plus élevés. • Les professions exercées par les travailleurs âgés (65 ans et plus) se caractérisent par un niveau de proximité physique avec les autres inférieur à celui de leurs collègues plus jeunes.
(Barbieri, Basso et Scicchitano, 2020)	Les travailleurs italiens en danger pendant l'épidémie de la COVID-19	• Cette étude écologique utilise des indices artificiels qui représentent la proximité physique sur le lieu de travail, l'exposition aux maladies et aux infections, et la possibilité de travailler	• Plusieurs secteurs nécessitent une proximité physique pour fonctionner : les travailleurs employés en Italie dans les secteurs dont l'indice de proximité physique est supérieur à la moyenne nationale sont plus de

prépublication		à distance au niveau professionnel et qui ont été créés à partir des données de l'Enquête italienne par échantillonnage sur les professions (ICP) et de l'Enquête sur la population active italienne de l'ISTAT. • Les auteurs déclarent que les opinions exprimées dans le document sont celles des auteurs et ne reflètent pas nécessairement celles de la Banque d'Italie ni celles de l'INAPP.	6,5 millions (la plupart d'entre eux travaillent dans le commerce de détail). • Les groupes à risque de contagion et de complications en raison de la COVID-19 (principalement des hommes de plus de 50 ans) travaillent dans des secteurs peu exposés à d'autres personnes, sont actuellement confinés ou peuvent travailler à distance. • Les secteurs présentant l'indice physique le plus élevé sont l'hôtellerie et la restauration, l'éducation, la santé et le commerce (principalement le commerce de détail).
(Lewandowski, Lipowska et Magda, 2020)	Le facteur sexe de l'exposition des professions à la contagion en Europe	• Cette étude écologique visait à mesurer l'exposition des professions aux maladies contagieuses en utilisant les données de O*Net 2018 et de l'Enquête européenne sur les conditions de travail (« EECS »), 2015). • Les auteurs analysent spécifiquement le facteur sexe dans l'exposition des professions. • Aucune déclaration de conflit d'intérêts n'est disponible.	• Les femmes sont 26 % plus susceptibles de travailler dans des professions très exposées qui nécessitent un contact avec des maladies, des contacts fréquents avec des clients et une grande proximité physique au travail. • Les femmes sont plus susceptibles que les hommes de ne pas pouvoir travailler à domicile en raison de leur profession. Les femmes plus âgées et les femmes ayant un niveau d'éducation supérieur étaient moins susceptibles d'exercer une profession très exposée. • Les professions où l'exposition aux contagions est élevée sont les travailleurs de soins personnels, les travailleurs de santé, les professionnels de santé associés, les travailleurs des services personnels et les travailleurs des services de protection. À l'exception de la dernière catégorie, les catégories antérieures sont à prédominance féminine. La prise en compte du secteur économique du sexe au travail n'est pas un prédicteur significatif de l'exposition aux contagions. Toutefois, dans certains secteurs, les jeunes femmes sont nettement plus susceptibles d'exercer des professions très exposées.

(Hawkins, 2020)	Risque professionnel différentiel der l'exposition au COVID-19 et à d'autres infections selon la race et l'origine ethnique	• Cette étude écologique visait à évaluer comment la ségrégation professionnelle selon la race et l'ethnicité contribue au risque de la COVID-19. • Les données de l'enquête Current Population Survey du Bureau of Labor Statistics ont été utilisées pour l'analyse. • Les auteurs ont déclaré qu'ils n'avaient pas d'intérêts concurrents.	• Cet article identifie que certaines professions à haut risque d'exposition emploient de manière disproportionnée certains groupes ethniques. • Les travailleurs noirs étaient plus susceptibles d'être employés dans des secteurs essentiels et dans des professions nécessitant fréquemment une grande proximité avec les autres (travailleurs de la santé, aide sociale, hôpital, chauffeurs de bus, aides aux soins personnels, industrie alimentaire). • Les travailleurs noirs et hispaniques avaient plus de deux fois plus de chances d'être employés dans le secteur de l'abattage et de la transformation des animaux, où de nombreuses éclosions de la COVID-19 se sont déclarées.
(Rogers et coll., 2020)	Disparités raciales dans la mortalité due à la COVID-19 chez les travailleurs essentiels aux États-Unis	• Cette étude écologique analyse les données de l'American Community Survey et de la Current Population Survey pour examiner la corrélation entre les décès dus à la COVID-19 et les différences professionnelles entre les groupes raciaux/ethniques dans les États américains. • Les données sur les décès dus à la COVID-19 jusqu'au 24 avril 2020 ont été incluses. • Les auteurs remercient une personne, qui a fourni une assistance éditoriale, et Data for Black Lives (http://d4bl.org/) qui a indirectement soutenu l'investigation en étant l'une des premières organisations à dresser une liste d'États ayant partagé publiquement les données d'incidence et de mortalité connexes à la COVID-	• Les personnes noires non hispaniques (NH) occupent de manière disproportionnée les 9 premiers emplois essentiels, ce qui augmente leur risque d'exposition à la COVID-19, y compris les 3 plus grandes disparités : transport et déplacement de matériel, soutien aux soins de santé, préparation et service des aliments. • Les personnes d'origine hispanique étaient proportionnellement plus nombreuses à travailler dans la préparation et le service des aliments, le nettoyage et l'entretien des bâtiments et des terrains et la production. • Les personnes d'origine asiatique sont plus susceptibles de travailler dans le secteur des soins et services personnels, des soins de santé et de la préparation et du service des aliments.

		19. La recherche a été partiellement soutenue par une subvention de National Institutes of Health.	
(Peters, 2020)	Sensibilité et résilience de la communauté à la COVID-19 dans le continuum rural-urbain aux États-Unis	• Dans cette étude écologique, une échelle de sensibilité à la COVID-19 est générée au niveau du pays en utilisant des données provenant du Census Bureau des États-Unis et du CDC. Les auteurs évaluent ensuite la santé et la résilience socio-économique des lieux sensibles dans le continuum rural-urbain aux États-Unis. • L'étude a été soutenue par le projet de recherche multi-états W4001 de la station d'expérimentation agricole de l'USDA. Les auteurs déclarent qu'il n'y a pas de conflits d'intérêts.	• Sur la base des données sur l'emploi, les usines de transformation de la viande augmentent le risque d'infection dans les zones rurales. • Les éclosions de COVID-19 dans les communautés rurales de conditionnement de la viande ont une incidence disproportionnée sur les travailleurs hispaniques et d'autres minorités.
Modèles prédictifs			
(Milligan et coll., 2020) *prépublication*	Incidence des travailleurs essentiels dans le contexte de la distanciation sociale pour le contrôle des épidémies	• Ce modèle SEIR a examiné des scénarios avec 3 groupes différents de travailleurs essentiels pour déterminer leur risque de contracter la COVID-19 : 1) les travailleurs essentiels en contact avec le public (caissiers, commerce de détail, transport), 2) les travailleurs essentiels en contact avec le public (employés d'usine, d'entrepôt et d'agriculture), et 3) les travailleurs de la santé. • Aucune déclaration de conflit d'intérêts n'est disponible.	• Les travailleurs essentiels courent un risque accru d'infection par la COVID-19 par rapport à la population générale. • Les travailleurs essentiels qui ne sont pas en contact avec le public sont susceptibles d'être exposés à des éclosions sur leur lieu de travail même après des pratiques de distanciation sociale, tandis que les travailleurs essentiels en contact avec le public ont un taux de contact élevé avec d'autres personnes et donc un risque plus élevé d'être exposés à une personne infectée que ceux qui restent à la maison. • Il a été constaté que différents types de travailleurs essentiels (caissiers, employés d'usine et travailleurs de santé) avaient des incidences différentes sur les

			scénarios de transmission. De même, les efforts d'atténuation (par exemple les masques, la distanciation physique, etc.) ont eu une incidence sur la transmission.
Revues			
(Rafeeman esh, Ahmadi et Memarzad eh, 2020)	Une revue des stratégies et des études sur la prévention et le contrôle du nouveau coronavirus sur les lieux de travail	• Revue documentaire publiée en avril 2020, pas de date de recherche ni de section sur la méthodologie. • Les auteurs ont voulu examiner les stratégies nécessaires pour prévenir et contrôler la COVID-19 sur le lieu de travail. • Stratégie de recherche et dates de la recherche non communiquées. • Les auteurs ont déclaré qu'ils n'avaient pas d'intérêts concurrents.	• Professions à haut risque d'exposition : o Le CDC a identifié les professions qui sont plus exposées à la COVID-19 : 1) les travailleurs de la santé (TS), 2) le personnel des cimetières et des pompes funèbres, 3) les fonctionnaires et le personnel des aéroports, des compagnies aériennes, des chemins de fer, des métros et de tous les transports publics (bus, taxis, etc.), 4) les gardes-frontières, 5) les travailleurs du secteur des déchets solides et des eaux usées, et 6) les employés qui se déplacent régulièrement, notamment dans les zones contaminées o Les dentistes et les maquilleurs sont également exposés à un risque élevé en raison de la communication en face à face avec les clients et de l'exposition à la salive, au sang et à l'haleine expirée o Les équipages des avions et des navires risquent d'être en contact avec des passagers infectés • Solutions de contrôle : o Contrôles techniques (isolement des symptômes, ventilation, barrières entre les personnes, outils jetables) o Contrôles administratifs (exclusion des travailleurs malades, formation à l'hygiène, réduction des heures de travail du personnel, télétravail, mise en cohorte, nettoyage et désinfection continus, restriction des rassemblements de personnel)

			○ Équipement de protection individuelle (masque facial approprié, protection des yeux, gants et vêtements spéciaux – selon les besoins) • Obstacles clés : ○ Le fait de continuer à travailler malgré la maladie (présentéisme) est un problème majeur. Des politiques de congé de maladie étendues aideront dans ce sens
(Leng et coll., 2020)	Voies de transmission du coronavirus nCov-2019 et contrôles en cabinet dentaire	• Revue documentaire publiée en avril 2020, pas de date de recherche ni de section sur la méthodologie • Les auteurs visent à donner un aperçu des voies de transmission et du risque d'exposition pour les personnes travaillant dans l'industrie dentaire. • Les auteurs ont déclaré qu'ils n'avaient pas d'intérêts concurrents.	• Voies de transmission ○ Il existe un risque élevé de transmission directe dans les cabinets dentaires en raison du travail direct avec la bouche et du contact avec les muqueuses buccales/nasales, ainsi que de l'exposition à la salive, au sang et à d'autres liquides respiratoires ○ Transmission par voie aérienne aux personnes sensibles dans la clinique ○ La transmission indirecte par des fomites peut également constituer un risque, car la manipulation d'instruments tranchants en contact direct avec des fluides corporels potentiellement chargés de virus peut se produire • Mesures de lutte contre les infections ○ Évaluation du patient, contrôle de la température ○ Hygiène des mains ○ Protection des barrières, notamment masque facial, protection des yeux, écran facial, vêtements de travail (par exemple, blouse de laboratoire) ○ Rinçage de bouche antimicrobien avant l'intervention dentaire, la digue en caoutchouc peut minimiser les éclaboussures de sang et de salive.

			○ L'utilisation de pièces à main anti-retrait à grande vitesse peut réduire le risque de contamination croisée. ○ Une désinfection stricte et continue
Évaluation des risques			
(Donoghue et coll., 2020) *prépublication*	Entreprises de super-propagation et risque de transmission de COVID-19	• Cette évaluation des risques explore les attributs des entreprises à super-propagation (ESP). Les ESP étaient les entreprises se situant dans les 5 % supérieurs de l'indice de risque de transmission de la COVID-19 en entreprise (Business Transmission Risk Index), qui est basé sur la fréquence, la durée et la superficie des entreprises avant la pandémie dans huit États américains. • Aucune déclaration de conflit d'intérêts n'est disponible.	• L'analyse binomiale négative a révélé une association positive entre les ESP et les cas hebdomadaires cumulés de COVID-19, où une augmentation de 1 % des ESP équivaut à une augmentation de 5 % des cas. • Les types d'entreprises les plus courants classés comme ESP comprennent les restaurants à service complet, les restaurants à service limité et les hôtels/motels. • Les attributs des ESP dans cette étude sont généralement des entreprises où les visiteurs restent plus longtemps et où les espaces sont plus bondés.
(Zaneti et coll., 2020) *prépublication*	EQRM du SRAS-CoV-2 pour les travailleurs dans les stations d'épuration des eaux usées	• Une évaluation quantitative des risques microbiens (EQRM) a été utilisée pour étudier les risques sanitaires potentiels du SRAS-CoV-2 dans les eaux usées pour les travailleurs des stations d'épuration des eaux usées (SEEU). • L'EQRM a été appliquée pour 3 scénarios de COVID-19 (modéré, agressif et extrême) afin d'étudier le risque pendant les différentes phases de la pandémie. • Aucune déclaration de conflit d'intérêts n'est disponible.	• Les charges virales estimées dans les eaux usées à l'entrée des stations d'épuration variaient de 1,03x102 à 1,31x104 CG/mL (GC= copies du génome), ce qui équivaut à 0,1 à 13,06 UFP/mL (UFP= unités formatrices de plaques). • On a supposé que la dose d'exposition était de 1mL et que la contamination se produisait à des concentrations allant de 1,03 x 10^2 GC/mL à 1,31 x 10^4 GC/mL dans des scénarios modérés à extrêmes. • Le résultat a été un risque estimé pour lequel l'OMS suggère un seuil de 1 x 10^{-3} (basé sur le risque tolérable d'infection par le rotavirus de l'eau potable) : Les scénarios extrêmes (3,1 x 10^{-2}), agressifs (6,5 x 10^{-3}) et

			modérés ($3,0 \times 10^{-4}$) rapportent un risque 31, 6,5 et 0,3 fois supérieur au seuil de l'OMS. • Les travailleurs des stations d'épuration exposés aux bioaérosols et aux particules en suspension dans l'air sont exposés à un risque professionnel que peu d'études ont examiné. • La lutte contre l'infection pourrait inclure l'utilisation d'un masque et d'un écran facial lors des travaux de nettoyage manuel et la réduction du temps passé dans les zones de traitement • Les charges virales dans les eaux usées pourraient être utilisées comme un outil d'alerte précoce pour la communauté et aider à prioriser des stratégies de contrôle des infections améliorées dans le secteur de l'assainissement.
(Zachreson, Mitchell, Lydeamore et coll., 2020) *prépublication*	Cartographie des risques d'éclosions de COVID-19 à l'aide de données sur la mobilité	• Une approche heuristique de l'estimation du risque de transmission basée uniquement sur des informations qualitatives concernant les facteurs épidémiologiques et éclairée par des estimations en temps quasi réel des schémas de mobilité. • Les éclosions liées aux rassemblements sont particulièrement bien adaptées à cette méthode. • Elles valident leurs estimations en utilisant 3 scénarios bien documentés d'éclosions de COVID-19 en Australie. Il s'agit notamment d'éclosions dans un abattoir, un hôtel et au sein d'une communauté. • Les données sur la mobilité ont été utilisées à partir de Facebook et les	• Facteurs spécifiques au lieu de travail (contexte) : o Localisation commune (entrée et sortie d'une zone d'éclosion) o Se trouvait sur le lieu de l'éclosion avant l'identification de l'éclosion o Statistiques des professions dans la zone ou le lieu étudié (aide à identifier un type d'activités communes dans la zone de l'éclosion) Remarque : la méthode ci-dessus peut être appliquée à tout endroit où les déplacements sont habituels. • Exemple : Éclosion de Cedar Meats en avril 2020, Australie o Une carte des risques de mobilité et le coefficient de corrélation de Spearman indiquent qu'avec des données de cas et de mobilité limitées, la localisation de l'éclosion associée à Cedar Meats à Brimbank aurait pu être identifiée très tôt. Ce résultat a encore

		données sur les cas ont été obtenues par l'intermédiaire des autorités sanitaires de l'État australien. • Aucune déclaration de conflit d'intérêts n'est disponible.	été amélioré grâce à l'ajout de données processionnelles pour la région. o Ces résultats montrent également comment les données sur la mobilité peuvent être un outil utile à l'estimation de la diffusion du risque de transmission de la COVID-19 à partir des lieux de l'éclosion et au début d'une éclosion. Cela peut être utilisé pour intensifier les mesures de santé publique à un stade précoce et aider à contenir une éclosion ou une transmission communautaire (comme le montrent les autres exemples), en particulier lorsque nous avons peu de cas et que nous nous efforçons de prévenir une résurgence des cas. • 2 autres exemples sont présentés concernant un rassemblement social et une transmission communautaire. Ils ne sont pas résumés ici.

TRANSMISSION SUR LE LIEU DE TRAVAIL

Un large éventail de lieux de travail ont été impliqués dans des cas de transmission du SRAS-CoV-2 et de nombreux cas de transmission, bien qu'ils aient été identifiés, n'ont pas fait l'objet d'une investigation approfondie ni d'une publication. Un projet en cours, accessible au public, visant à compiler les événements de super-propagation de la COVID-19 (>5 cas) a été identifié et les 1500 événements signalés dans cette liste soulignent l'ampleur de l'insuffisance de signalement des événements de transmission (Swinkels, 2020). Les événements de transmission omis dans la littérature publiée et préimprimée ont été enregistrés sur les tableaux de bord des pays et par les médias. Ces derniers ont été exclus de cette revue, car ils ne sont souvent pas signalés avec suffisamment de détails pour évaluer l'événement de transmission ou l'investigation.

- Le tableau 2 énumère 37 publications qui décrivent un ou plusieurs événements de transmission considérés comme s'étant produits sur un lieu de travail impliquant des travailleurs, classés en gros dans les catégories suivantes : environnement de bureau, usines de transformation de la viande, autres usines, travail des migrants, centres de remise en forme, navires, autres professions liées aux services, transports et études de grappes multiples.

- Quatre éclosions ont été identifiées dans des bureaux (centre d'appels, bureau administratif, réunions). Les principaux facteurs facilitant la transmission du SRAS-CoV-2 dans un bureau sont l'activité (par exemple, parler), la proximité d'une personne infectée (par exemple, s'asseoir à côté d'elle) et la durée pendant laquelle la personne infectée est proche.
- Les éclosions dans les usines de transformation de la viande en Allemagne et aux États-Unis sont décrites dans cinq publications. Les facteurs de risque d'infection ont été identifiés comme suit : difficultés d'éloignement physique, contact étroit prolongé avec des collègues de travail, facteurs environnementaux tels que l'air recyclé refroidi, l'hygiène des mains, le logement partagé, le transport partagé pour se rendre au travail et en revenir, et les contacts communautaires fréquents avec les collègues de travail.
    - L'investigation sur le plus grand complexe de transformation de la viande en Allemagne fait état d'un taux d'attaque élevé des travailleurs se trouvant à moins de huit mètres du poste de travail fixe des cas index (Guenther et coll., 2020).
- Une étude de séroprévalence menée dans une usine en Croatie a révélé que des anticorps ont été détectés chez 1,27 % des participants (IC de 95 % : de 0,77 à 1,98 %, n=1,494). Cependant, aucune éclosion n'a été détectée dans l'usine et aucun des travailleurs hébergés dans les logements fournis par l'employeur ne présentait d'anticorps. L'employeur avait adopté des mesures de protection renforcées (par exemple, des stations de désinfection des mains, le nettoyage régulier des postes de travail, la fermeture des stations communes de vente de café et de nourriture, le contrôle de la température, l'auto-isolement pour les personnes revenant de l'étranger et le travail à domicile pour une partie du personnel commercial et administratif) (Jerkovic et coll., 2020).
- Les travailleurs migrants logés dans des logements partagés ont été associés à une importante éclosion à Singapour (Koh, 2020a).
- Dans trois éclosions survenues sur des bateaux (le navire de croisière Diamond Princess, un navire de pêche et un navire de la marine américaine), le partage de logement et le travail à proximité immédiate ont été identifiés comme des facteurs de risque de transmission du SRAS-CoV-2.
- Une importante éclosion liée à une salle de sport multicentrique a été retracée jusqu'à un atelier où plusieurs instructeurs ont été infectés et ont transmis le SRAS-CoV-2 à d'autres employés et clients dans les centres où ils étaient employés (Jang, Han et Rhee, 2020).
- Une étude transversale a estimé la séroprévalence de 104 personnes employées dans une épicerie du Massachusetts, aux États-Unis. Les résultats d'une analyse multivariée révèlent que les employés directement exposés aux clients avaient cinq fois plus de chances d'obtenir un résultat positif au test de dépistage du SRAS-CoV-2 (RC 4,7; IC de 95 % : de 1,2 à 32,0) (Lan, Suharlim, Kales et Yang, 2020). Une deuxième étude (Caban-Martinez et coll., 2020) a fait état d'un résultat similaire chez les pompiers et les ambulanciers.

- Trois études ont montré que l'emploi dans le secteur des transports constituait un facteur de risque chez les chauffeurs de taxi et les chauffeurs de bus, mais aucun cas de transmission à une hôtesse de l'air n'a été documenté à ce jour.
- Il a été suggéré que le partage des logements ou des installations (par exemple, les toilettes) et l'absence de mesures préventives (par exemple, un masque facial) ont contribué à plusieurs éclosions dans les centres commerciaux, les magasins de détail, les bars, les boîtes de nuit, les restaurants, les salles de concert et les camps de nuit.
- Les éclosions sont plus susceptibles de se produire dans un environnement intérieur (RC de 18,7; IC de 95 % : de 6,0 à 57,9) (Nishiura et coll., 2020).
- Les principales mesures de protection identifiées comprennent la pratique d'un contrôle exemplaire des infections dans les environnements fermés, des politiques d'exclusion des travailleurs malades du lieu de travail et le respect des précautions personnelles de contrôle des infections au travail.

Tableau 2. Trente-sept publications sur les événements de transmission sur le lieu de travail.

Référence	Titre de la publication	Détails de l'étude	Résultats pertinents
Environnement du bureau			
(Park et coll., 2020)	Éclosion de coronavirus dans un centre d'appel, Corée du Sud	• Données agrégées provenant d'investigations épidémiologiques rétrospectives. • Menée sur une éclosion de COVID-19 dans un centre d'appel à Séoul, en Corée du Sud, en mars 2020. • Aucune déclaration de conflit d'intérêts n'est disponible.	• Le premier cas confirmé a été identifié au centre d'appel le 8 mars 2020. Le centre d'appel est situé aux étages 7 à 9 et 11 d'un immeuble de 19 étages. En général, les employés ne se déplacent pas d'un étage à l'autre et ils ne disposent pas d'un restaurant interne pour les repas. Les résidents et les employés de l'immeuble avaient des contacts fréquents dans le hall ou les ascenseurs. • Le bâtiment a été fermé le 9 mars 2020 et des tests ont été proposés à tous les occupants du bâtiment. • Sur 1143 personnes testées pour la COVID-19, 97 (8,5 %) étaient positives. La majorité des employés (94/97) travaillaient dans un centre d'appel du 11^{e} étage comprenant 216 employés. Le taux d'attaque était donc de 43,5 % (IC de 95 % : de 36,9 à 50,4 %). En

			outre, la plupart des cas au 11e étage se trouvaient du même côté du bâtiment. • Le taux d'attaque secondaire à domicile parmi les cas symptomatiques était de 16,2 % (IC de 95 % : de 11,6 à 22 %). • La durée de l'interaction (ou du contact) a très probablement été le principal facteur facilitant la transmission.
(Zhang et coll., 2020)	Enquête épidémiologique sur une nouvelle épidémie de pneumonie à coronavirus en grappe dans des unités collectives de Tianjin	• Article en chinois. • Investigation épidémiologique rétrospective menée en janvier 2020. • L'éclosion s'est produite dans le bureau administratif d'une usine qui compte 906 employés à Tianjin, en Chine. • Les auteurs déclarent qu'il n'y a pas de conflit d'intérêts.	• Le premier cas a été identifié le 15 janvier 2020 et s'est propagé à 10 autres collègues avant que des mesures de contrôle ne soient mises en place le 24 janvier 2020. • Le cas index et le cas initial sont liés à des voyages professionnels à Wuhan. • Les cas secondaires et tertiaires ont soit voyagé ou participé à des réunions avec les cas infectés, soit se sont assis à proximité d'eux.
(Böhmer et coll., 2020; Rothe et coll., 2020)	Transmission de l'infection au coronavirus nCoV-2019 à partir d'un contact asymptomatique en Allemagne Enquête sur une éclosion de COVID-19 en Allemagne résultant d'un seul cas primaire associé à un	• Investigation épidémiologique rétrospective • 2 études décrivant la transmission du SRAS-CoV-2 d'une résidente chinoise qui s'est rendue en Allemagne pour des raisons professionnelles à ses collègues en janvier 2020. • Böhmer et coll. fournissent une investigation détaillée de l'éclosion. • Les auteurs déclarent qu'il n'y a pas de conflit d'intérêts.	• Le patient 0 était une employée de la branche chinoise d'une société allemande basée à Munich. Elle s'est rendue de Shanghai à Munich en avion le 19 janvier 2020 pour animer des ateliers et assister à des réunions dans le bâtiment de l'entreprise. Elle a pris un vol de nuit pour retourner à Shanghai le 22 janvier 2020 et a été testée positive à l'infection par le SRAS-CoV-2 le 26 janvier 2020. • L'entreprise allemande a été informée de l'infection le 27 janvier 2020. Les premiers tests effectués sur les contacts à haut risque ont permis d'identifier les patients 1 à 4 comme des cas de première génération. Le site de la société a été fermé le 11 février 2020. Au 19 février 2020, 16 cas ultérieurs ont été identifiés. • L'intervalle sériel médian était de 4,0 jours (IQR de 3,0 à 5,0).

	voyage : une série de cas		• Dix patients en plus du patient 0 étaient des employés de l'entreprise. Les 5 autres étaient des contacts familiaux. L'investigation a révélé que la transmission du patient 0 aux 10 autres s'est probablement produite au cours des scénarios suivants : ○ Accompagnement du patient 0 dans ses activités multiples en Allemagne et retour par le même avion ○ Dans les réunions de travail (de 60 à 90 minutes) où les collègues étaient assis à proximité les uns des autres. ○ Les collègues ont travaillé simultanément sur le même ordinateur pendant une courte période. ○ Après s'être assis ensemble au cours d'une réunion de 90 minutes pendant la journée, deux collègues ont également passé la soirée ensemble dans l'une de leurs maisons. Cependant, la partenaire du collègue hôte qui était également présent ce soir-là n'a pas été testée positive. ○ Deux collègues se sont rencontrés lors d'une visite à la cantine où ils se sont assis dos à dos. L'un d'eux s'est tourné vers l'autre pour lui emprunter la salière.
(Hall, Bui, Rowe et Do, 2020)	Investigation des cas de COVID-19 et des cas contacts dans un espace de travail de bureau	• Investigation épidémiologique rétrospective menée en mars 2020, • L'éclosion s'est produite aux États-Unis dans un espace de travail comprenant à la fois des bureaux militaires et des bureaux civils. • Pas de déclaration de conflit d'intérêts disponible	• Le cas index a involontairement exposé 150 collègues au SRAS-CoV-2 en participant à des covoiturages, des conférences et de petites réunions sur une période de 3 jours. • Sur les 150 expositions, 37 ont été considérées comme un risque moyen et 113 comme un risque faible. 5 personnes ont signalé des symptômes de type COVID-19 et 5 ont développé des symptômes pendant la quarantaine de 14 jours. Aucun des contacts n'a été testé positif à une infection par le SRAS-CoV-2.

			• Aucun des collègues exposés pendant le covoiturage n'a développé de symptômes et malgré le contact étroit, il semble qu'ils n'ont pas été infectés. • L'identification rapide des personnes exposées au risque d'infection et la mise en œuvre ultérieure d'efforts d'atténuation et de contrôle ont permis de contrôler la propagation du SRAS-CoV-2.
Usines de transformation de la viande			
(Dyal et coll., 2020)	Présence de la COVID-19 au sein des travailleurs d'usines de transformation de la viande et de la volaille — 19 États, avril 2020	• Données agrégées provenant d'investigations épidémiologiques rétrospectives. • Le rapport fournit des données globales sur les cas positifs de COVID-19 dans 115 usines de transformation de la viande et de la volaille dans 19 États américains jusqu'au 27 avril 2020. • Aucun conflit d'intérêts potentiel n'a été révélé.	• Parmi les quelque 130 000 travailleurs de ces installations, 4 913 cas (environ 3,0 %) et 20 d'entre eux sont décédés. • Ces chiffres reflètent les pratiques inadéquates de contrôle des infections suivies dans ces installations, notamment une faible distance sociale, des mesures de contrôle à la source (par exemple, l'utilisation de couvre-visages en tissu) et une charge de travail accrue. • Les facteurs de risque d'infection identifiés sont les difficultés liées à l'éloignement physique, à l'hygiène et aux conditions de vie et de transport surpeuplées (de nombreux travailleurs vivent dans des lieux surpeuplés et multigénérationnels et partagent parfois le transport pour se rendre au travail et en revenir).
(Waltenburg et coll., 2020)	Mise à jour : Présence de la COVID-19 au sein des travailleurs d'usines de transformation de la viande et de la volaille — 19	• Données agrégées provenant d'investigations épidémiologiques rétrospectives. • Ceci est une mise à jour du rapport ci-dessus. • Le rapport fournit des données agrégées sur les cas positifs de COVID-19 parmi 239 usines de transformation de la viande	• Dans 239 usines, il y a eu 16 233 cas de COVID-19 et 86 décès liés à la COVID-19 parmi les travailleurs (264 usines / 17 358 cas / 91 décès dans les deux publications (Dyal et coll., 2020; Waltenburg et coll., 2020)). • Parmi les 14 États ayant déclaré le nombre total de travailleurs dans les usines de transformation de la viande et de la volaille touchées (112 616), la COVID-19 a été diagnostiquée chez 9,1 % des travailleurs.

	États, avril à mai 2020	et de la volaille dans 23 États américains jusqu'au 31 mai 2020. • Aucun conflit d'intérêts potentiel n'a été révélé.	• Sur 9919 (61 %) cas dont la race/ethnicité a été signalée, 87 % concernaient des travailleurs issus de minorités raciales et ethniques. • Les facteurs qui augmentent le risque d'exposition pour ces travailleurs comprennent un contact étroit et prolongé sur le lieu de travail avec des collègues (à moins de 1,80 m pour une durée ≥15 minutes) pendant de longues périodes (équipes de travail de 8 à 12 heures), des espaces de travail partagés, un transport partagé pour se rendre au lieu de travail et en revenir, un logement collectif et des contacts communautaires fréquents avec des collègues. • Les données provenant de 111 usines dans 14 États révèlent la mise en œuvre des stratégies de prévention et de contrôle suivantes : dépistage des travailleurs à l'entrée (89 sur 111), obligation pour tous les travailleurs de porter un couvre-visage (86 sur 111), augmentation de la disponibilité des postes d'hygiène des mains (72 sur 111), sensibilisation des travailleurs à la propagation communautaire (70 sur 111), installation de barrières physiques entre les travailleurs (69 sur 111), offre de tests aux employés (41 sur 111) et fermeture temporaire (24 sur 111). • En utilisant les données de 7 usines qui ont mis en place des tests à l'échelle de l'usine, la prévalence brute des infections asymptomatiques ou présymptomatiques parmi les 5572 travailleurs qui ont été testés positifs à l'infection par le SRAS-CoV-2 était de 14,4 %.
(Steinberg et coll., 2020)	Éclosion de COVID-19 parmi les employés d'une usine de	• Investigation épidémiologique rétrospective	• Au total, 929 sur 3635 cas (25,6 %) de COVID-19 ont été diagnostiqués parmi les employés de l'usine A, dont 39 ont été hospitalisés et 2 sont décédés.

	transformation de la viande – Dakota du Sud, mars à avril 2020	• Effectuée entre le 16 mars et le 25 avril 2020 dans une usine de transformation de la viande (usine A). • Aucun conflit d'intérêts potentiel n'a été révélé.	• De plus, 210 sur 2408 cas (8,7 %) ont été identifiés parmi les contacts des employés ayant reçu un diagnostic de COVID-19. 9 d'entre eux ont été hospitalisés. • Le taux d'attaque de l'usine A entre le 16 mars et le 25 avril 2020 était de 25,6 %. Les groupes de services où les employés travaillaient à proximité (c.-à-d. < 1,8 m) les uns des autres sur la chaîne de production avaient les taux d'attaque les plus élevés (groupes de services : découpe – 30,2 %, conversion – 30,1 % et collecte – 29,4 %). • Le taux d'attaque était plus élevé chez les employés non salariés (26,8 %) que chez les salariés (14,8 %). • Le taux d'attaque a été multiplié par cinq environ au cours des trois premières semaines de l'éclosion. En moyenne, 67 cas de COVID-19 se sont produits par jour parmi les employés au cours de la quatrième semaine. Le nombre de cas parmi les employés est tombé à environ 10 par jour dans les 7 jours suivant la fermeture de l'usine.
(Richmond, Sabin, Jobe, Lovrich et Kenny, 2020) *prépublication*	Diffusion interrégionale du SRAS-CoV-2 à partir d'une seule éclosion d'introduction dans une usine de conditionnement de viande dans le nord-est de l'Iowa	• Étude d'épidémiologie moléculaire. • Cette étude décrit une analyse phylogénétique des cas de COVID-19 identifiés dans 3 États voisins des États-Unis (Wisconsin, Iowa et Minnesota). • Aucune déclaration de conflit d'intérêts n'est disponible.	• Les résultats de l'analyse phylogénétique révèlent une grande grappe d'une seule souche de SRAS-CoV-2 parmi les individus associés à une usine de conditionnement de viande à Postville, dans l'Iowa. • Depuis le 6 avril 2020, 27 cas viraux attribués à cette sous-souche ont été identifiés. Les auteurs pensent que cela ne représente qu'un échantillon des cas résultant de cette éclosion. • Des cas liés à cette éclosion ont été détectés dans 7 comtés de 3 États, touchant au total 13 municipalités. Cette région s'étend sur une superficie de 480 kilomètres carrés.

(Guenther et coll., 2020) *prépublication*	Investigation d'un événement de super-propagation précédant la plus grande éclosion de SRAS-CoV-2 liée à une usine de transformation de la viande en Allemagne	• Investigation épidémiologique rétrospective. • Réalisée du 16 mars au 25 avril 2020, dans le plus grand complexe de transformation de la viande en Allemagne. • Le complexe comprend 2 usines MPP-R et MPP-D. MPP-R effectue l'abattage et la transformation fine ainsi que le conditionnement de la viande bovine et porcine et MPP-D est une usine de transformation spécialisée dans le désossage des truies qui se trouve à 30 km de MPP-R.	• Les tests sériels effectués par les autorités sanitaires un mois après le premier cas ont permis d'identifier plus de 1400 cas positifs. • L'évaluation des séquences virales montre que tous les cas partagent un ensemble de 8 mutations de nucléotides uniques représentant une nouvelle sous-branche dans le clade C20 du SRAS-CoV-2. • La transmission initiale s'est produite dans une zone confinée d'une usine de transformation de viande bovine dans laquelle l'air est constamment recyclé et refroidi à 10°C. Le cas index a transmis le virus à plus de 60 % (17 sur 26) de leurs collègues dans un rayon de plus de 8 mètres pendant les postes de travail de 3 jours consécutifs. • Des relations statistiques ont également été identifiées pour un appartement partagé, une chambre à coucher et des groupes de covoiturage. Les corrélations entre le fait de travailler à moins de 8 mètres du cas index et le taux d'infection dans l'appartement, la chambre ou le groupe de covoiturage indiquent que la majorité des cas de transmission se seraient produits dans l'usine de transformation de viande bovine. • Les résultats indiquent qu'une distance physique de 2 mètres n'est pas suffisante pour empêcher la transmission dans cet environnement de faible échange d'air frais et de refroidissement continu, ce qui peut favoriser la transmission. Les auteurs recommandent des mesures supplémentaires telles que l'amélioration de la ventilation et de la circulation d'air, l'installation de dispositifs de filtrage et l'utilisation de masques faciaux de haute qualité pour réduire le risque d'infection dans ces environnements.
Autre usine			

(Jerkovic et coll., 2020) *prépublication*	Séroprévalence des anticorps anti-SRAS-CoV-2 chez des travailleurs d'usine en Split-Dalmatie et dans le comté de Šibenik-Knin, en Croatie	• Cette étude transversale a estimé la séroprévalence sur 1494 employés d'usine vivant dans la région de Split-Dalmatie et le comté de Šibenik-Knin (Croatie) et a été menée entre le 23 et le 28 avril 2020. • L'usine (groupe DIV) est spécialisée dans la production et le commerce de vis et d'autres pièces mécaniques et métalliques. Elle possède deux sites de production importants situés à Split (comté de Split-Dalmatie) et à Knin (comté de Šibenik-Knin), qui emploient respectivement environ 2200 et 400 personnes. • Les auteurs déclarent qu'il n'y a pas de conflit d'intérêts.	• À partir du 25 février 2020, le groupe DIV a mis en place des mesures de protection telles que la mise en place de stations de désinfection des mains dans toutes les pièces, des protocoles de nettoyage régulier des postes de travail, la fermeture des stations communes de vente de café et de nourriture, des contrôles de température, l'auto-isolation pour les personnes revenant de l'étranger et le travail à domicile pour une partie du personnel commercial et administratif. Le nombre total d'employés travaillant dans les usines a été réduit à environ 1300 et 300, respectivement. • Dans un échantillon total d'employés testés (n=1 494), des anticorps ont été détectés chez 1,27 % des participants (IC de 95 % : de 0,77 à 1,98 %). • Une partie des employés de l'usine de Split vivent sur la propriété de l'usine. • À l'usine de Split 13 sur 1316 (0,99 %, IC de 95 % : de 0,53 à 1,68 %) des participants ont été testés positifs, dont 13 sur 1079 (1,20 %, IC de 95 %) : de 0,64 à 2,05 %) des personnes qui vivaient en dehors de l'usine et 0 sur 237 (0 %, IC de 95 % : de 0 à 1,26 %) des personnes qui vivaient à l'intérieur des installations. À l'usine de Knin, 6 sur 178 (3,37 %, IC de 95 % : de 1,25 à 7,19 %) des participants ont été testés positifs aux anticorps. • Tous les participants vivants dans les locaux de l'usine et dont la mobilité était limitée pendant les mesures de confinement ont obtenu un résultat négatif au test de dépistage des anticorps. Par conséquent, l'exposition n'était probablement pas liée au logement sur le lieu de travail dans le cas de cette éclosion.
Travail des migrants			

(Koh, 2020a)	Les travailleurs migrants et la COVID-19	• Investigation épidémiologique rétrospective. • Les chiffres quotidiens des cas de COVID-19 à Singapour de mars à mai 2020 ont été analysés afin de déterminer la cause de l'augmentation des cas en avril 2020. La réglementation sur le logement des travailleurs migrants a été étudiée. • Les auteurs déclarent qu'il n'y a pas de conflit d'intérêts.	• La majorité des cas associés à un pic en avril 2020 se sont produits chez des travailleurs migrants peu qualifiés vivant dans des dortoirs de travailleurs étrangers. Au 6 mai 2020, il y avait 17 758 cas confirmés de COVID-19 parmi les travailleurs vivant en dortoirs (88 % des 20 198 cas confirmés au niveau national). • Dans un dortoir de 13 000 travailleurs environ, 2526 cas ont été confirmés, ce qui représente 12,5 % de tous les cas dans le pays. • La réponse nationale a consisté à soumettre les travailleurs vivant en dortoirs à des tests approfondis, à séparer les travailleurs sains des travailleurs infectés et à observer quotidiennement la fièvre et les symptômes. En outre, 24 dortoirs ont été déclarés « zones d'isolement » pour que les résidents soient mis en quarantaine pendant 14 jours. Des logements publics, des camps militaires, des centres d'exposition et des hôtels flottants ont été mis à la disposition des travailleurs, afin de permettre une distanciation sociale appropriée.
Centre de remise en forme			
(Jang et coll., 2020)	Grappe de maladies à coronavirus associée aux cours de danse de remise en forme, Corée du Sud	• Investigation épidémiologique rétrospective. • Une éclosion associée à un atelier national de professeurs de danse de remise en forme qui s'est tenu le 15 février 2020 à Cheonan, en Corée du Sud. • Aucune déclaration de conflit d'intérêts n'est disponible.	• Dans le cadre de l'atelier national des instructeurs de danse de remise en forme, les instructeurs se sont entraînés intensément pendant 4 heures. Sur les 27 instructeurs qui ont participé, 8 ont eu des résultats positifs à la RT-PCR pour l'infection par le SRAS-CoV-2. Tous étaient asymptomatiques le jour de l'atelier. • Le 9 mars 2020, 112 cas de COVID-19 associés à des cours de danse de remise en forme dans 12 installations sportives différentes ont été identifiés. Parmi eux, 82 (73,2 %) étaient symptomatiques et 30 (26,8 %) étaient asymptomatiques.

			• La transmission des instructeurs aux participants des cours de remise en forme a représenté 57 cas (50,9 %). La transmission au sein des familles des instructeurs et des élèves a donné lieu à 38 cas (33,9 %) alors que 17 cas (15,2 %) étaient dus à une transmission lors de réunions avec des collègues ou des connaissances. • Avant la fermeture des installations sportives, 217 élèves ont été exposés dans 12 installations, soit un taux d'attaque de 26,3 % (IC de 95 % : de 20,9 à 32,5%). • Les contacts étroits des instructeurs de remise en forme et des élèves ont fait l'objet d'un suivi (n=830) et 34 cas de COVID-19 ont été identifiés, ce qui se traduit par un taux d'attaque secondaire de 4,10 % (IC de 95 % : de 2,95 à 5,67%). Sur ces 34 cas, 418 contacts étroits ont été suivis et 10 cas quaternaires ont été identifiés, ce qui donne un taux d'attaque tertiaire de 2,39 % (IC de 95 % : de 1,30 à 4,35%). • Les cours de remise en forme à partir desquels les cas de COVID-19 secondaires ont été identifiés comprenaient de 5 à 22 élèves faisant 50 minutes d'exercice intense dans une salle d'environ 60 m^2. Aucun cas parmi les classes de moins de 5 participants n'a été identifié. • Un des instructeurs infectés a enseigné le Pilates et le yoga à des classes de 7 à 8 élèves dans le même établissement en même temps qu'un autre instructeur infecté, mais aucun de ses élèves n'a été testé positif pour le virus. • Les auteurs spéculent que la faible intensité du Pilates et du yoga n'a pas provoqué les mêmes effets de transmission que les cours de danse de remise en forme plus intenses.
Navires			

(Kakimoto et coll., 2020)	Investigation initiale sur la transmission de la COVID-19 parmi les membres d'équipage pendant la quarantaine d'un navire de croisière – Yokohama, Japon, février 2020	• Investigation épidémiologique rétrospective d'une éclosion sur le navire de croisière Diamond Princess de 3700 passagers et membres d'équipage qui a débuté le 3 février 2020. • Les auteurs déclarent qu'il n'y a pas de conflit d'intérêts.	• L'investigation sur la propagation du SRAS-CoV-2 parmi le personnel a conclu que l'infection s'était apparemment propagée parmi les personnes dont les cabines se trouvaient sur le même pont (pont 3) et qui travaillaient dans le même groupe professionnel (restauration), probablement par contact ou par propagation de gouttelettes, ce qui est conforme à la compréhension actuelle de la transmission de la COVID-19. • Huit des 20 membres d'équipage positifs avaient des compagnons de cabine, dont 5 sur 8 sont devenus positifs à la COVID-19.
(Addetia et coll., 2020)	Des anticorps neutralisants en corrélation avec la protection contre le SRAS-CoV-2 chez l'homme lors d'une éclosion sur un navire de pêche avec un taux d'attaque élevé	• Investigation épidémiologique rétrospective. • Cette étude décrit une éclosion de SRAS-CoV-2 sur un navire de pêche qui a quitté Seattle, Washington, en mai 2020. • Avant le départ du navire, les membres de l'équipage ont été soumis à un test de dépistage d'une infection active par le SRAS-CoV-2 par RT-PCR et à un test sérologique pour détecter les signes d'une infection antérieure ou en cours. • Les auteurs déclarent qu'il n'y a pas de conflit d'intérêts.	• Le taux d'attaque à bord était de 85,2 % (104 sur 122 individus). • Trois membres de l'équipage ont été testés positifs avant le départ du bateau lors du dépistage sérologique initial et ont présenté des anticorps neutralisants et réactifs aux pics lors des tests de suivi. Aucun de ces membres d'équipage n'a présenté de signes d'infection virale ou n'a éprouvé de symptômes pendant l'éclosion. • Les membres de l'équipage ayant des anticorps neutralisants provenant d'une infection antérieure ont été protégés contre la réinfection.
(Payne et coll., 2020)	Infections par le SRAS-CoV-2 et réponses sérologiques d'un échantillon de membres des services de la	• Enquête épidémiologique rétrospective sur une éclosion survenue sur le USS Theodore Roosevelt en mars/avril 2020 avec environ 1000 militaires à bord. • L'investigation s'est déroulée du 20 au 24 avril 2020, une fois le navire amarré à Guam.	• L'infection antérieure ou actuelle était plus élevée chez les participants qui ont déclaré avoir été en contact avec une personne connue comme ayant la COVID-19 (64,2 %), par rapport à ceux qui ne l'ont pas fait (41,7 %) (RC = 2,5; IC de 95 % = de 1,1 à 5,8). • La prévalence était également plus élevée chez les militaires qui ont déclaré avoir partagé la même

	marine américaine – USS Theodore Roosevelt, avril 2020	• Un échantillon commode de 382 (27 % du total des membres du service sur le navire ou à la base navale de Guam).
		• questionnaires, tests sérologiques et tests RT-PCR a été réalisé pour créer l'ensemble de données.
			couchette avec un membre d'équipage dont le test de dépistage était positif (65,6 %), par rapport à ceux qui ne l'ont pas fait (36,4 %) (RC = 3,3; IC de 95 % = de 1,8 à 6,1).
			• Le fait de prendre des mesures de protection était associé à un risque plus faible d'être positif à la COVID-19 :
			  • Revêtement du visage (55,8 % contre 80,8 %; RC = 0,3; IC de 95 % = de 0,2 à 0,5)
			  • Éviter les zones communes (53,8 % contre 67,5 %; RC = 0,6; IC de 95 % = de 0,4 à 0,9)
			  • Éloignement social (54,7 % contre 70,0 %; RC = 0,5; IC de 95 % = de 0,3 à 0,8)

Autres professions liées aux services			
(Liu et coll., 2020)	Analyse des cas de grappe de COVID-19 à Tianjin	• Données agrégées provenant d'investigations épidémiologiques rétrospectives. • Cette étude décrit toutes les grappes de cas de COVID-19 confirmés à Tianjin en date du 22 février 2020. • Les auteurs déclarent qu'il n'y a pas de conflit d'intérêts.	• Il y avait des grappes de familles (28 cas, 71 cas), des grappes d'unités (1 cas, 10 cas), des grappes de transport (3 cas, 8 cas) et une grappe de lieux publics (1 cas, 26 cas). • Une grappe dans la section passagers d'un train a impliqué 10 cas. Après des investigations épidémiologiques, il a finalement été déterminé que 2 employés ayant des antécédents de sorties à Wuhan étaient des cas de première génération. • L'éclosion dans un grand magasin était due à un vendeur infecté qui a contaminé 26 clients et collègues.
(Wu et coll., 2020)	Investigation et analyse sur les caractéristiques d'une grappe de COVID-19 associée à l'exposition dans	• Article en chinois. • Investigation épidémiologique rétrospective • Une éclosion associée à une exposition dans un grand magasin. • Les auteurs déclarent qu'il n'y a pas de conflit d'intérêts.	• Le premier cas confirmé d'employé du magasin a été enregistré le 31 janvier 2020. • Il y a 40 cas associés à un grand magasin, ce qui représente 75,47 % du nombre de cas confirmés (53 cas) dans la juridiction. • L'analyse a révélé que 6 cas (15 %) concernaient des employés d'un grand magasin, 19 cas (47,5 %) étaient

	un grand magasin de Tianjin		des clients du grand magasin et 15 cas (37,5 %) étaient des contacts étroits.
(Leffler et Hogan, 2020) *prépublication*	Dépendance de la mortalité due aux nouvelles maladies à coronavirus (COVID-19) en fonction de l'âge dans les populations fortement exposées : Travailleurs et résidents des transports en commun de New York et passagers du Diamond Princess	• Des données transversales provenant de plusieurs sources et milieux ont été obtenues et les données de mortalité ont été comparées. • Les auteurs ont utilisé des sources accessibles au public pour estimer la mortalité due à la COVID-19 pour chaque groupe d'âge sur le bateau de croisière Diamond Princess, aux États-Unis, dans la ville et l'État de New York, et parmi les travailleurs de la New York Metropolitan Transit Authority (MTA). • Les auteurs déclarent qu'il n'y a pas de conflit d'intérêts.	• À New York, la mortalité des travailleurs des transports en commun était estimée à 1 sur 7329 pour les 30 à 39 ans, 1 sur 1075 pour les 40 à 49 ans, 1 sur 343 pour les 50 à 59 ans et 1 sur 178 pour les 60 à 69 ans. • Parmi les travailleurs de la MTA décédés des suites de la COVID-19, 106 sur 109 personnes au 6 mai 2020, faisaient partie de la division des métros et des bus, qui compte 55000 employés. • Il n'est pas clair si la transmission de ces travailleurs s'est produite sur le lieu de travail ou en dehors du lieu de travail. • Parmi les travailleurs de la MTA de New York, plus de 6000 travailleurs (8 %) ont soit été testés positifs (plus de 2000), soit mis en quarantaine (4000 travailleurs).
(Lan et coll., 2020b) *prépublication*	Association entre l'infection par le SRAS-CoV-2, le risque d'exposition et la santé mentale au sein d'une cohorte de travailleurs essentiels du commerce de détail aux États-Unis	• Cette étude transversale a estimé la séroprévalence de 104 personnes employées dans une épicerie de détail de la région métropolitaine de Boston dans le Massachusetts, aux États-Unis, et a été menée pendant 3 jours consécutifs au début du mois de mai 2020. • Aucune déclaration de conflit d'intérêts n'est disponible.	• Parmi les travailleurs testés, 21 sur 104 (20 %) ont eu des tests viraux positifs. Parmi ceux-ci, 76 % des cas étaient asymptomatiques. • Les résultats d'une analyse multivariée révèlent que les employés directement exposés aux clients avaient cinq fois plus de chances d'obtenir un résultat positif au test de dépistage du SRAS-CoV-2 (RC de 4,7; IC de 95 % : de 1,2 à 32,0). Les fumeurs avaient 90 % de chances en moins d'être testés positifs (RC 0,1; IC de 95 % : de 0,01 à 0,8).

(Yang et coll., 2020)	L'analyse préliminaire sur les caractéristiques de la grappe pour la COVID-19	• Article en chinois. • Données agrégées provenant d'investigations épidémiologiques rétrospectives. • Cette étude décrit 377 investigations en grappes rétrospectives sur des infections par le SRAS-CoV-2 impliquant 1719 cas dans des établissements non médicaux entre le 1er janvier et le 20 février 2020. • Les auteurs déclarent qu'il n'y a pas de conflit d'intérêts.	• Sur les 377 grappes, le lieu probable où le SRAS-CoV-2 a été contracté a été attribué aux facteurs suivants : les grappes familiales représentaient 79 %, les repas pris ensemble 10 %, les centres commerciaux ou les supermarchés 6 %, les lieux de travail 3 % et les véhicules de transport 2 %. • Les détails des grappes de transmission sur le lieu de travail n'ont pas été présentés.
(Hendrix, Walde, Findley et Trotman, 2020)	Absence de transmission apparente du SRAS-CoV-2 par deux stylistes après une exposition dans un salon de coiffure appliquant une politique de couverture universelle du visage – Springfield, Missouri, mai 2020	• Investigation épidémiologique rétrospective. • Deux coiffeurs dans un seul salon au Missouri, aux États-Unis, ont interagi avec environ 139 clients alors qu'ils étaient infectés par le SRAS-CoV-2 en mai 2020. • Les clients et les coiffeurs portaient des masques. • Les auteurs déclarent qu'il n'y a pas de conflit d'intérêts.	• Sur les 139 clients qui ont été exposés, 67 ont été testés. • Aucun cas secondaire symptomatique n'a été signalé, ce qui est très probablement dû à l'utilisation de masques faciaux. • Taux d'attaque : 0/139
(Cai et coll., 2020)	Transmission indirecte du virus dans une grappe de cas de COVID-	• Investigation épidémiologique rétrospective sur une éclosion associée à un centre commercial à Wenzhou, en Chine.	• Après avoir identifié un cas positif, le centre commercial a été fermé le 22 janvier 2020. • Du 19 janvier au 9 février 2020, la COVID-19 a été diagnostiquée chez 7 employés et 10 clients du centre commercial.

	19, Wenzhou, Chine, 2020	• Les auteurs déclarent qu'il n'y a pas de conflit d'intérêts.	• Des contacts étroits associés au centre commercial ont été retracés, et la COVID-19 a été confirmée chez 11 personnes. • Une seule source commune n'a pas été identifiée, certains espaces communs ont été utilisés par des employés infectés, on soupçonne donc une exposition à la transmission de virus ou de fomites sous forme d'aérosol, peut-être en utilisant des toilettes ou un ascenseur commun.
(Szablewski et coll., 2020)	Transmission du SRAS-CoV-2 et infection parmi les participants à un camp de nuit – Géorgie, juin 2020	• Investigation épidémiologique rétrospective d'une éclosion associée à un camp de nuit en Géorgie, aux États-Unis. • Un camp de nuit (camp A) a été organisé pour l'orientation de 138 stagiaires et 120 membres du personnel du 17 au 20 juin 2020 • Les membres du personnel sont restés pour la première session du camp, prévue du 21 au 27 juin 2020, et ont été rejoints par 363 campeurs et 3 membres de la direction le 21 juin 2020. • Les auteurs déclarent qu'il n'y a pas de conflit d'intérêts.	• 597 résidents de Géorgie ont fréquenté le camp A. Parmi ceux qui ont été testés, 260 sur 344 (76 %) ont été déclarés positifs au SRAS-CoV-2. • Le taux d'attaque global était de 44 % (260/597), les membres du personnel ayant le taux d'attaque le plus élevé (56 %). Le taux d'attaque a augmenté avec la durée du séjour au camp. • L'occupation des 31 cabines était en moyenne de 15 personnes par cabine (fourchette de 1 à 26). Le taux d'attaque médian des cabines était de 50 % (fourchette de 22 à 70 %) parmi les 28 cabines qui ont connu un ou plusieurs cas. • Le camp a suivi toutes les recommandations du CDC, à l'exception de l'ouverture des fenêtres et des portes afin d'accroître la ventilation des bâtiments et du port de masques en tissu par les campeurs (mais le personnel portait des masques).
(Caban-Martinez et coll., 2020)	Épidémiologie des anticorps anti-SRAS-CoV-2 chez les pompiers et les paramédicaux d'un service	• Cette étude transversale a estimé la séroprévalence des anticorps anti-SRAS-CoV-2 chez 203 pompiers de première ligne/paramédicaux de Floride, aux États-Unis, données recueillies les 16 et 17 avril 2020.	• Sur les 203 pompiers/paramédicaux testés, 18 étaient positifs au SRAS-CoV-2 (8,9 %). • Le nombre moyen de contacts de cas de COVID-19 (c'est-à-dire à moins de 1,80 m d'une personne infectée pendant une durée ≥ 15 min) était significativement plus élevé (13,3 ±4,8 contacts de cas contre 7,31 ±4,8 contacts; p = 0,022) chez les pompiers

	d'incendie américain : étude transversale	• La recherche a été financée en partie par l'État de Floride, l'Administration fédérale de gestion des urgences et l'Institut national du cancer des National Institutes of Health. • Les auteurs déclarent qu'il n'y a pas de conflits d'intérêts.	et les paramédicaux qui étaient positifs aux anticorps du SRAS-CoV-2 que chez les pompiers dont les tests de dépistage aux anticorps étaient négatifs. • Parmi les pompiers/paramédicaux ayant obtenu un résultat positif, aucun n'a déclaré avoir reçu le vaccin annuel contre la grippe, comparé aux pompiers/paramédicaux ayant obtenu un résultat négatif aux anticorps du SRAS-CoV-2 (0,0 % contre 21,0 %; p = 0,027).
(Valencia et coll., 2020) *prépublication*	Transmissions asymptomatique et présymptomatique de l'infection du nouveau coronavirus 2019 (COVID-19) : une estimation à partir d'une grappe de cas confirmés à Hô Chi Minh Ville, au Vietnam	• Investigation épidémiologique rétrospective d'un rassemblement dans un bar à Hô Chi Minh Ville, au Vietnam. • Les informations démographiques, cliniques et de laboratoire de tous les cas confirmés de COVID-19 et les contacts d'un rassemblement de bar le 14 mars 2020 ont été recueillies. • Les auteurs déclarent qu'il n'y a pas de conflits d'intérêts.	• Sur les 298 personnes qui ont assisté à un rassemblement dans un bar à Hô Chi Minh Ville, 13 ont été testées positives au SRAS-CoV-2. • La recherche de contacts parmi 4466 personnes a permis d'identifier 6 autres cas. • Le R0 spécifique de la grappe était de 2,64 (IC de 90 % : de 1,41 à 3,68). • 3 contextes de transmission après une investigation sur le terrain ont été identifiés (bar, ménage, lieu de travail). Le bar constituait 68 %, le lieu de travail 21 %, et le ménage 11 % des transmissions. • Dans la deuxième génération, 3 (50 %) des transmissions étaient liées au lieu de travail, dont 2 (67 %) ont signalé des symptômes après avoir été exposés à un cas qui n'a pas signalé de symptômes.
(Bao et coll., 2020)	Éclosion de COVID-19 suite à l'exposition d'un seul patient sur un site de divertissement : Une étude épidémiologique	• Investigation épidémiologique rétrospective d'une éclosion associée à une piscine dans un lieu de divertissement à Wuhan, en Chine. • Les informations démographiques, cliniques et de laboratoire de tous les cas et contacts confirmés de COVID-19 ont été recueillies en janvier et février 2020.	• Un travailleur infecté par la COVID-19qui est rentré chez lui après avoir quitté Wuhan, a provoqué une éclosion en se rendant dans une piscine le 20 janvier, où il a infecté certains travailleurs et clients. • L'infection a ensuite été transmise par un employé de la piscine qui a continué de travailler et par un client qui a participé à une fête familiale et à un dîner avec des collègues.

		• Les auteurs déclarent qu'il n'y a pas de conflits d'intérêts.	• L'employé de piscine qui a continué de travailler jusqu'au 26 janvier a causé des infections par le SRAS-CoV-2 chez 12 clients. • Un dîner avec des collègues a réuni 36 collègues le 22 janvier. La personne infectée a chanté avec 7 collègues dans un espace fermé. L'infection des 7 collègues a été confirmée par la suite • Le taux d'attaque secondaire pour le dîner avec les collègues était de 20,5 (IC de 95 % : de 7,8 à 33,2). • Au total, 56 cas ont été confirmés dans 8 districts avec une population résidente de 3,9 millions de personnes.
Transport			
(Yang et coll., 2020)	Grappe de transmission de la COVID-19 en vol : une série de cas rétrospectifs	• Investigation épidémiologique rétrospective. • Cette étude décrit une grappe de transmission de la COVID-19 en vol. • Les données ont été collectées du 25 janvier au 28 février 2020. • Les politiques de masques faciaux n'ont pas été mises en œuvre à l'époque de cette grappe. • Les auteurs déclarent qu'il n'y a pas de conflit d'intérêts.	• Après un vol, 12 cas de COVID-19 ont été identifiés et associés au vol. • Aucun agent de bord n'a été infecté, ce qui démontre l'absence de transmission aux agents de bord.
(Pongpirul , Pongpirul, Ratnarathon et Prasithsirikul, 2020)	Voyage d'un chauffeur de taxi thaïlandais et nouveau Coronavirus	• Cette étude de cas décrit une infection par le SRAS-CoV-2 chez un chauffeur de taxi en Thaïlande en janvier 2020. • Aucune déclaration de conflit d'intérêts n'est disponible.	• Le chauffeur de taxi est tombé malade le 20 janvier 2020 et s'est rendu dans une clinique de soins primaires le 23 janvier 2020. • Il a rapporté avoir été en contact avec des touristes chinois dans son taxi qui toussaient fréquemment, mais qui portaient des masques. Il n'avait aucun antécédent de voyage en Chine.
Autre ou combiné			

(Qian et coll., 2020) *prépublication*	Transmission du SRAS-CoV-2 à l'intérieur	• Données agrégées provenant d'investigations épidémiologiques rétrospectives. • Cette étude a analysé toutes les éclosions impliquant trois cas ou plus signalées par les commissions sanitaires municipales en Chine du 4 janvier au 11 février. • Les travaux ont été financés par le Conseil des bourses de recherche de Hong et la Fondation nationale des sciences naturelles de Chine. Les auteurs ne déclarent aucun conflit d'intérêts.	• 318 éclosions intérieures sont décrites dans 120 villes. • 80 % des éclosions ont concerné moins de 5 personnes. • Les lieux où les éclosions sont apparues ont été divisés en 6 catégories : 79,9 % se sont produits dans un ménage, suivis de 34 % dans les transports, 4,4 % au restaurant, 2,2 % dans un centre commercial et 9,7 % dans d'autres lieux. De nombreuses éclosions ont impliqué plus d'une catégorie de lieux.
(Nishiura et coll., 2020) *prépublication*	Les environnements fermés facilitent la transmission secondaire de la maladie à coronavirus 2019 (COVID-19)	• Données agrégées provenant d'investigations épidémiologiques rétrospectives. • Cette étude rapporte les données épidémiologiques de 11 grappes de 110 cas au total qui se sont produites au Japon à partir du 26 février 2020 : 4 à Tokyo et 1 dans chacune des préfectures de Aichi, Fukuoka, Hokkaido, Ishikawa, Kanagawa et Wakayama. • Les auteurs déclarent qu'il n'y a pas de conflit d'intérêts.	• Toutes les grappes étaient associées à des environnements intérieurs : gymnase, restaurant, hôpital et un festival où l'on mangeait sous des tentes. • Les informations quant à savoir si les cas étaient des employés ou des clients n'ont pas été fournies. • Cette étude a estimé que la probabilité de transmettre dans un environnement fermé par rapport à un environnement en plein air avait un OR de 18,7 (IC de 95 % de 6,0 à 57,9). • Cette analyse n'a pas permis de contrôler les facteurs de confusion ou l'interaction potentielle avec d'autres indicateurs. La définition d'« environnement en plein air » n'a pas été décrite
(Pung et coll., 2020)	Investigation sur trois grappes de COVID-19 à Singapour : implications pour les mesures de surveillance et de réaction	• Investigation épidémiologique rétrospective de 3 grappes liées à un groupe de touristes chinois, une conférence d'entreprise et une église à Singapour en février 2020. • Les auteurs déclarent qu'il n'y a pas de conflit d'intérêts.	• L'analyse a révélé que 36 cas de COVID-19 confirmés ont été liés à 3 grappes locales, composées de 11, 20 et 5 personnes. • La première éclosion a touché 11 personnes d'un groupe de touristes venus de Chine. Cinq assistants d'un magasin où le groupe de touristes s'est arrêté ont été testés positifs au SRAS-CoV-2. Les assistants ont indiqué qu'ils aidaient les clients à appliquer des

			échantillons d'huile médicinale sur leur corps, et que le lavage des mains n'était généralement pas effectué entre les clients. • La deuxième grappe a été une conférence à laquelle ont assisté au moins 111 participants de 19 pays différents, du 20 au 22 janvier 2020. Vingt personnes ont été infectées. Cinq des cas ont été assis à la même table lors d'un dîner de type banquet durant trois heures et quatre autres cas ont participé à une réunion de quatre heures.
(Furuse et coll., 2020)	Grappes de maladies à coronavirus dans les communautés, Japon, de janvier à avril 2020	• Investigation épidémiologique rétrospective de 3184 cas au Japon signalés entre le 15 janvier et le 4 avril 2020. • Les auteurs déclarent qu'il n'y a pas de conflit d'intérêts.	• Pendant cette période, 61 grappes de cas ont été identifiées dans des établissements de soins de santé (18 grappes), d'autres établissements de soins tels que des maisons de repos et des centres de soins de jour (10), des restaurants et des bars (10), des lieux de travail (8), des événements musicaux (7), des gymnases (5), des fonctions cérémonielles (2) et un incident lié au transport dans un avion (1). • La plus grande grappe non liée aux soins de santé observée concernait plus de 30 personnes ayant assisté à un concert de musique en direct, y compris les artistes, les membres du public et le personnel de l'événement. • Les auteurs identifient 22 patients primaires probables responsables de ces grappes. La plupart d'entre eux étaient âgés de 20 à 39 ans et étaient présymptomatiques ou asymptomatiques au moment de la transmission.
(Ministère de la Santé Manatū	COVID-19 – grappes importantes	• Le gouvernement néo-zélandais a dressé une liste des grappes importantes en Nouvelle-Zélande en date du 17 août 2020. • Aucun détail épidémiologique sur les grappes n'a été fourni.	• Les grappes signalées dans les lieux de travail potentiels sont les suivants : mariage, lieu d'accueil, conférence et bateau de croisière.

Hauora, 2020)			
(Département de la santé publique et de l'environnement du Colorado, 2020)	Données sur les éclosions	• Liste de toutes les éclosions confirmées de COVID-19 signalées dans le Colorado, aux États-Unis, au 12 août 2020. • Aucun détail épidémiologique sur les grappes n'a été fourni.	• Des grappes ont été signalées dans de multiples lieux de travail potentiels dans le Colorado, aux États-Unis. Quelques exemples : sites de construction, prison, centre de distribution, services de blanchisserie, entrepôt de pommes de terre, usine de transformation de la viande, usine d'aliments pour chiens, épicerie, etc.
(Kim, 2020)	Distanciation sociale et directives de santé publique sur les lieux de travail en Corée : réponses à la maladie à coronavirus-19	• Données agrégées provenant d'investigations épidémiologiques rétrospectives. • Cette étude résume les politiques publiques et du lieu de travail en réponse à la COVID-19 en Corée. • Une vue d'ensemble des éclosions sur le lieu de travail pendant la période du 20 janvier au 15 mai 2020 est décrite à l'aide des données du Centre coréen de contrôle des maladies et du siège central de gestion des catastrophes. • Les auteurs déclarent qu'il n'y a pas de conflit d'intérêts.	Transmission sur le lieu de travail en Corée : • Sur les 11 018 cas de COVID-19 identifiés au 15 mai 2020, 15,7 % se sont produits sur des lieux de travail tels que des établissements de soins de santé, des centres d'appel, des clubs sportifs, des karaokés et des lieux de vie nocturne • 111 cas ont été associés à des clubs de remise en forme après l'infection des instructeurs lors d'un atelier (Jang et coll., 2020) • 192 cas ont été associés à l'éclosion dans un centre d'appel • 95 cas sont liés au service public (par exemple, le service de santé, les agents correctionnels, les pompiers et la police). Cependant, la raison de leur exposition n'a pas été identifiée. • Des lignes directrices ont été élaborées avant le 29 février 2020 et sont considérées comme ayant été efficaces pour limiter la transmission sur le lieu de travail après leur mise en œuvre. Le ministère de l'Emploi et du Travail a inclus des directives sur le lieu de travail portant sur la COVID-19 :

			• Distanciation sociale, horaires de travail flexibles, identification précoce des travailleurs suspectés d'être infectés et désinfection des lieux de travail • Pour prévenir la propagation de l'infection sur le lieu de travail, les lignes directrices suggèrent d'éviter les réunions en face à face, les voyages d'affaires, l'éducation et la formation
Revue			
(Prakash, 2020) *prépublication*	Manger, prier, travailler : une méta-analyse du risque de transmission de la COVID-19 dans les activités communes de travail et de loisirs	• Revue documentaire. • L'auteur a rassemblé des données provenant d'études de cas (20 situations et 425 cas) recueillies par le biais d'une revue documentaire afin d'identifier les schémas de transmission et d'estimer les taux d'attaque. • L'auteur a voulu étudier les activités sociales qui pourraient comporter un risque de transmission de COVID-19 après l'assouplissement des mesures de confinement par le gouvernement. • Les méthodes de revue et d'analyse documentaires manquent de détails et de clarté. Aucune déclaration de conflit d'intérêts n'est disponible.	• Les événements tels que les dîners de famille et les réunions de travail ont un taux d'attaque plus élevé et, par conséquent, comportent des risques importants. • Au total, 20 situations ayant entraîné 418 infections dans 32 cas pour 44 personnes sont décrites ci-dessous. • Situation (taux de transmission) : o Repas/événements familiaux (de 15,7 % à 66,7 %) o Réunions – réunion privée d'une heure (72,7 %, IC de 95 % : de 43,6 à 98,0 %) o Espace de travail ouvert avec mouvement de personnes (78,7 %, IC de 95 % : de 70,3 à 85,3%) o Chant – pratique de 2 heures (86,7 %, IC de 95 % : de 76,2 à 93,2%) o Service de prière (a entraîné 1 à 7 infections secondaires par personne infectée) o Voyager en voiture (environnement fermé) et parler présentait un risque élevé (100 %, IC de 95 % : de 20 à 100%) o Transports publics, port d'un masque sans parler (0 %) o Hôtels (53,3 %, IC de 95 % : de 30,1 à 75,2 %)/Bateaux de croisière (28,1 %, IC de 95 % : de 27,3 à 29,0 %) où l'espace est partagé pendant des jours

			○ Interaction directe avec un agent de vente infecté (25,0 %, IC de 95 % : de 10,2 à 49,5%) ○ Discothèque, taux d'attaque parmi les contacts directs >50 %, parmi les clients de la discothèque (6,27 %, IC de 95 % : de 5,15 à 7,61%) ○ Taux d'attaque global dans les restaurants (9,9 %, IC de 95 % : de 5,3 à 17,7 %) par rapport à ceux des personnes infectées ensuite (45 %, IC de 95 % : de 25,8 à 65,8%) • Parmi tous ces événements de super-propagation, le nombre d'infections causées dépend du nombre de contacts étroits et dans la plupart des cas, le patient zéro n'était pas détectable au moment de la transmission.

ÉLÉMENTS DE PREUVE DE GRAPPES DE COVID-19 DANS DES LOGEMENTS FOURNIS PAR L'EMPLOYEUR

Dans certaines professions, le logement est fourni aux travailleurs. En général, le logement partagé entraîne un contact étroit des travailleurs pendant de longues périodes. Huit publications sur la COVID-19 dans des lieux de travail où l'employeur a fourni un logement ont été identifiées (tableau 3). Dans la plupart de ces investigations, il n'est pas possible de séparer le risque de transmission dû à la vie en communauté du risque lié aux activités sur le lieu de travail. Cependant, les taux d'attaque élevés parmi les travailleurs dans les lieux de vie en communauté soulignent que la transmission se produit dans des situations où les gens passent du temps ensemble et où le nombre de contacts (ou la densité de personnes) est associé au nombre d'événements de transmission qui peuvent se produire dans un cadre donné.

- Deux résumés séquentiels de 264 éclosions survenues dans des usines de transformation de la viande jusqu'au 31 mai 2020 aux États-Unis ont indiqué que le partage des locaux était un facteur de risque de transmission du SRAS-CoV-2, mais ces résumés ne fournissent pas de données spécifiques sur le nombre d'éclosions où le partage des locaux était un facteur potentiel ou sur les investigations qui en ont résulté (Dyal et coll., 2020; Waltenburg et coll., 2020).

- Une éclosion associée à l'hébergement partagé des employés sur un bateau de croisière (le Diamond Princess) où les colocataires et les personnes qui travaillaient avec des cas infectés étaient plus susceptibles d'être infectés. Une autre éclosion sur un bateau de pêche a eu un taux d'attaque de 85 % (N=122) sur le petit bateau pendant ses 16 jours en mer malgré un dépistage préalable de l'infection par le SRAS-CoV-2. La troisième éclosion s'est produite sur un navire de la marine américaine. L'investigation a révélé une probabilité plus élevée de résultats positifs chez les personnes ayant déclaré avoir partagé la même couchette avec un membre d'équipage dont les résultats étaient positifs, RC = 3,3; IC de 95 % = de 1,8 à 6,1 (Payne et coll., 2020).
- Lors du pic initial de l'éclosion de cas de COVID-19 à Singapour, 88 % (17 758 sur 20 198 au 6 mai 2020) des cas nationaux ont été attribués à des travailleurs migrants peu qualifiés vivant dans des dortoirs pour travailleurs étrangers.
- Lors d'une éclosion dans un camp d'été avec hébergement partagé, le taux d'attaque des membres du personnel a augmenté avec la durée du séjour dans le camp. Les gens séjournaient dans des cabines; il y avait en moyenne 15 personnes par cabine (fourchette entre 1 et 26). Le taux d'attaque médian des cabines était de 50 % (fourchette de 22 à 70 %) parmi les 28 cabines qui présentaient un ou plusieurs cas suggérant une association entre le risque de transmission et le fait de séjourner dans une cabine.
- Une étude de séroprévalence réalisée dans une usine spécialisée dans la production de pièces mécaniques où 237 sur 1316 employés vivaient dans les installations de l'usine a déterminé qu'aucun des 13 travailleurs présentant des anticorps IgG (antécédents d'infection par le SRAS-CoV-2) ne faisait partie des personnes vivant dans les installations de l'établissement.

Tableau 3. Huit publications sur la COVID-19 dans un lieu de travail où l'employeur fournissait l'hébergement.

(Jerkovic et coll., 2020) *prépublication*	Séroprévalence des anticorps anti-SRAS-CoV-2 chez des travailleurs d'usine en Split-Dalmatie et dans le comté de	• Cette étude transversale a estimé la séroprévalence sur 1494 employés d'usine vivant dans la région de Split-Dalmatie et le comté de Šibenik-Knin (Croatie) et a été menée entre le 23 et le 28 avril 2020. • L'usine (groupe DIV) est spécialisée dans la production et le commerce de vis et d'autres pièces mécaniques et métalliques. Elle possède deux sites de production	• À partir du 25 février 2020, le groupe DIV a mis en place des mesures de protection telles que la mise en place de stations de désinfection des mains dans toutes les pièces, des protocoles de nettoyage régulier des postes de travail, la fermeture des stations communes de vente de café et de nourriture, des contrôles de température, l'auto-isolation pour les personnes revenant de l'étranger et le travail à domicile pour une partie du personnel commercial et

	Šibenik-Knin, en Croatie	importants situés à Split (comté de Split-Dalmatie) et à Knin (comté de Šibenik-Knin), qui emploient respectivement environ 2200 et 400 personnes. • Les auteurs déclarent qu'il n'y a pas de conflit d'intérêts.	administratif. Le nombre total d'employés travaillant dans les usines a été réduit à environ 1300 et 300, respectivement. • Dans un échantillon total d'employés testés (n=1 494), des anticorps ont été détectés chez 1,27 % des participants (IC de 95 % : de 0,77 à 1,98 %). • Une partie des employés de l'usine de Split vivent sur la propriété de l'usine. • À l'usine de Split 13 sur 1316 (0,99 %, IC de 95 % : de 0,53 à 1,68 %) des participants ont été testés positifs, dont 13 sur 1079 (1,20 %, IC de 95 % : de 0,64 à 2,05 %) des personnes qui vivaient en dehors de l'usine et 0 sur 237 (0 %, IC de 95 % : de 0 à 1,26 %) des personnes qui vivaient à l'intérieur des installations. À l'usine de Knin, 6 sur 178 (3,37 %, IC de 95 % : de 1,25 à 7,19 %) des participants ont été testés positifs aux anticorps. Tous les participants vivants dans les locaux de l'usine et dont la mobilité était limitée pendant les mesures de confinement ont obtenu un résultat négatif au test de dépistage des anticorps. Par conséquent, l'exposition n'était probablement pas liée au logement sur le lieu de travail dans le cas de cette éclosion,
(Koh, 2020a)	Les travailleurs migrants et la COVID-19	• Investigation épidémiologique rétrospective. • Les chiffres quotidiens des cas de COVID-19 à Singapour de mars à mai 2020 ont été analysés afin de déterminer la cause de l'augmentation des cas en avril. La réglementation sur le logement des travailleurs migrants a été étudiée. • Les auteurs déclarent qu'il n'y a pas de conflit d'intérêts.	• La majorité des cas associés à un pic en avril se sont produits chez des travailleurs migrants peu qualifiés vivant dans des dortoirs de travailleurs étrangers. Au 6 mai 2020, il y avait 17 758 cas confirmés de COVID-19 parmi les travailleurs vivant en dortoirs (88 % des 20 198 cas confirmés au niveau national). • Dans un dortoir de 13 000 travailleurs environ, 2526 cas ont été confirmés, ce qui représente 12,5 % de tous les cas dans le pays. • La réponse nationale a consisté à soumettre les travailleurs vivant en dortoirs à des tests approfondis, à

			séparer les travailleurs sains des travailleurs infectés et à observer quotidiennement la fièvre et les symptômes. En outre, 24 dortoirs ont été déclarés « zones d'isolement » pour que les résidents soient mis en quarantaine pendant 14 jours. Des logements publics, des camps militaires, des centres d'exposition et des hôtels flottants ont été mis à la disposition des travailleurs, afin de permettre une distanciation sociale appropriée.
(Dyal et coll., 2020)	Présence de la COVID-19 au sein des travailleurs d'usines de transformation de la viande et de la volaille — 19 États, avril 2020	• Données agrégées provenant d'investigations épidémiologiques rétrospectives. • Le rapport fournit des données agrégées sur les cas positifs de COVID-19 parmi 115 usines de transformation de la viande et de la volaille dans 19 États américains jusqu'au 27 avril 2020. • Aucun conflit d'intérêts potentiel n'a été révélé.	• Parmi les quelque 130 000 travailleurs de ces installations, 4 913 cas (environ 3,0 %) et 20 d'entre eux sont décédés. • Ces chiffres reflètent les pratiques inadéquates de contrôle des infections suivies dans ces installations, notamment une faible distance sociale, des mesures de contrôle à la source (par exemple, l'utilisation de couvre-visages en tissu) et une charge de travail accrue. • Les facteurs de risque d'infection identifiés sont les difficultés liées à l'éloignement physique, à l'hygiène et aux conditions de vie et de transport surpeuplées (de nombreux travailleurs vivent dans des lieux surpeuplés et multigénérationnels et partagent parfois le transport pour se rendre au travail et en revenir).
(Waltenburg et coll., 2020)	Mise à jour : Présence de la COVID-19 au sein des travailleurs d'usines de transformation de la viande et de la volaille — 19	• Données agrégées provenant d'investigations épidémiologiques rétrospectives. • Ceci est une mise à jour du rapport ci-dessus. • Le rapport fournit des données agrégées sur les cas positifs de COVID-19 parmi 239 usines de transformation de la viande	• Dans 239 usines il y a eu 16 233 cas de COVID-19 et 86 décès liés à la COVID-19 parmi les travailleurs (264 usines / 17 358 cas / 91 décès dans les deux publications (Dyal et coll., 2020; Waltenburg et coll., 2020)). • Parmi les 14 États ayant déclaré le nombre total de travailleurs dans les usines de transformation de la viande et de la volaille touchées (112 616), la COVID-19 a été diagnostiquée chez 9,1 % des travailleurs.

	États, avril à mai 2020	et de la volaille dans 23 États américains jusqu'au 31 mai 2020. • Aucun conflit d'intérêts potentiel n'a été révélé.	• Sur 9919 (61 %) cas dont la race/ethnicité a été signalée, 87 % concernaient des travailleurs issus de minorités raciales et ethniques. • Les facteurs qui augmentent le risque d'exposition pour ces travailleurs comprennent un contact étroit et prolongé sur le lieu de travail avec des collègues (à moins de 1,80 m pour une durée ≥15 minutes) pendant de longues périodes (équipes de travail de 8 à 12 heures), des espaces de travail partagés, un transport partagé pour se rendre au lieu de travail et en revenir, un logement collectif et des contacts communautaires fréquents avec des collègues. • Les données provenant de 111 usines dans 14 États révèlent la mise en œuvre des stratégies de prévention et de contrôle suivantes : dépistage des travailleurs à l'entrée (89 sur 111), obligation pour tous les travailleurs de porter un couvre-visage (86 sur 111), augmentation de la disponibilité des postes d'hygiène des mains (72 sur 111), sensibilisation des travailleurs à la propagation communautaire (70 sur 111), installation de barrières physiques entre les travailleurs (69 sur 111), offre de tests aux employés (41 sur 111) et fermeture temporaire (24 sur 111). • En utilisant les données de 7 usines qui ont mis en place des tests à l'échelle de l'usine, la prévalence brute des infections asymptomatiques ou présymptomatiques parmi les 5572 travailleurs qui ont été testés positifs à l'infection par le SRAS-CoV-2 était de 14,4 %.
(Kakimoto et coll., 2020)	Investigation initiale sur la transmission de la COVID-19 parmi	• Investigation épidémiologique rétrospective d'une éclosion sur le navire de croisière Diamond Princess de 3700	• L'investigation sur la propagation du SRAS-CoV-2 parmi le personnel a conclu que l'infection s'était apparemment propagée parmi les personnes dont les cabines se trouvaient sur le même pont (pont 3) et qui

	les membres d'équipage pendant la quarantaine d'un navire de croisière – Yokohama, Japon, février 2020	passagers et membres d'équipage qui a débuté le 3 février 2020. • Les auteurs déclarent qu'il n'y a pas de conflit d'intérêts.	travaillaient dans le même groupe professionnel (restauration), probablement par contact ou par propagation de gouttelettes, ce qui est conforme à la compréhension actuelle de la transmission de la COVID-19. • Huit des 20 membres d'équipage positifs avaient des compagnons de cabine, dont 5 sur 8 sont devenus positifs à la COVID-19.
(Addetia et coll., 2020)	Des anticorps neutralisants en corrélation avec la protection contre le SRAS-CoV-2 chez l'homme lors d'une éclosion sur un navire de pêche avec un taux d'attaque élevé	• Investigation épidémiologique rétrospective. • Cette étude décrit une éclosion de SRAS-CoV-2 sur un navire de pêche qui a quitté Seattle, Washington, en mai 2020. • Avant le départ du navire, les membres de l'équipage ont été soumis à un test de dépistage d'une infection active par le SRAS-CoV-2 par RT-PCR et à un test sérologique pour détecter les signes d'une infection antérieure. • Les auteurs déclarent qu'il n'y a pas de conflit d'intérêts.	• Le taux d'attaque à bord était de 85,2 % (104 sur 122 individus) et la métagénomique suggère que l'éclosion provient d'une seule source. • Les données de l'éclosion ne donnent que peu d'informations sur la dynamique probable de la transmission sur le bateau, mais le taux d'attaque élevé indique que la plupart des personnes ont probablement été exposées. • 3 personnes ayant des anticorps neutralisants avant le départ du navire n'ont pas été réinfectées sur la base des éléments de preuve présentés, indiquant qu'elles avaient probablement une certaine protection.
(Payne et coll., 2020)	Infections par le SRAS-CoV-2 et réponses sérologiques d'un échantillon de membres des services de la marine américaine – USS Theodore Roosevelt, avril 2020	• Enquête épidémiologique rétrospective sur une éclosion survenue sur l'USS Theodore Roosevelt en mars/avril 2020 avec environ 1000 militaires à bord. • L'investigation s'est déroulée du 20 au 24 avril 2020, une fois le navire amarré à Guam. • Un échantillon commode de 382 (27 % du total des membres du service sur le navire ou à la base navale de Guam).	• L'infection antérieure ou actuelle était plus élevée chez les participants qui ont déclaré avoir été en contact avec une personne connue comme ayant la COVID-19 (64,2 %), par rapport à ceux qui ne l'ont pas fait (41,7 %) (RC = 2,5; IC de 95 % = de 1,1 à 5,8). • La prévalence était également plus élevée chez les militaires qui ont déclaré avoir partagé la même couchette avec un membre d'équipage dont le test de dépistage était positif (65,6 %), par rapport à ceux qui ne l'ont pas fait (36,4 %) (RC = 3,3; IC de 95 % = de 1,8 à 6,1).

		• questionnaires, tests sérologiques et tests RT-PCR a été réalisé pour créer l'ensemble de données.
		• Les auteurs déclarent qu'il n'y a pas de conflit d'intérêts.
			• Le fait de prendre des mesures de protection était associé à un risque plus faible d'être positif à la COVID-19 :
			  • Revêtement du visage (55,8 % contre 80,8 %; RC = 0,3; IC de 95 % = de 0,2 à 0,5)
			  • Éviter les zones communes (53,8 % contre 67,5 %; RC = 0,6; IC de 95 % = de 0,4 à 0,9)
			  • Distanciation sociale (54,7 % contre 70,0 %; RC = 0,5; IC de 95 % = de 0,3 à 0,8)

(Szablewski et coll., 2020)	Transmission du SRAS-CoV-2 et infection parmi les participants à un camp de nuit – Géorgie, juin 2020	• Investigation épidémiologique rétrospective d'une éclosion associée à un camp de nuit en Géorgie, aux États-Unis • Un camp de nuit (camp A) a été organisé pour l'orientation de 138 stagiaires et 120 membres du personnel du 17 au 20 juin 2020. • Les membres du personnel sont restés pour la première session du camp, prévue du 21 au 27 juin 2020, et ont été rejoints par 363 campeurs et 3 membres de la direction le 21 juin 2020. • Les auteurs déclarent qu'il n'y a pas de conflit d'intérêts.	• 597 résidents de Géorgie ont fréquenté le camp A. Parmi ceux qui ont été testés, 260 sur 344 (76 %) ont été déclarés positifs au SRAS-CoV-2. • Le taux d'attaque global était de 44 % (260/597), les membres du personnel ayant le taux d'attaque le plus élevé (56 %). Le taux d'attaque a augmenté avec la durée du séjour au camp. • L'occupation des 31 cabines était en moyenne de 15 personnes par cabine (fourchette de 1 à 26). Le taux d'attaque médian des cabines était de 50 % (fourchette de 22 à 70 %) parmi les 28 cabines qui ont connu un ou plusieurs cas. • Le camp a suivi toutes les recommandations du CDC, à l'exception de l'ouverture des fenêtres et des portes afin d'accroître la ventilation des bâtiments et du port de masques en tissu par les campeurs. Le personnel était censé utiliser des masques en tissu et les campeurs étaient en cohorte, mais le respect de ces mesures de prévention n'a pas pu être évalué.

ÉLÉMENTS DE PREUVE DE GRAPPES DE COVID-19 DANS LE TRANSPORT OU LES DÉPLACEMENTS VERS LE LIEU DE TRAVAIL

Il existe peu de données sur les grappes de COVID-19 résultant du transport ou des déplacements vers le lieu de travail. Cinq publications relatives à la COVID-19 ont été identifiées sur ce sujet (tableau 4).

- Deux publications résument 264 éclosions associées à des usines de transformation de la viande aux États-Unis jusqu'au 31 mai 2020. Le transport partagé vers et depuis le lieu de travail a été déterminé comme un facteur de risque d'exposition au SRAS-CoV-2 (Dyal et coll., 2020; Waltenburg et coll., 2020). Cependant, aucune donnée spécifique n'est présentée.
- Lors d'une éclosion dans un espace de travail combiné de bureau militaire et civil, aucun des 150 collègues qui ont été exposés pendant trois jours au cours du covoiturage n'a développé de symptômes ou n'a été considéré comme infecté (Hall et coll., 2020).
- Une étude sur les facteurs de risque d'infection par la COVID-19 au Royaume-Uni et aux États-Unis a révélé que les risques d'infection étaient nettement plus élevés chez les travailleurs américains qui utilisent les transports publics pour se rendre au travail. Ce résultat va dans le même sens, mais n'est pas significatif pour les répondants britanniques. Les raisons de cette différence peuvent être liées à la différence des mesures de santé publique mises en œuvre dans les zones étudiées (Anand et coll., 2020).

Tableau 4. Cinq publications sur la COVID-19 relatives au transport ou aux déplacements du domicile au travail.

Référence	Titre de la publication	Détails de l'étude	Résultats pertinents
(Hall et coll., 2020)	Investigation des cas de COVID-19 et des cas contacts dans un espace de travail de bureau	• Investigation épidémiologique rétrospective menée en mars 2020. • L'éclosion s'est produite aux États-Unis dans un espace de travail comprenant à la fois des bureaux militaires et des bureaux civils. • Aucune déclaration de conflit d'intérêts n'est disponible.	• Le cas index a involontairement exposé 150 collègues au SRAS-CoV-2 en participant à des covoiturages, des conférences et de petites réunions sur une période de 3 jours. • Sur les 150 expositions, 37 ont été considérées comme un risque moyen et 113 comme un risque faible. 5 personnes ont signalé des symptômes de type COVID-19 et 5 ont développé des symptômes pendant la quarantaine de 14 jours. Aucun des contacts n'a été testé positif à une infection par le SRAS-CoV-2.

			• Aucun des collègues exposés pendant le covoiturage n'a développé de symptômes et malgré le contact étroit, il semble qu'ils n'ont pas été infectés. • L'identification rapide des personnes exposées au risque d'infection et la mise en œuvre ultérieure d'efforts d'atténuation et de contrôle ont permis de contrôler la propagation du SRAS-CoV-2.
(Dyal et coll., 2020)	Présence de la COVID-19 au sein des travailleurs d'usines de transformation de la viande et de la volaille — 19 États, avril 2020	• Données agrégées provenant d'investigations épidémiologiques rétrospectives. • Le rapport fournit des données agrégées sur les cas positifs de COVID-19 parmi 115 usines de transformation de la viande et de la volaille dans 19 États américains jusqu'au 27 avril 2020. • Aucun conflit d'intérêts potentiel n'a été révélé.	• Parmi les quelque 130 000 travailleurs de ces installations, 4 913 cas (environ 3,0 %) et 20 d'entre eux sont décédés. • Ces chiffres reflètent les pratiques inadéquates de contrôle des infections suivies dans ces installations, notamment une faible distance sociale, des mesures de contrôle à la source (par exemple, l'utilisation de couvre-visages en tissu) et une charge de travail accrue. • Les facteurs de risque d'infection identifiés sont les difficultés liées à l'éloignement physique, à l'hygiène et aux conditions de vie et de transport surpeuplées (de nombreux travailleurs vivent dans des lieux surpeuplés et multigénérationnels et partagent parfois le transport pour se rendre au travail et en revenir).
(Waltenburg et coll., 2020)	Mise à jour : Présence de la COVID-19 au sein des travailleurs d'usines de transformation de la viande et de la volaille — 19 États, avril à mai 2020	• Données agrégées provenant d'investigations épidémiologiques rétrospectives. • Ceci est une mise à jour du rapport ci-dessus. • Le rapport fournit des données agrégées sur les cas positifs de COVID-19 parmi 239 usines de transformation de la viande et de la volaille dans 23 États américains jusqu'au 31 mai 2020.	• Dans 239 usines, il y a eu 16 233 cas de COVID-19 et 86 décès liés à la COVID-19 parmi les travailleurs (264 usines / 17 358 cas / 91 décès dans les deux publications (Dyal et coll., 2020; Waltenburg et coll., 2020)). • Parmi les 14 États ayant déclaré le nombre total de travailleurs dans les usines de transformation de la viande et de la volaille touchées (112 616), la COVID-19 a été diagnostiquée chez 9,1 % des travailleurs.

		• Aucun conflit d'intérêts potentiel n'a été révélé.	• Sur 9919 (61 %) cas dont la race/ethnicité a été signalée, 87 % concernaient des travailleurs issus de minorités raciales et ethniques. • Les facteurs qui augmentent le risque d'exposition pour ces travailleurs comprennent un contact étroit et prolongé sur le lieu de travail avec des collègues (à moins de 1,80 m pour une durée ≥15 minutes) pendant de longues périodes (équipes de travail de 8 à 12 heures), des espaces de travail partagés, un transport partagé pour se rendre au lieu de travail et en revenir, un logement collectif et des contacts communautaires fréquents avec des collègues. • Les données provenant de 111 usines dans 14 États révèlent la mise en œuvre des stratégies de prévention et de contrôle suivantes : dépistage des travailleurs à l'entrée (89 sur 111), obligation pour tous les travailleurs de porter un couvre-visage (86 sur 111), augmentation de la disponibilité des postes d'hygiène des mains (72 sur 111), sensibilisation des travailleurs à la propagation communautaire (70 sur 111), installation de barrières physiques entre les travailleurs (69 sur 111), offre de tests aux employés (41 sur 111) et fermeture temporaire (24 sur 111). • En utilisant les données de 7 usines qui ont mis en place des tests à l'échelle de l'usine, la prévalence brute des infections asymptomatiques ou présymptomatiques parmi les 5572 travailleurs qui ont été testés positifs à l'infection par le SRAS-CoV-2 était de 14,4 %.
(Anand et coll., 2020) *prépublication*	Prédicteurs professionnels et personnels de la	• Cette étude transversale analyse les prédicteurs professionnels et personnels de l'expérience de transmission de la COVID-19 aux États-Unis et au Royaume-Uni	• Les résultats aux États-Unis étaient différents de ceux au Royaume-Uni, les auteurs théorisent que cela est dû à la rigueur des mesures de santé publique. Les résultats indiquent que la profession, les traits

	transmission de la COVID-19	• Une enquête en ligne a été menée auprès de 2000 participants la première semaine de juin 2020. • Aucune déclaration de conflit d'intérêts n'est disponible.	personnels, les circonstances et les comportements ont tous une incidence sur le risque d'exposition à la COVID-19 et sur la capacité à s'éloigner physiquement. • L'analyse britannique a indiqué un risque plus élevé d'être testé positif à la COVID-19 pour les personnes sans revenu, à revenu moyen inférieur, qui partageaient une cuisine et avaient un emploi où les interactions avec les clients et le personnel étaient permanentes. • L'analyse américaine a indiqué que le risque plus élevé d'être infecté par la COVID-19 était lié à un faible revenu (CR entre 5,8 et 6,3), à une cuisine partagée (3,6), à un diplôme universitaire (2,7), à une profession liée au transport (8,5), à l'appartenance à un syndicat (4,8), à une consultation sur la transmission de la COVID-19 au travail (2,5) et au fait d'avoir dû prendre les transports publics pour se rendre au travail (3,2).
(Leffler et Hogan, 2020) *prépublication*	Dépendance de la mortalité due aux nouvelles maladies à coronavirus (COVID-19) en fonction de l'âge dans les populations fortement exposées : Travailleurs et résidents des transports en commun de New York et passagers	• Des données transversales provenant de plusieurs sources et milieux ont été obtenues et les données de mortalité ont été comparées. • Les auteurs ont utilisé des sources accessibles au public pour estimer la mortalité due à la COVID-19 pour chaque groupe d'âge sur le bateau de croisière Diamond Princess, aux États-Unis, dans la ville et l'État de New York, et parmi les travailleurs de la New York Metropolitan Transit Authority (MTA). • Les auteurs déclarent qu'il n'y a pas de conflit d'intérêts.	• À New York, la mortalité des travailleurs des transports en commun était estimée à 1 sur 7329 pour les 30 à 39 ans, 1 sur 1075 pour les 40 à 49 ans, 1 sur 343 pour les 50 à 59 ans et 1 sur 178 pour les 60 à 69 ans. • Parmi les travailleurs de la MTA décédés des suites de la COVID-19, 106 sur 109 personnes au 6 mai 2020, faisaient partie de la division des métros et des bus, qui compte 55000 employés. • Il n'est pas clair si la transmission de ces travailleurs s'est produite sur le lieu de travail ou en dehors du lieu de travail. • Parmi les travailleurs de la MTA de New York, plus de 6000 travailleurs (8 %) ont soit été testés positifs (plus de 2000), soit mis en quarantaine (4000 travailleurs).

	du Diamond Princess		

ÉLÉMENTS DE PREUVE DE L'EXISTENCE DE GRAPPES DE CAS DE COVID-19 PROVENANT DE VOYAGES LIÉS AU TRAVAIL

Cinq publications sur la COVID-19 résultant de voyages liés au travail ont été identifiées (tableau 5).

- La première grappe publiée a débuté avec un employé infecté qui se déplaçait entre les branches chinoise et allemande d'une organisation pour animer des ateliers et assister à des réunions.
- Lors de la deuxième éclosion, le cas index et les expositions initiales ont été liés à des voyages professionnels à Wuhan, en Chine. Les employés infectés lors d'un voyage d'affaires ont déclenché une éclosion sur leur lieu de travail.
- Les deux dernières études font état de grappes de cas liées à des conférences, qui sont souvent des événements sociaux et de réseautage (ministère de la Santé Manatū Hauora, 2020; Pung et coll., 2020). Les facteurs de risque identifiés sont liés à la proximité et à la durée de la période passée avec les cas primaires (par exemple, s'asseoir à la même table pendant un repas).

Tableau 5. Cinq publications sur la COVID-19 comprenant des grappes documentées associées aux voyages liés au travail.

Référence	Titre de la publication	Détails de l'étude	Résultats pertinents
(Böhmer et coll., 2020; Rothe et coll., 2020)	Transmission de l'infection au coronavirus nCoV-2019 à partir d'un contact asymptomatique en Allemagne Enquête sur une éclosion de COVID-19 en	• Investigation épidémiologique rétrospective. • 2 études décrivant la transmission du SRAS-CoV-2 d'une résidente chinoise qui s'est rendue en Allemagne pour des raisons professionnelles à ses collègues en janvier 2020. • Böhmer et coll. fournissent une investigation détaillée de l'éclosion. • Les auteurs déclarent qu'il n'y a pas de conflit d'intérêts.	• Le patient 0 était une employée de la branche chinoise d'une société allemande basée à Munich. Elle s'est rendue de Shanghai à Munich en avion le 19 janvier 2020 pour animer des ateliers et assister à des réunions dans le bâtiment de l'entreprise. Elle a pris un vol de nuit pour retourner à Shanghai le 22 janvier 2020 et a été testée positive à l'infection par le SRAS-CoV-2 le 26 janvier 2020. • L'entreprise allemande a été informée de l'infection le 27 janvier 2020. Les premiers tests effectués sur les contacts à haut risque ont permis d'identifier les patients 1 à 4 comme des cas de première génération.

	Allemagne résultant d'un seul cas primaire associé à un voyage : une série de cas		Le site de la société a été fermé le 11 février 2020. Au 19 février 2020, 16 cas ultérieurs ont été identifiés. • L'intervalle sériel médian était de 4,0 jours (IQR de 3,0 à 5,0). • Dix patients en plus du patient 0 étaient des employés de l'entreprise. Les 5 autres étaient des contacts familiaux. L'investigation a révélé que la transmission du patient 0 aux 10 autres s'est probablement produite au cours des scénarios suivants : ○ Accompagnement du patient 0 dans ses activités multiples en Allemagne et retour par le même avion ○ Dans les réunions de travail (de 60 à 90 minutes) où les collègues étaient assis à proximité les uns des autres. ○ Les collègues ont travaillé simultanément sur le même ordinateur pendant une courte période. ○ Après s'être assis ensemble au cours d'une réunion de 90 minutes pendant la journée, deux collègues ont également passé la soirée ensemble dans l'une de leurs maisons. Cependant, la partenaire du collègue hôte qui était également présent ce soir-là n'a pas été testée positive. ○ Deux collègues se sont rencontrés lors d'une visite à la cantine où ils se sont assis dos à dos. L'un d'eux s'est tourné vers l'autre pour lui emprunter la salière.
(Zhang et coll., 2020)	Enquête épidémiologique sur une nouvelle épidémie de pneumonie à coronavirus en	• Article en chinois. • Investigation épidémiologique rétrospective menée en janvier 2020.	• Le premier cas a été identifié le 15 janvier et s'est propagé à 10 autres collègues avant que des mesures de contrôle ne soient mises en place le 24 janvier 2020. • Le cas index et le cas initial sont liés à des voyages professionnels à Wuhan.

	grappe dans des unités collectives de Tianjin	• L'éclosion s'est produite dans le bureau administratif d'une usine qui compte 906 employés à Tianjin, en Chine. • Les auteurs déclarent qu'il n'y a pas de conflit d'intérêts.	• Les cas secondaires et tertiaires ont soit voyagé ou participé à des réunions avec les cas infectés, soit se sont assis à proximité d'eux.
(Pung et coll., 2020)	Investigation sur trois grappes de COVID-19 à Singapour : implications pour les mesures de surveillance et de réaction	• Investigation épidémiologique rétrospective de 3 grappes liées à un groupe de touristes chinois, une conférence d'entreprise et une église à Singapour en février 2020. • Les auteurs déclarent qu'il n'y a pas de conflit d'intérêts.	• L'analyse a révélé que 36 cas de COVID-19 confirmés ont été liés à 3 grappes locales, composées de 11, 20 et 5 personnes. • La première éclosion a touché 11 personnes d'un groupe de touristes venus de Chine. Cinq assistants d'un magasin où le groupe de touristes s'est arrêté ont été testés positifs au SRAS-CoV-2. Les assistants ont indiqué qu'ils aidaient les clients à appliquer des échantillons d'huile médicinale sur leur corps, et que le lavage des mains n'était généralement pas effectué entre les clients. • La deuxième grappe a été une conférence à laquelle ont assisté au moins 111 participants de 19 pays différents, du 20 au 22 janvier 2020. Vingt personnes ont été infectées. Cinq des cas ont été assis à la même table lors d'un dîner de type banquet durant trois heures et quatre autres cas ont participé à une réunion de quatre heures.
(Ministère de la Santé Manatū Hauora, 2020)	COVID-19 – grappes importantes	• Le gouvernement néo-zélandais a dressé une liste des grappes importantes en Nouvelle-Zélande en date du 17 août 2020. • Aucun détail épidémiologique sur les grappes n'a été fourni.	• Les grappes signalées dans les lieux de travail potentiels sont les suivants : mariage, lieu d'accueil, conférence et bateau de croisière.

ÉLÉMENTS DE PREUVE DE L'EXISTENCE DE GRAPPES DE COVID-19 RÉSULTANT DE RASSEMBLEMENTS SOCIAUX DE COLLÈGUES

En plus de l'activité liée au SRAS-CoV-2 dans la communauté, les activités qu'un travailleur exerce en dehors du lieu de travail détermineront le risque individuel qu'une personne apporte son entreprise. Trois grappes de COVID-19 résultant de rassemblements sociaux de collègues en dehors du lieu de travail ont été identifiées (tableau 6). Dans les trois grappes, un groupe de collègues se sont rencontrés en dehors du lieu de travail et ont été infectés. Un groupe s'est réuni dans un bar, l'autre a organisé un dîner au cours duquel il a chanté dans un espace clos, et le troisième groupe a « des antécédents de sorties à Wuhan ». Dans les trois scénarios, les infections acquises lors de réunions sociales de collègues ont entraîné des infections supplémentaires sur le lieu de travail.

Tableau 6. Trois grappes de COVID-19 associées à des rassemblements sociaux de collègues en dehors du lieu de travail.

Référence	Titre de la publication	Détails de l'étude	Résultats pertinents
(Valencia et coll., 2020) *prépublication*	Transmissions asymptomatique et présymptomatique de l'infection du nouveau coronavirus 2019 (COVID-19) : une estimation à partir d'une grappe de cas confirmés à Hô Chi Minh Ville, au Vietnam	• Investigation épidémiologique rétrospective d'un rassemblement dans un bar à Hô Chi Minh Ville, au Vietnam. • Les informations démographiques, cliniques et de laboratoire de tous les cas confirmés de COVID-19 et les contacts d'un rassemblement de bar le 14 mars 2020 ont été recueillies. • Les auteurs déclarent qu'il n'y a pas de conflits d'intérêts.	• Sur les 298 personnes qui ont assisté à un rassemblement dans un bar à Hô Chi Minh Ville, 13 ont été testées positives au SRAS-CoV-2. • La recherche des contacts parmi 4466 personnes a permis d'identifier 6 autres cas. • Le R0 spécifique de la grappe était de 2,64 (IC de 90 % : de 1,41 à 3,68). • 3 contextes de transmission après une investigation sur le terrain ont été identifiés (bar, ménage, lieu de travail). Le bar constituait 68 %, le lieu de travail 21 %, et le ménage 11 % des transmissions. o Dans la deuxième génération, 3 (50 %) des transmissions étaient liées au lieu de travail, dont 2 (67 %) ont signalé des symptômes après avoir été exposés à un cas qui n'a pas signalé de symptômes
(Bao et coll., 2020)	Éclosion de COVID-19 suite à	• Investigation épidémiologique rétrospective	• Un travailleur infecté par la COVID-19 qui est rentré chez lui après avoir quitté Wuhan, a provoqué une

	l'exposition d'un seul patient sur un site de divertissement : Une étude épidémiologique	d'une éclosion associée à une piscine dans un lieu de divertissement à Wuhan, en Chine. • Les informations démographiques, cliniques et de laboratoire de tous les cas et contacts confirmés de COVID-19 ont été recueillies en janvier et février 2020. • Les auteurs déclarent qu'il n'y a pas de conflits d'intérêts.	éclosion en se rendant dans une piscine le 20 janvier 2020, où il a infecté certains travailleurs et clients de l'établissement. • L'infection a ensuite été transmise par un employé de la piscine qui a continué de travailler et par un client qui a participé à une fête familiale et à un dîner avec des collègues. • L'employé de piscine qui a continué de travailler jusqu'au 26 janvier 2020 a causé des infections par le SRAS-CoV-2 chez 12 clients. • Un dîner avec des collègues a réuni 36 collègues le 22 janvier 2020. La personne infectée a chanté avec 7 collègues dans un espace fermé. L'infection des 7 collègues a été confirmée par la suite. • Le taux d'attaque secondaire pour le dîner avec les collègues était de 20,5% (IC de 95 % : de 7,8 à 33,2).
(Liu et coll., 2020)	Analyse des cas de grappe de COVID-19 à Tianjin	• Données agrégées provenant d'investigations épidémiologiques rétrospectives. • Cette étude décrit toutes les grappes de cas de COVID-19 confirmés à Tianjin en date du 22 février 2020. • Les auteurs déclarent qu'il n'y a pas de conflit d'intérêts.	• Il y avait des grappes de familles (28 cas, 71 cas), des grappes d'unités (1 cas, 10 cas), des grappes de transport (3 cas, 8 cas) et une grappe de lieux publics (1 cas, 26 cas). • Une grappe dans la section passagers d'un train a impliqué 10 cas. Après des investigations épidémiologiques, il a finalement été déterminé que 2 employés ayant des antécédents de sorties à Wuhan étaient des cas de première génération. • L'éclosion dans un grand magasin était due à un vendeur infecté qui a contaminé 26 clients et collègues.

ÉLÉMENTS DE PREUVE DE STRATÉGIES DE RÉDUCTION DES RISQUES RÉUSSIES SUR LE LIEU DE TRAVAIL

Il y a eu 21 publications sur les stratégies visant à réduire le risque d'infection par le SRAS-CoV-2 sur le lieu de travail (tableau 7). La majorité (75 %) d'entre elles sont des modèles mathématiques. Ces études ont porté sur les stratégies de prévention, l'incidence et la levée des mesures de santé publique, et la gestion des travailleurs migrants (tableau 7).

- Cinq études ont démontré l'efficacité de l'incitation à ne pas travailler pendant la maladie par la mise en place d'un programme de soutien au revenu (PSR), de politiques de congé et de politiques de quarantaine (Brotherhood et Jerbashian, 2020; Coleman, 2020).
- La limitation des contacts sociaux par une réintroduction progressive des personnes sur le lieu de travail, ainsi que la réduction du nombre de personnes et du temps passé sur le lieu de travail en général, sont efficaces pour ralentir la propagation des infections par le SRAS-CoV-2 (Kim, 2020; Koralnik et Tyler, 2020; Shaw et coll., 2020; Yilmazkuday, 2020).
- La disponibilité de lignes directrices et de mesures de protection personnelle au travail a amélioré le comportement individuel de protection personnelle (Wang, Yi Wong et Ho, 2020).
- L'efficacité des stratégies de dépistage sur le lieu de travail a été examinée comme moyen d'identifier une éclosion. Les stratégies explorées comprenaient des tests environnementaux et des tests sur les travailleurs.
    - Une étude des lieux de travail au Royaume-Uni et aux États-Unis a examiné les tests environnementaux. Les résultats de ces tests ont conclu que les lieux de travail dont les échantillons environnementaux étaient positifs étaient dix fois plus susceptibles d'avoir une personne infectée sur le lieu de travail (Marshall et coll., 2020).
    - Les tests des travailleurs ont été étudiés pour différents R0 : si R0=2,4, les travailleurs devraient être testés au moins tous les 3 à 4 jours pour prévenir une éclosion sur le lieu de travail alors que si R0=3,0, les tests devraient avoir lieu tous les 2 jours (Chin, Lo, Huynh, Murrill et Basu, 2020). Des stratégies moins fréquentes, comme une fois par semaine ou lors du retour au travail, étaient moins susceptibles de prévenir une éclosion.

Tableau 7. Vingt et une publications sur les stratégies de réduction des risques sur le lieu de travail.

Référence	Titre de la publication	Détails de l'étude	Résultats pertinents
Limiter les contacts sociaux			

(Shaw et coll., 2020) *prépublication*	Leçons de l'écologie des déplacements pour le retour au travail : modélisation des contacts et de la diffusion de la COVID-19	• 2 modèles SEIR sont utilisés : 1) un modèle des déplacements pour explorer les mouvements entre le domicile et le lieu de travail, et 2) un modèle de réseau pour explorer les modèles de contact dans l'environnement de travail. • Une étude de cas de réseau d'un laboratoire universitaire et d'un immeuble de bureaux pour explorer les compromis entre la limitation des contacts, des personnes ou du temps sur le campus. • Aucune déclaration de conflit d'intérêts n'est disponible.	• Les résultats des modèles montrent que les limitations des contacts sociaux, par la réduction du nombre de personnes ou du temps passé sur le lieu de travail, sont des stratégies équivalentes pour ralentir la propagation des agents pathogènes • Restreindre les activités sur le campus aux laboratoires (plutôt qu'aux laboratoires et aux bureaux) pourrait modifier considérablement (modulariser) la structure du réseau de contacts et donc, potentiellement, réduire le risque relatif de propagation des agents pathogènes. • Si les déplacements domicile-travail augmentent spécifiquement le risque de transmission (c'est-à-dire le partage des transports), la réduction du nombre de personnes sur le campus est la stratégie la plus efficace pour réduire le taux de propagation de l'infection.
(Brotherhood et Jerbashian, 2020) *prépublication*	Comportement en entreprise pendant une épidémie	• Les auteurs en déduisent un modèle mathématique dans lequel une entreprise représentative opère dans un environnement épidémique. • Les stratégies de l'entreprise pour réduire les infections et les coûts associés comprennent l'affectation des employés au télétravail et aux congés, et leur rotation entre le travail sur site, le télétravail et les congés. • Aucune déclaration de conflit d'intérêts n'est disponible.	• Les résultats des simulations montrent que la lutte contre les infections dans les entreprises a un effet significatif sur la dynamique de l'épidémie. Parmi les stratégies qui ont fait leurs preuves, citons le développement du télétravail, la rotation/mise en cohortes des employés sur site et la mise en place de possibilités de congé appropriées. • Une subvention de 3 % au télétravail réduit le pic de l'épidémie d'environ 3 % et le nombre total d'infections symptomatiques et le taux de mortalité de près de 9 %. • Les politiques de congé sont efficaces pour réduire les infections et les décès. • Par rapport à une situation hypothétique où une entreprise ne lutte pas contre les infections, les choix d'affectation et de rotation des employés dans les entreprises réduisent de 5 % le nombre maximum d'employés malades présentant des symptômes. Ces choix aplatissent également la courbe des infections en

			réduisant de 18 % le nombre total d'infections symptomatiques. En conséquence, le taux de mortalité diminue également de 18 %.
(Gallardo, de Arroyabe et Arranz, 2020)	Prévention des éclosions internes de COVID-19 dans les entreprises et les établissements publics : une méthodologie basée sur l'analyse des réseaux sociaux pour soutenir la prise de décision des services de santé et de sécurité au travail	• Cette étude applique les techniques d'analyse des réseaux sociaux pour aider les services de santé et de sécurité au travail à concevoir et à sélectionner des mesures préventives pour réduire le risque d'épidémies parmi les employés. • Les auteurs déclarent qu'il n'y a pas de conflit d'intérêts.	• La méthodologie a été démontrée dans un cas réel, un centre de recherche espagnol, fournissant des résultats prometteurs. • Les auteurs utilisent le concept de réseau d'employés dont l'interaction est causée par des déclencheurs, qui sont définis comme des circonstances communes entre 2 travailleurs qui peuvent entraîner une contagion, comme le fait de partager un bureau ou de participer au même conseil d'administration. • Par exemple, un lieu partagé avec un espace élargi entre les personnes, qui est désinfecté quotidiennement, est moins susceptible d'être un déclencheur de contagion qu'un même lieu encombré et sans désinfection régulière.
(Kim, 2020)	Distanciation sociale et directives de santé publique sur les lieux de travail en Corée : réponses à la maladie à coronavirus-19	• Données agrégées provenant d'investigations épidémiologiques rétrospectives. • Cette étude résume les politiques publiques et du lieu de travail en réponse à la COVID-19 en Corée. • Une vue d'ensemble des éclosions sur le lieu de travail pendant la période du 20 janvier au 15 mai 2020 est décrite à l'aide des données du Centre coréen de contrôle des maladies et du siège central de gestion des catastrophes. • Les auteurs déclarent qu'il n'y a pas de conflit d'intérêts.	• Transmission sur le lieu de travail en Corée : o Sur les 11 018 cas de COVID-19 identifiés au 15 mai 2020, 15,7 % se sont produits sur des lieux de travail tels que des établissements de soins de santé, des centres d'appel, des clubs sportifs, des karaokés et des lieux de vie nocturne. o 111 cas ont été associés à des clubs de remise en forme après l'infection des instructeurs lors d'un atelier (Jang et coll., 2020). o 192 cas ont été associés à l'éclosion dans un centre d'appel. o 95 cas sont liés au service public (par exemple, le service de santé, les agents correctionnels, les

			pompiers et la police). Cependant, la raison de leur exposition n'a pas été identifiée. • Des lignes directrices ont été élaborées avant le 29 février 2020 et sont considérées comme ayant été efficaces pour limiter la transmission sur le lieu de travail après leur mise en œuvre. Le ministère de l'Emploi et du Travail a inclus des directives sur le lieu de travail portant sur la COVID-19 : o Distanciation sociale, horaires de travail flexibles, identification précoce des travailleurs suspectés d'être infectés et désinfection des lieux de travail o Pour prévenir la propagation de l'infection sur le lieu de travail, les lignes directrices suggèrent d'éviter les réunions en face à face, les voyages d'affaires, l'éducation et la formation o Les réunions en petits groupes, les activités de club et les dîners sociaux sur le lieu de travail ont été limités et une culture du retour à la maison juste après le travail a été encouragée
Politiques « rester à la maison »/de quarantaine			
(Coleman, 2020) *prépublication*	Interactions motivées par l'économie et propagation des maladies	• Ce modèle SIR a analysé les déplacements de personnes tout au long de la journée pour faire correspondre les données à la répartition des ménages selon la taille et l'âge des occupants, à la répartition des écoles et collèges de la maternelle à la 12e année selon la taille et les ratios personnel-élève, et aux établissements de bureaux et de vente au détail selon le nombre d'employés. Le modèle a ensuite été utilisé pour évaluer le respect à grande échelle d'une	• Les simulations révèlent qu'une politique d'atténuation où toutes les personnes symptomatiques restent chez elles est suffisante pour contrôler la propagation de la COVID-19 sans effets perceptibles sur l'emploi. • Cela est vrai même si jusqu'à 60 % de la population est asymptomatique.

		politique d'atténuation des symptômes obligeant les personnes symptomatiques à rester chez elles. • Aucune déclaration de conflit d'intérêts n'est disponible.	
(Yilmazkuday, 2020) *prépublication*	« Rester à la maison » est efficace pour lutter contre la COVID-19 : éléments de preuve internationaux de données de mobilité de Google	• Étude écologique. • A utilisé les données quotidiennes de Google sur la mobilité couvrant 130 pays entre le 15 février et le 2 mai 2020. • Aucune déclaration de conflit d'intérêts n'est disponible.	• Une réduction hebdomadaire de 1 % des visites sur les lieux de travail a été assimilée à environ (SE de 6,3, $p < 0,01$) moins de cas de COVID-19 et 2,0 (0,5, $P < 0,01$) moins de décès dus à la COVID-19.
(Koo et coll., 2020)	Interventions visant à atténuer la propagation précoce du SRAS-CoV-2 à Singapour : une étude de modélisation	• Ce modèle de simulation d'épidémie de grippe publié en mars 2020 a étudié les possibilités d'intervention précoce à Singapour en cas d'échec du confinement local. • Les auteurs déclarent qu'il n'y a pas de conflit d'intérêts.	• La modélisation effectuée dans les premiers jours de la pandémie a suggéré que si une transmission communautaire se produisait, la mise en œuvre de l'intervention combinée de la mise en quarantaine des personnes infectées et des membres de leur famille, de la distanciation sur le lieu de travail et de la fermeture des écoles pourrait réduire considérablement le nombre d'infections par le SRAS-CoV-2.
Dépistage et recherche des contacts			
(Chen et coll., 2020) *prépublication*	Fréquence du dépistage routinier du SRAS-CoV-2 afin de réduire la transmission	• Ce modèle SEIR a simulé différentes fréquences de tests nécessaires au sein de la population active pour contrôler l'épidémie après la levée des politiques d'hébergement sur place. • Aucune déclaration de conflit d'intérêts n'est disponible.	• Si R0=2,4, les travailleurs devraient être testés au moins tous les 3 à 4 jours pour réduire $R0 < 1$ et empêcher une éclosion parmi les travailleurs. • Avec un R0 plus élevé (3,0), les tests devraient avoir lieu tous les 2 jours. Comme cela est probablement irréaliste, d'autres stratégies telles que la distanciation

	parmi les travailleurs		sociale et la recherche des contacts devraient également être mises en œuvre.
(Foncea, Mondscheinet Massouh, 2020) *prépublication*	Des espaces de travail plus sûrs à l'heure du coronavirus : une nouvelle utilisation des tests d'anticorps	• Un modèle de simulation de Monte-Carlo a été utilisé pour analyser l'efficacité du dépistage périodique des anticorps anti-SRAS-CoV-2 afin de réduire le risque d'infection sur le lieu de travail. • Aucune déclaration de conflit d'intérêts n'est disponible.	• Ce modèle de simulation préliminaire suggère qu'avec un dépistage d'anticorps deux fois par semaine et la mise en quarantaine des travailleurs suspectés d'être infectés par le SRAS-CoV-2, il est possible de réduire le nombre d'infections tout en améliorant la productivité de l'entreprise. • Les auteurs sont actuellement en train d'appliquer certaines combinaisons des protocoles du modèle avec des entreprises et des agences gouvernementales spécifiques et feront rapport à ce sujet lorsque les résultats seront disponibles.
(Bicher, Rippinger, Urach, Brunmeir et Popper, 2020) *prépublication*	Simulation basée sur des agents pour l'évaluation des politiques de recherche des contacts contre la propagation du SRAS-CoV-2	• Ce modèle basé sur les agents quantifie l'incidence de la recherche des contacts et du relâchement des mesures de confinement sur la propagation de la maladie. L'incidence de la localisation des ménages et des lieux de travail a été évaluée séparément et en combinaison avec différents niveaux de conformité. • Aucune déclaration de conflit d'intérêts n'est disponible.	• Dans le cadre de la recherche des contacts sur le lieu de travail, le lieu de travail d'un cas confirmé de COVID-19 est temporairement fermé et tous les collègues sont mis en quarantaine. • La recherche des contacts dans les espaces de travail partagé réduit le pic de 30 %, quel que soit le niveau de conformité, tandis que la recherche des cas contacts dans les ménages est plus performante à mesure que la conformité augmente. • Ces mesures combinées permettent d'atteindre la plus grande réduction de pointe et donnent les meilleurs résultats avec un niveau élevé de conformité. Une recherche des contacts individuels supplémentaire entraînerait une réduction plus importante.
(Leng et coll., 2020) *prépublication*	L'effet des mesures de contrôle sur la transmission de la	• Étude écologique, l'effet causal de différentes mesures de contrôle sur la transmission de la COVID-19 et la reprise du travail dans 5 pays : La Chine,	• Les deux mesures politiques les plus efficaces pour l'endiguement de la maladie et la reprise du travail sont la recherche numérique des contacts et la délégation de responsabilités claires à la communauté locale.

	COVID-19 et la reprise du travail : preuves internationales	l'Italie, l'Allemagne, le Royaume-Uni et les États-Unis ont été quantifiés. • Les auteurs reconnaissent le soutien financier de la Fondation nationale des sciences naturelles de Chine, de la Fondation nationale des sciences sociales de Chine et de la bourse des sciences humaines et sociales du ministère de l'Éducation chinois. Aucune déclaration de conflit d'intérêts n'est disponible.	• La recherche des contacts à l'échelle de la population contribue à l'effet le plus important sur la reprise du travail, en encourageant la reprise du travail de 2,4 %. • Une augmentation de 1 % de la rigueur de la distanciation sociale a encouragé la reprise du travail de 1,2 %. • Des campagnes d'information du public, déléguant clairement la responsabilité à la communauté locale, ont encouragé la reprise du travail à environ de 0,9 à 1,0 %. • Les mesures fiscales telles que les prêts, la déduction fiscale et la déduction du prix des facteurs contribuent moins à la reprise du travail (environ 0,5 %), alors que la rigueur des soins de santé n'apporte aucune aide directe.
(Way, Champneys, Dyson et coll., 2020) *prépublication*	Les avantages de la transparence entre pairs dans le fonctionnement sûr du lieu de travail après un confinement dû à une pandémie	• Un modèle SEIR a été utilisé pour étudier la transmission sur le lieu de travail dans deux groupes différents de travailleurs, en supposant que tous les travailleurs sont régulièrement testés pour une infection par le SRAS-CoV-2 : 1) ceux qui sont transparents sur les tests, qui partagent leurs résultats avec leurs collègues et qui s'isolent dès qu'un contact est positif, 2) ceux qui sont opaques et qui ne font rien de tout cela. • Les lieux de travail considérés dans l'analyse sont les services administratifs, ou les usines où les employés sont supposés avoir un réseau statique de collègues avec lesquels ils interagissent régulièrement et où toutes les autres	• Plus la connectivité entre collègues est grande, plus l'opacité doit être faible entre employés pour réduire la transmission. • La transparence des employés présente un double avantage : elle permet de maximiser la productivité et de minimiser le taux d'infection global.

		interactions sur le lieu de travail seraient socialement distantes. • Aucune déclaration de conflit d'intérêts n'est disponible.	
Réduction des mesures de santé publique			
(Asfaw, 2020) *prépublication*	L'effet du programme de soutien du revenu sur la mobilité professionnelle, les cas de COVID-19 et la croissance de la mortalité	• L'étude écologique sur le programme de soutien au revenu (PSR) vise à atténuer les conséquences économiques de la pandémie tout en augmentant le respect des mesures de distanciation sociale. Cette étude analyse l'effet du PSR sur la mobilité au travail, ainsi que la croissance des cas et de la mortalité due à la COVID-19 à l'aide d'un modèle d'analyse multi-événement. • Aucune déclaration de conflit d'intérêts n'est disponible.	• La mobilité sur le lieu de travail a été réduite dans une fourchette de 4,4 à 8,29 % une semaine après l'introduction du PSR et de 21,8 à 47,7 % après trois semaines. • 5 semaines après la mise en œuvre du programme, on a constaté une réduction de 21,8 à 47,0 % et de 17,1 à 29,7 % de la croissance des cas et de la mortalité due à la COVID-19, respectivement. • En l'absence de programmes PSR, les auteurs estiment que le nombre cumulé mondial de cas et de mortalité due à la COVID-19 aurait été de 3,69 millions et 160 000 de plus que les cas et décès dus à la COVID-19 observés et enregistrés au 15 mai 2020.
(Koralnik et Tyler, 2020) *prépublication*	Étude épidémiologique II sur la COVID-19 : sortie progressive du confinement à Mumbai	• Un simulateur de ville à base d'agents a été utilisé pour modéliser des scénarios de sortie progressive du confinement à Mumbai, en Inde, à partir du 1er juin 2020. • L'étude a été financée par le centre IISc-Cisco Centre pour l'intelligence réseautée, le centre Robert Bosch pour les systèmes cyberphysiques, l'Institut indien de la Science et le ministère de l'Énergie atomique du gouvernement indien. • Aucune déclaration de conflit d'intérêts n'est disponible.	• Les résultats montrent qu'une ouverture progressive des lieux de travail, à un niveau de fréquentation conservateur de 20 à 33 %, est un bon moyen de relancer l'activité économique tout en garantissant que la capacité de soins médicaux de la ville reste suffisante pour faire face à l'augmentation possible du nombre de cas de COVID-19 en juin et juillet 2020. • Cela permettra de maintenir le taux d'occupation des trains et des bus de banlieue à un niveau bas similaire, réduisant ainsi la propagation de l'infection dans les systèmes de transport public surchargés. • Dans le cas des trains, l'occupation devrait être limitée à environ 20 % pendant les premières semaines, avec

			l'application d'une distance physique stricte et le port obligatoire de masques de protection.
(López et Rodó, 2020)	Fin du confinement social en Espagne et risque de réémergence de la COVID-19	• Ce modèle SEIR simule diverses stratégies potentielles post-confinement en Espagne, telles que le déconfinement massif instantané de différentes populations et le retour progressif des personnes au travail. • Les auteurs déclarent qu'il n'y a pas de conflit d'intérêts.	• Les résultats montrent que le confinement actuel devrait être prolongé d'au moins 2 semaines supplémentaires pour éviter une nouvelle escalade des cas et des décès, ainsi qu'une deuxième vague dans quelques mois. • Parmi tous les scénarios modélisés, le meilleur scénario consiste à réintégrer progressivement les travailleurs dans la société dans une proportion quotidienne supérieure de 30 % au maximum à celle du confinement précédent. Cela permettra de réduire l'incidence et le nombre de victimes. Pour maximiser les effets positifs, cette stratégie ne devrait pas commencer avant la fin avril 2020.
Surveillance et contrôle de l'environnement			
(Marshall et coll., 2020) *prépublication*	La surveillance environnementale du coronavirus sentinelle peut contribuer à détecter les propagateurs asymptomatiques du virus du SRAS-CoV-2 et peut vérifier l'efficacité des contrôles contre la COVID-19 sur le lieu de travail	• Une étude de cohorte prospective visait à évaluer l'efficacité de l'utilisation de la surveillance environnementale du SRAS-CoV-2 comme outil de détection des agents de propagation asymptomatiques et présymptomatiques et de la réalisation de tests cliniques et environnementaux de surface sur les lieux de travail pour minimiser les infections. • Neuf lieux de travail en Europe et aux États-Unis ont participé à l'étude. Sur ces trois sites, un ou plusieurs employés étaient infectés par le SRAS-CoV-2.	• Les endroits dont les surfaces étaient contaminées par le SRAS-CoV-2 étaient dix fois plus susceptibles d'avoir des employés dont le test de dépistage du SRAS-CoV-2 était positif que les endroits dont les surfaces n'étaient pas ou très peu contaminées. • Les surfaces les plus fréquemment contaminées étaient les chaises des salles de détente, les bancs de travail et les poignées de porte. • Comme les lieux où l'on a détecté de nombreux prélèvements positifs dans l'environnement avaient un employé infecté pendant la période d'étude, la surveillance de l'environnement semble être un outil utile pour informer les tests cliniques nécessaires à la détection de propagateurs de virus asymptomatiques ou présymptomatiques et à la mise en œuvre de mesures de contrôle appropriées.

		• Les auteurs indiquent que le financement de l'étude a été assuré par les lieux et les laboratoires participants.	
(Gunawardana et coll., 2020) *prépublication*	Surveillance et caractérisation longitudinale de la COVID-19 sur le lieu de travail avec des points de contrôle de santé publique et de diagnostic	• Une cohorte prospective a été menée pour évaluer si la surveillance longitudinale des maladies sur le lieu de travail serait une approche efficace pour contrôler le SRAS-CoV-2 chez les employés et les membres de leur ménage. Les résultats entre le 23 mars et le 22 juin 2020 sont présentés. • Dans une petite organisation du sud de la Californie (Oak Crest), 54 volontaires (27 employés et 27 membres de ménages) ont fourni des échantillons fréquents pour le dépistage du SRAS-CoV-2. Seuls les participants ayant obtenu un résultat négatif au test pouvaient entrer dans la « zone de sécurité » du lieu de travail. • Une combinaison d'un modèle SEIR et d'un modèle mixte non linéaire bayésien a été utilisée pour prédire le nombre d'employés et de membres de ménages qui auraient été infectés en l'absence du programme de surveillance. • Les auteurs affirment que l'étude a été entièrement financée par des fonds institutionnels discrétionnaires.	• En utilisant la prévalence actuelle dans le comté de Los Angeles, le modèle prévoyait, sans intervention de surveillance, jusqu'à 7 employés (IC de 95 % : de 3 à 10) auraient été infectés avec au maximum 1 d'entre eux nécessitant une hospitalisation et 0 décès. • Pendant la période d'étude, deux participants à l'étude ont été très infectés par le SRAS-CoV-2. L'un était un employé et l'autre un membre du ménage. • L'employé n'a pas été autorisé à entrer sur le lieu de travail de la zone de sécurité avant d'avoir été testé négatif 3 fois consécutives sur une période de 7 jours. Aucun autre employé ou membre du ménage n'a contracté le SRAS-CoV-2 au cours de l'étude.
Orientation sur le lieu de travail			

(Wang et coll., 2020) *prépublication*	Disponibilité d'une politique de prévention des maladies à coronavirus 2019 sur le lieu de travail et son lien avec les comportements de protection personnelle : une enquête menée auprès des employés	• Une étude transversale utilisant un questionnaire en ligne évaluant les directives sur le lieu de travail et le comportement en matière de protection personnelle des résidents de Hong Kong ayant un emploi (n=1048) a été menée entre le 17 et le 27 février 2020. • Les auteurs déclarent qu'il n'y a pas de conflit d'intérêts.	• 1048 questionnaires ont été analysés dans 5 groupes professionnels. • Dans la plupart des professions, l'existence de directives et de mesures de prévention contre la COVID-19 sur le lieu de travail a permis d'améliorer les comportements de protection personnelle tels que l'hygiène des mains, le port d'un masque facial et la distanciation sociale.
Gestion des travailleurs migrants			
(Maji, Choudhari et Sushma, 2020)	Implications du rapatriement de travailleurs migrants sur la diffusion de la COVID-19 et les exigences de transport	• Ce modèle SEIR a permis d'étudier l'augmentation potentielle des cas confirmés et actifs d'infection par la COVID-19 en Inde et d'évaluer la taille du parc de trains et d'autobus nécessaire au rapatriement des travailleurs migrants. • En faisant des prévisions à partir des données du recensement de 2011 et en les comparant avec les informations rapportées dans les médias, on a pu estimer la population de travailleurs migrants rapatriés. • Aucune déclaration de conflit d'intérêts n'est disponible.	• Les résultats indiquent que la réduction du taux d'arrivée quotidien de travailleurs migrants dans les États où le flux sortant de migrants est très élevé (c'est-à-dire l'Uttar Pradesh et le Bihar) peut contribuer à diminuer la hausse des cas confirmés et actifs. • Cependant, cela pourrait créer une disparité dans le nombre de jours nécessaires pour transporter tous les travailleurs migrants rapatriés vers leur État d'origine. Il a été recommandé d'organiser le voyage d'environ 100 000 travailleurs migrants par jour vers l'Uttar Pradesh et le Bihar, d'environ 50 000 par jour vers le Rajasthan et le Madhya Pradesh, de 20 000 par jour vers le Maharashtra et de moins de 20 000 par jour vers les autres États de l'Inde. • Les auteurs suggèrent que des mesures strictes de contrôle des travailleurs migrants avant l'embarquement et une politique d'isolement stricte

			après l'arrivée pourraient contrôler la hausse des cas confirmés et actifs.
(Han et Jia, 2020) *prépublication*	La réduction de la population migrante réduit le nombre de cas de COVID-19 : une étude de cas en Chine	• Un modèle additif généralisé (MAG) a été utilisé pour modéliser la relation entre la population migrante et le nombre de cas confirmés de COVID-19 en Chine. • L'étude a été financée par la Bourse pour start-up de l'université de Pékin. Les auteurs déclarent qu'il n'y a pas de conflit d'intérêts.	• En utilisant la Chine comme étude de cas, les résultats montrent que le nombre de cas de COVID-19 confirmés était corrélé avec la migration de la population et la densité régionale de la population (R2aj = 0,873, déviance expliquée = 89,6 %). Le nombre de cas confirmés augmentera avec la croissance de ces variables. • Par conséquent, la restriction des déplacements de la population peut réduire considérablement le nombre de cas confirmés et limiter l'expansion de la maladie. • Une fois que la population migrante retournera au travail, le nombre de cas confirmés atteindra 27 483 (IC de 95 % : de 16 074 à 48 097). L'augmentation moyenne dans 73 villes était de 85,53 % (IC de 95 % : de 19,53 à 189,81%).
(Maji, Sushma et Choudhari, 2020) *prépublication*	Implication des mouvements interétatiques de travailleurs migrants pendant le confinement dû à la COVID-19 en utilisant le modèle SEIR modifié	• Ce modèle SEIR évalue l'effet du transport interétatique des travailleurs migrants pendant la période de confinement en Inde. À partir du 5 mai 2020, on suppose que les travailleurs migrants commenceront à arriver à leurs destinations respectives et le modèle a analysé le taux d'arrivée quotidien de 20 000 à 100 000 travailleurs migrants par État. • Aucune déclaration de conflit d'intérêts n'est disponible.	• On estime que les États comptant un nombre important de travailleurs migrants connaissent une augmentation des cas confirmés et actifs • Les auteurs suggèrent que des mesures strictes de contrôle des travailleurs migrants avant l'embarquement et un isolement strict après l'arrivée peuvent contribuer à maîtriser la hausse des cas confirmés et actifs.

Méthodologies

Toute la littérature sur la COVID-19 a été compilée et organisée par le Groupe des sciences émergentes de l'Agence de la santé publique du Canada depuis le début de l'éclosion. Cela implique une analyse documentaire quotidienne de tous les articles publiés et prépubliés. Les recherches visant à retrouver la littérature pertinente à la COVID-19 sont menées dans PubMed, Scopus, BioRxiv, MedRxiv, ArXiv, SSRN et Research Square. Les résultats sont recoupés avec la littérature figurant sur la liste documentaire sur la COVID de l'Organisation mondiale de la santé et les centres d'information sur la COVID-19 gérés par Lancet, BMJ, Elsevier et Wiley. Le résumé quotidien et les résultats complets de l'analyse sont conservés dans une base de données RefWorks et un fichier Excel consultable. Chaque article est étiqueté en fonction de divers critères permettant d'identifier le thème central de l'article (par exemple, épidémiologie, données cliniques, thérapeutiques, etc.). Une recherche ciblée par mot-clé est effectuée dans ces bases de données pour identifier les citations pertinentes sur la COVID-19 et le SRAS-CoV-2. Les termes de recherche inclus dans cette revue étaient : lieu de travail, travail*, profession, collègue, fabrication, usine, et employé, rassemblement, et super-propagation*. Il n'y avait pas de restrictions linguistiques. Chaque référence potentiellement pertinente a été analysée pour confirmer sa pertinence et les données ont été extraites dans la revue. Des articles supplémentaires et des rapports de littérature grise ont été ajoutés à la base de données au fur et à mesure qu'ils ont été identifiés. La littérature grise se limitait aux rapports du gouvernement et des établissements de santé publique. Les sources médiatiques et les bulletins d'information n'ont pas été jugés suffisamment fiables ou détaillés pour être inclus. Une recherche en boule de neige a été effectuée, qui comprenait le recoupement des listes de référence des revues publiées et des articles pertinents pour les recherches pertinentes omises par la recherche. Comme il s'agit d'une revue rapide, les études incluses n'ont pas fait l'objet d'un double filtrage ou d'une extraction d'articles et d'une évaluation formelle de la qualité (risque de biais). Cette revue contient les recherches publiées jusqu'au 21 août 2020.

Nouveaux éléments de preuve sur la COVID-19

Synthèse sur la désescalade des bulles sociales

Introduction

Quelles sont les données probantes disponibles à propos de la désescalade des « bulles des ménages »? Y a-t-il des suggestions sur la façon dont nous pouvons réduire la segmentation des communautés en réseaux plus importants?

Cet examen portera sur les données probantes relatives au concept de segmentation des réseaux mis en œuvre pour le grand public sous forme de « bulles sociales ». Ce concept fait référence aux limitations des interactions individuelles avec les personnes en dehors de leur réseau fermé (par exemple, la famille proche). Alors que nous passons à différentes phases de l'épidémie, il est intéressant de comprendre quelle incidence l'augmentation de la taille de la bulle sociale ou la segmentation des réseaux peut avoir sur l'épidémie. Cette note d'information comprend la littérature jusqu'au 15 juin 2020.

Points clés

- On a défini une prépublication qui modélise directement les bulles sociales et les options du monde réel en utilisant le Royaume-Uni comme étude de cas. L'étude indique que les bulles familiales ont réduit le nombre de cas de 17 %. Dans son modèle, on étudie la possibilité d'assouplir la bulle du ménage unique pour différents scénarios de ménages multiples en utilisant trois taux d'attaque secondaire différents et le taux de reproduction de base (R0) comme résultat. Il est démontré que le R0 augmente à mesure que les restrictions sont assouplies, mais certaines des options limitées semblent présenter une augmentation minimale du risque.
- Trois modèles de réseaux sociaux prouvent également que des réseaux plus vastes, mais toujours fermés et segmentés, offrent un effet protecteur contre l'introduction du SRAS-CoV-2. Plus un réseau segmenté est grand, plus il y a de contacts en dehors de ce réseau, plus le risque d'introduction du virus est élevé.
- Il existe de nombreuses études qui examinent l'incidence de l'éloignement social de manière plus générale et en combinaison avec d'autres interventions. Elles ne sont pas résumées dans cette note d'information, mais elles sont disponibles sur demande, car elles sont recueillies dans le cadre de l'examen permanent sur les interventions de santé publique.
- On a également défini un protocole pour une étude systématique sur les interventions d'éloignement physique, mais il ne sera pas déployé avant octobre 2020.

Vue d'ensemble des éléments de preuve

Le concept de réduction de la transmission du SRAS-CoV-2 en limitant les interactions étroites à un petit réseau très strict (c'est-à-dire une seule famille) est une intervention efficace. Il est important d'augmenter la

taille du réseau ou de désamorcer l'intervention avec prudence et pas trop rapidement afin de maintenir le contrôle sur l'épidémie tout en levant lentement les restrictions. Comme il y a peu d'observations dans la littérature, les données probantes se trouvent majoritairement dans quelques prépublications récentes qui font état de modèles prédictifs. Ces modèles sont basés sur des scénarios et sont paramétrés à partir des données d'observation de l'épidémie. La mesure dans laquelle les résultats peuvent être généralisés au contexte local est variable et doit être utilisée avec prudence.

TABLE DES MATIÈRES

BULLES SOCIALES

Quatre modèles prédictifs ont étudié les concepts de bulles sociales en utilisant des modèles basés sur les agents et d'autres modèles de réseau pour démontrer l'incidence protectrice du fait d'avoir des réseaux de contacts fermés et limités pendant l'épidémie de COVID-19 (Block *et al.*, 2020; leng *et al.*, 2020; Sneppen et Simonsen, 2020; St-Onge, Thibeault, Allard, Dube et Hebert-Dufresne, 2020). Un modèle étudie directement une gamme d'options d'assouplissement des restrictions de contact et en étudie les implications à l'aide du R0 (Leng *et al.*, 2020). Ces modèles étudient et expliquent le concept de réseaux communautaires à petits segments offrant une résistance accrue à l'introduction du virus dans des réseaux plus petits. Ils explorent également les activités qui dégradent la protection d'un réseau segmenté. Cela se produit lorsqu'un individu issu d'un réseau fermé interagit avec d'autres réseaux, et cela est particulièrement plus risqué lorsque l'interaction se fait dans le cadre d'un événement de rassemblement fortuit où se mêlent des inconnus, par exemple dans les transports publics, lors de déplacements vers un lieu de travail en dehors du réseau segmenté, dans les lieux de socialisation tels que les bars et les restaurants, ou lors d'événements sportifs. Cependant, on ne sait pas dans quelle mesure on peut utiliser ces estimations, car elles sont basées sur la dynamique de l'épidémie dans un endroit précis.

Tableau 1 : Études de modélisation sur les bulles sociales ou les réseaux sociaux restreints

Référence	Description de l'étude	Résultats pertinents
(Leng *et al.*, 2020) Prépublication	Modèle basé sur l'individu : En utilisant le Royaume-Uni comme étude de cas, on a utilisé un modèle mathématique pour évaluer l'efficacité de diverses stratégies de bulles sociales dans le cadre d'une stratégie de sortie de déconfinement progressive.	Maintenir le taux d'attaque secondaire = 20 % constant. Le scénario de base est celui du R0 = 0,8 dans les bulles unifamiliales. Les scénarios suivants montrent la manière dont le Ro devrait évoluer avec un assouplissement modéré des restrictions de contact :

	En utilisant un cas de base où les boutiques et les écoles non essentielles sont fermées, le taux d'attaque des ménages est de 20 % et R0 = 0,8, on simule un certain nombre de stratégies de bulles sociales. Les résultats montrent que dans le scénario de ce cas de base, les bulles sociales ont réduit les cas et les décès de 17 % par rapport à une augmentation non groupée des contacts. Le regroupement des contacts en dehors du ménage dans des bulles sociales exclusives est une stratégie efficace pour augmenter les contacts tout en limitant une partie de l'augmentation du risque d'épidémie qui y est associée.	1. Autoriser tous les ménages ayant des enfants d'âge scolaire à se réunir, R0= 0,85 2. Autoriser tous les ménages ayant des enfants de tous âges à se réunir, R0 = 0,90 3. Autoriser tous les ménages individuels à se réunir avec d'autres ménages individuels, R0 = 0,85 4. Autoriser tous les ménages individuels à se réunir avec tout autre ménage, R0 = 1,00 5. Scénarios 1 et 3, Ro = 0,90 6. Tous les ménages se réunissent, Ro = 1,11
(Block *et al.*, 2020)	Modèle stochastique : en adoptant une approche de réseau social, nous évaluons l'efficacité de trois stratégies d'éloignement conçues pour garder la courbe plate et aider à la conformité dans un monde d'après-confinement. Nous démontrons qu'une réduction stratégique des contacts basée sur les réseaux sociaux renforce fortement l'efficacité des mesures d'éloignement social tout en maintenant les risques à un niveau plus bas.	Trois scénarios d'éloignement social - « renforcer la communauté et rechercher des stratégies de similarité ». - Les individus choisissent leurs contacts en fonction de la similarité d'une caractéristique individuelle prédéterminée. Cela facilite la formation de petits groupes, par exemple dans le quartier ou dans une petite organisation. - Les individus tiennent compte des interactions de leurs contacts et ne voient personne d'autre en dehors d'un réseau de contacts défini. Créer des bulles par des contacts répétés. Les individus décident avec qui ils veulent interagir. On peut également utiliser ce système avec les unités de travail. Il est difficile pour le virus de pénétrer dans ces microcommunautés.
(St-Onge *et al.*, 2020) Prépublication	Modèles SIS-SIR d'auteurs canadiens (Université Laval) utilisant un cadre scientifique de réseau pour examiner l'incidence de structures telles que les rassemblements (groupes/classes/équipes sportives, etc.).	- Ils démontrent que les épidémies localisées peuvent être mises en échec si la taille du groupe ou du rassemblement reste en dessous d'un certain seuil. - Le seuil pour le régime de localisation mésoscopique, avec un taux de transmission β = 0,07, était de 23 personnes et moins.

(Sneppen et Simonsen, 2020) *Prépublication*	Ce modèle à base d'agents a étudié l'incidence des événements de superpropagation. Dans le modèle de base, les événements de superpropagation ont eu peu d'effet sur l'épidémie, mais selon diverses stratégies d'intervention, la limitation des contacts sociaux diffus – lors de rassemblements fortuits – dans les milieux tels que les bars, les transports, les restaurants, les fêtes, les concerts et les salles de conférence est bien plus efficace que la limitation du même nombre d'événements de contact à la maison et au travail.	- La limitation des rassemblements fortuits a eu une incidence importante sur le risque de super propagation des événements dans ce modèle dans le cadre de scénarios où diverses stratégies d'intervention sont mises en œuvre.

PROTOCOLE DE RECHERCHE EN COURS

On a défini un protocole d'examen systématique qui résumera les données probantes sur les stratégies d'isolement, de quarantaine et d'éloignement social.

Tableau 2 : Protocoles de recherche

Référence	Description de l'étude	
(Regmi et Lwin, 2020)	Quelle a été l'incidence des mesures d'éloignement social pour la prévention de la maladie à coronavirus 2019 [COVID-19]?	Les études seront ciblées de juillet à octobre 2020 et se limiteront à des articles en anglais évalués par des pairs.

Méthodologies

Une analyse documentaire quotidienne (ouvrages publiés et en prépublication) est effectuée par le Groupe des sciences émergentes de l'Agence de la santé publique du Canada (ASPC). L'analyse a compilé les ouvrages sur la COVID-19 depuis le début de l'éclosion et est mise à jour quotidiennement. Les recherches visant à extraire les ouvrages pertinents sur la COVID-19 sont menées dans Pubmed, Scopus, BioRxiv, MedRxiv, ArXiv, SSRN et Research Square, et les résultats sont recoupés avec les ouvrages figurant sur la liste de la documentation sur la COVID de l'Organisation mondiale de la Santé et des centres d'information sur la COVID-19 gérés par Lancet, BMJ, Elsevier et Wiley. Le résumé quotidien et les résultats complets de l'analyse sont conservés dans une base de données RefWorks et dans une liste Excel consultable. Une recherche ciblée par mot-clé est effectuée dans ces bases de données pour recenser les citations pertinentes sur la COVID-19 et le SRAS-CoV-2. Les termes de recherche utilisés étaient les suivants : social ET (bulle ou bulles ou réseau). Les résultats ont été recoupés avec l'examen permanent sur les interventions de santé publique. La présente revue contient des recherches publiées jusqu'au 15 juin 2020.

Chaque référence potentiellement pertinente a été examinée pour confirmer qu'elle comportait des données pertinentes, qui ont été extraites dans la revue.

Emerging Evidence on COVID-19

Evidence Brief on viral load and the likelihood of transmission during the infectious period of SARS-CoV-2

Introduction

What is the relationship between viral load and the likelihood of transmission during the infectious period of SARS-CoV-2? Does this vary by presence of symptoms, severity of symptoms, risk factors (e.g., age, chronic health conditions) or by infection with the currently circulating SARS-CoV-2 variants of concern?

The correlation between viral load and likelihood of transmission has been studied throughout the pandemic in order to characterize when during an infection with SARS-CoV-2 a person may be more infectious and most likely to transmit the virus. Research has also attempted to characterize the attributes of individuals or characteristics of infection that may be associated with higher risk of transmission. During Winter 2021 new research has indicated that variants of concern (e.g., B.1.1.7, B.1.351, and P.1) may have different transmission dynamics and virulence than wild-type strains that were circulating earlier in the pandemic. This could be due to a multitude of interlacing factors (e.g., longer persistence of viral RNA shedding, decreased immune response, or lower binding energy between the SARS-CoV-2 spike protein and human receptors). The current evidence base is conflicting on whether variants of concern have higher viral loads. Some studies have reported higher viral loads in variant cases (B.1.1.7 and P.1) compared to wild-type (1-5), while three new studies reported no significant difference (6-8). Further investigations are necessary to determine what factors are contributing to the increased transmission observed with the circulating variants of concern. On the other hand, recent vaccination studies indicate that vaccination may prevent against symptomatic infection and may reduce viral load by 1.6 times to 20 times in infections occurring after the first dose of vaccine (9-11). Thus, even if vaccines do not fully prevent infection, reducing viral load during infection will also likely reduce transmission. This evidence brief focuses on research that investigates the relationship between viral load and likelihood of transmission during the infectious period of SARS-CoV-2 published up to March 31, 2021.

The most common proxy measurement of SARS-CoV-2 viral load is the cycle threshold (Ct) value, which is the number of cycles during reverse transcription polymerase chain reaction (RT-PCR) required to reach a threshold of detection for a certain gene target. Within this model, lower Ct values indicate a higher viral load and where provided, an estimate of viral load, copies/mL, can be calculated. The calculation of copies/mL requires a standardization process based on the amplification target in the extract and the Ct value. There are several downsides to using Ct values as a proxy of viral load. First, amplification efficiency is influenced by the assay itself and factors associated with sample collection (e.g., amount of sample material collected) (12, 13). Studies are often highly heterogeneous in the sampling methods, detection assay, and gene targets used. Second, the Ct value upper bound cut-off that determines a positive PCR result has been inconsistent among

studies, though most reported positive values at Ct ≤35. It is recommended that a standard curve using reference materials or in-house plasmid controls with known viral copy numbers be utilized to interpret Ct values as viral loads – this would allow for appropriate quantification (e.g., copies/mL) (14). However, there has been wide heterogeneity and inconsistency of the standard curves calculated across studies, so precaution is necessary when interpreting viral load results in the COVID-19 literature.

Detection of viral RNA by RT-PCR does not provide proof of infectivity as this test also gives positive results when non-infectious virus particles are present. Recovery of replication-competent virus has been used as a measure of infectiousness (i.e., transmission potential). This is most often accomplished using cell culture. The detection of subgenomic RNA has also been recommended as a potential proxy for shedding of replication-competent virus (15), although consensus on this application is lacking (16). While viral RNA shedding is often observed in respiratory samples collected more than 15-17 days post symptom onset (17), replicative virus has in most instances not been isolated past 10 days in mild cases (18-22). The correlation of SARS-CoV-2 viral loads and Ct values with isolation of replicative virus is an important topic of interest when investigating transmission potential and is explored in this review.

Key Points

- The evidence brief identified 27 studies including 2 systematic reviews, 5 prospective cohorts, 5 retrospective cohorts, 1 case-control, 7 cross-sectional studies, 1 surveillance study, 4 case series, 1 contact tracing study, and 2 modelling studies.

- Across all studies, transmission is most likely to occur when, samples contained replicative virus, which occurred when Ct values were low (<30) and the sample was taken less than 8-10 days from symptom onset.

Studies that investigate an association between viral load and evidence of replicative virus (Culture/subgenomic RNA) (n=15):

- Replicative virus was most likely to be isolated from samples with Ct values <30 or viral loads >1x 10^6 copies/mL. Samples with Ct values ≤25 demonstrated replicative virus at a rate >90%.

- The most recently published systematic review on this topic reported significant correlation between Ct value and culture positivity rates. The probability of recovery of virus from specimens with Ct > 35 was 8.3% (95% CI: 2.8% to 18.4%). Further, the odds for culturing replicative virus has been reported to decrease by 0.64 for every one unit increase in Ct (95% CI 0.49 to 0.84, p<0.001).

- Recovery of replicative virus was unlikely in samples collected >8-10 days post symptom onset, even in samples with Ct values <35. Thus, Ct value and days post symptom onset assessed in tandem may be an effective method for deciding the likelihood an individual is still infectious.

- Cases with positive culture identified at greater than 8-10 days or at Ct values >35 were more likely to be severe or immunocompromised cases.

- There was heterogeneity in the sampling and detection methods used across studies. The overall association between Ct value and isolation of replicative virus did not appear to differ depending on SARS-CoV-2 gene target (e.g., Nucleocapsid (N), Envelope (E), Spike protein (S)) used for the PCR test.

Studies that investigate an association between viral load and likelihood of transmission (n=12):

- Modelling studies demonstrated that viral loads peak on average 5 days post expsoure and 1-2 days post symptom onset, with a short period (<2 days) of high transmission risk after which the likelihood of transmission quickly diminishes by 7-10 days post symptom onset. Highly infectious cases can shed tens to thousands of SARS-CoV-2 virions/min, especially between 1-5 days post symptom onset.

- Index cases with high viral loads (>10^6 copies/mL or Ct values <30) were more likely to transmit SARS-CoV-2 to household contacts.

- Transmission from index cases with high Ct values (>35) have occurred, but the transmission risk is much lower (8%).

- The majority of secondary household cases were detected within 10 days post symptom onset of the index case.

- High viral loads have been reported during the pre-symptomatic period and up to 8-10 days post symptom onset. It is during this time when Ct values are low (<30) that there is a high probability of transmission.

Overview of the Evidence

A total of 27 studies were included in this review, including several observational studies. Multiple studies are pre-prints and have not undergone a peer-review process. Prospective cohorts are at lower risk of bias than retrospective cohorts and cross-sectional analyses of medical record data or routinely collected surveillance data on COVID-19. Some of these studies appeared to have good generalizability as they represented large or national databases. However, retrospective cohorts and cross-sectional studies are at higher risk of bias due to their retrospective nature, as well as the increased risk of having missing and confounding data. Case series suffer from low sample size, selection bias and recall bias (e.g., self-report symptom onset) and lack of generalizability. Predictive models were also included in this review, and their analyses represent an approximation of a real situation and can be used to compare options or scenarios, keeping in mind the limitations of the models used. Case reports and studies/reviews published prior to the latest relevant systematic reviews on this topic (search conducted up to September 2020) were excluded from this review, as it was expected they would be captured in the systematic reviews (23, 24).

Studies were highly heterogeneous in the designs, sampling methods, detection tests, and gene targets used. Thus, results cannot be directly compared across studies. The RT-PCR test results depend on the quality of the sample as well as the assay used (i.e., the chosen primers, reagents, and gene targeted) which determine the accuracy of the test. These technical differences in how the tests were conducted also made comparisons across studies difficult.

While many studies reported that viral loads differed by symptoms or risk factors, very few actually reported on this relationship in the context of transmission potential. Similarly, evidence to date on the potential relationship between viral load and increased transmissibility of SARS-CoV-2 variants of concern such as B.1.1.7 and P.1 are currently assumed to be related based on surveillance data reporting lower Ct values among infections (1-5) and recent models of rising VOC cases (25). However, the evidence is currently conflicting on whether B.1.1.7 and P.1 do in fact result in higher viral loads than wild-type SARS-CoV-2 (6-8). Evidence on whether other variants of concern, such as B.1.351, might be associated with higher viral loads has not yet been substantiated by primary data. Future empirical research will hopefully help close these knowledge gaps. No studies were identified that directly analyzed how the relationship between viral load and likelihood of transmission varied by infection with the currently circulating SARS-CoV-2 variants of concern. As such, the evidence presented below reflects wild-type strains as opposed to variants of concern.

CONTENTS

ASSOCIATION BETWEEN VIRAL LOAD AND EVIDENCE OF REPLICATIVE VIRUS

- Thirteen studies reported detection of replicative virus via cell culture and three studies reported detection via subgenomic RNA.
- Across all studies, replicative virus was more likely to be isolated from samples with lower Ct values than samples with high Ct values. Detection of replicative virus varied by viral load and timing of collection post symptom onset. No studies reported whether the association between viral load and evidence of replicative virus varied by risk factors (e.g., age, sex) or by infection with SARS-CoV-2 variants of concern.
    - Replicative virus was most likely to be isolated from samples with Ct values <30 (26-34) or viral loads >1x 10^6 copies/mL (23, 35).
        - A systematic review estimated that the probability of recovery of virus from specimens with Ct > 35 was 8.3% (95% CI: 2.8% to 18.4%) (23). Further, the odds for culturing live

virus has been reported to decrease by 0.64 for every one unit increase in Ct (95% CI 0.49 to 0.84, p<0.001) (23).
    - At Ct=25, up to 70% of patients remain positive in culture. At Ct=30 this value drops to 20%. At Ct=35 only <3% of cultures are positive (30).
    - In both mild and severe groups, viral replication was significantly more likely to be detected for samples with lower Ct values (p<0.001) (36). Samples with Ct values ≤ 25 demonstrated replicative virus at a rate >90% (36).
- Recovery of replicative virus was unlikely in samples collected >8-10 days post symptom onset, even in samples with Ct values <35 (34, 37-39). Thus, the probability of isolating replicative virus is highest prior to 8-10 days post symptom onset when Ct levels are low.
- Evidence of replicative virus has been detected in immunocompetent asymptomatic/mild cases with high Ct values (>35) (26, 33, 36), but such instances appear to be rare. In general, cases with positive culture identified at greater than 8-10 days or at Ct values >35 were more likely to be severe or immunocompromised cases (36, 39).

- There was heterogeneity in the sampling and detection methods used across studies.
    - RT-PCR gene targets reported across studies included the SARS-CoV-2 N gene (28, 29, 31, 37), E gene (27, 28, 30, 32, 36), S gene (26, 29), and ORF1ab (29). The overall association between viral load and isolation of replicative virus did not appear to differ depending on gene target.
    - The majority of studies were conducted using nasopharyngeal swabs (26-30, 30, 33-38, 38). However, oropharyngeal (34, 35, 37), sputum (34, 37), bronchial aspirate (36), serum (37), urine (37) and stool (37) swabs were also reported. Culture was more likely to be positive in nasopharyngeal, oropharyngeal, and sputum swabs than other specimen types (37).

Table 1: Studies that investigate association between viral load and evidence of replicative virus (n=15)

STUDY	METHOD	KEY OUTCOMES
Culture studies (n=13)		
Jefferson (2020) (23) Systematic review UK* Dec 2020*	Searched databases for studies attempting to culture or observe SARS-CoV-2 in specimens with RT-PCR positivity published up to September 10, 2020. Twenty-nine studies were captured, ten of which analysed the relationship between Ct values and virus culture.	- 5 studies reported no growth in specimens based on Ct cut-offs >24 to 35. The estimated probability of recovery of virus from specimens with Ct > 35 was 8.3% (95% CI: 2.8% to 18.4%). All donors with Ct > 35 (n=5) producing live culture were symptomatic. - One study reported the odds for culturing live virus decreased by 0.64 for every one unit increase in Ct (95% CI 0.49 to 0.84, p<0.001). - One study reported similar results in line with empirical evidence of an increased Ct of 0.58 per day since symptoms started.

		- One study reported that no successful viral culture was obtained from samples with viral loads less than 1x 10^6 copies/mL. - Viral load and probability of growing live virus of SARS-CoV-2 appears to peak much sooner than that of SARS CoV-1 or MERS-CoV.
Killerby (2021) (37) Prospective cohort study USA Mar 2021*	Nasopharyngeal (NP) swabs, oropharyngeal (OP) swabs, sputum (if available), serum, urine and stool specimens were collected every 2–3 days from the first 14 symptomatic patients detected in the USA and tested by rRT-PCR (targeting the N1, N2, or N3 gene). For a sample to be positive, all three gene targets had to be detected. Inconclusive results meant two gene targets were detected. Viral culture (Vero CCL-81 cells) was attempted on rRT-PCR positive and inconclusive specimens (n=131) collected during days 0-29 post illness onset.	- Virus was not recovered from respiratory specimens collected more than 8 days post symptom onset. - Successful culture was observed in 14% (8/57) of NP swabs, 10% (4/92) of OP swabs, and 14% (2/14) of sputum specimens with nucleocapsid (N)1, N2, and N3 Cts ranging from 16.5–32.5, 17.7–32.6, and 16.7–31.4 respectively. - Ct values were all significantly lower ($p<0.0001$ for all 3 gene targets) among specimens from which virus was successfully recovered in culture versus not. - Live virus was not recovered from serum or stool specimens, from inconclusive respiratory specimens, or from specimens collected after symptom resolution, despite continued detection of viral RNA.
Antar (2021) (34) *Preprint* Prospective cohort study USA Apr-July 2020	Outpatients (n=95) self-collected mid-turbinate nasal, oropharyngeal (OP), and oral fluid a median of 6 times over 1-3 months. Samples were tested for viral RNA using the RT-PCR Abbott m2000 platform targeting. Ct values < 31.5 were considered positive. Positive nasal-OP samples by RT-PCR were tested for propagation of SARS-CoV-2 in cell culture (methods not described). Also analyzed whether oral fluid anti-SARS-CoV-2 IgG could be used to predict which	- No samples collected more than 11 days post symptom onset tested positive for viral culture, even in an immunocompromised case who had positive RT-PCRs with low Ct values two months post symptom onset. - Virus culture was positive only in samples with Ct values <17. - Mean Ct values were all significantly lower among specimens from which virus was successfully recovered in culture versus culture negative samples ($p<0.00001$). - 14/15 positive for oral fluid anti-S-RBD IgG, with Ct values <20, were negative for virus culture. The one culture positive sample was collected on day 11 post symptom onset, which is around the time of expected first detection of this antibody.

	samples with low Ct values were negative for virus culture.	
Owusu (2021) (38) Prospective cohort study USA Mar-May 2020	Collected serial nasopharyngeal specimens at various time points from individuals (n=109) with rRT-PCR-confirmed COVID-19. Viral culture (Vero CCL-81 cells) was attempted for rRT-PCR-positive nasopharyngeal specimens (n=35) collected ≥10 days after symptom onset. Participants were classified into three categories based on their viral RNA shedding duration: Persistent (≥14 days), not persistent (<14 days), or indeterminate.	- The Ct values of the 35 specimens collected ≥10 days after symptom onset ranged from 26.3-38.4. - Culture was not successful for any of these specimens.
Folgueira (2021) (36) Cross-sectional study Spain Feb 2021*	Respiratory samples (186 nasopharyngeal exudates and seven bronchial aspirates) were processed by rRT-PCR (targeting the E gene) and cell culture (Vero E6 cells) from asymptomatic (n=11), mild (n=91) and severe (n=87) patients, obtained at various times from clinical diagnosis to follow-up.	- In both the mild and severe groups, the samples that showed viral replication had significantly lower median Ct values than the samples without viable virus: 23.3 (IQR: 20.5–28.0) vs. 36.4 (IQR: 31.8–39.1), respectively, for mild COVID-19 and 27.7 (IQR: 23.2–30.0) vs. 33.0 (IQR: 30.4–38.0), respectively, for severe COVID-19) ($p < 0.001$). - The samples with Ct ≤ 25 in both patient groups showed viable virus at a rate >90%. However, even the samples with Ct ≥ 35 could harbour viable virus (5% for mild COVID-19 and 15% for severe illness).
Felix (2021) (26) *Preprint* Cross-sectional study Brazil Feb 2021*	Patients with confirmed mild COVID-19 were invited to participate by providing nasopharyngeal (NP) samples at the day 10 if illness (n=53). Cell-cultured SARS-COV-2 RT-PCR (targeting the S gene) positive respiratory samples (n=29) at 10 days post symptom onset in VeroE6 cells. After two passages, cytopathic effect and cycle threshold lower than that obtained in the original sample were used to determine positivity of culture.	- Forty patients (79%) were SARS-CoV-2 positive by RT-PCR at day 10 (79%) with the median Ct of 25.7 (range 12-32). Of these, 29 were submitted for culture testing. - Culture was successful for 24% (7/29) of the samples tested. - The positivity in cell culture was strongly associated with low Ct values in clinical samples. Mean Ct value was 20 (IQR 16.5-21) in culture positive samples vs. 29 (IQR, 24-32.3) in culture negative samples, $p<0.0001$. - Two patients for which culture was successful reported having no symptoms on day 10.

Marot (2021) (27) LTE Cross-sectional study France Aug-Sept 2020	Conducted real-time RT-PCR assays to detect the presence of the viral E (envelope) subgenomic RNA and E negative-strand RNA in clinical samples. Also attempted to isolate virus via culture (Vero CCL-81 cells, incubated 2-7 days) from samples to associate the presence of positive-stranded replicative intermediate RNAs (RIs) with the detection of viable virus. Data were obtained from 61 immunocompetent healthcare workers (HCWs) diagnosed with SARS-CoV-2 infection by RT-PCR on nasopharyngeal samples.	- No isolate was recovered via culture when Ct > 28 (i.e., viral load below 5.83 log_{10} copies/mL).
Piralla (2020) (28) Cross-sectional study Italy Apr-Aug 2020	A series of nasal swabs collected from convalescent patients positive for SARS-CoV-2 RNA detected by rRT-PCR (targeting the E or N gene) with Ct >30 were included in the study (n=387). Cell culture (Vero E6 cells incubated up to 7 days) was conducted to investigate the infectious potential of samples. Note: No time point (i.e., day of illness) was provided for when samples were collected, however it is specified that all samples were drawn from clinically recovered patients.	- The median Ct value of convalescent samples was 36.8 (range: 30.0–39.4). For the E gene, the median Ct value was 36.9 (range 30.0–39.4) while the N gene was 35.5 (range 32.0–39.4). - Culture of convalescent specimens was successful for only 9 samples (2.3%, 9/387). - The median Ct value of culture-positive samples was not significantly different from that observed in culture-negative samples (35.6 vs. 36.9, p = 0.37).
Romero-Gómez (2020) (29) LTE	Investigated samples obtained from patients with SARS-CoV-2, comparing the results obtained by RT-PCR with the growth capacity of the virus via cell culture (Vero E6 cells, incubated for 4 days). 72	- Culturable samples had significantly lower Ct values (<30) than those with non-culturable samples (>30) (p<0.0001, see figures 1&2 in article). - Isolation of virus in culture was successful in samples with Ct between 21.54 and 37.73. - The highest Ct values in samples with positive cultures were found to be 36.08, 37.73 and 37.41 for

Cross-sectional study Spain Feb-June 2020	nasopharyngeal specimens taken at various time points of infection from 66 patients were analysed in this study. 17 samples were successfully isolated.	the ORF1ab, N and S genes, respectively, taken 1 day post symptom onset from a patient with a cough and fever.
Jaafar (2020) (30) LTE Cross-sectional study France* May 2020	Performed 250,566 SARS-CoV-2 RT-PCR tests on nasopharyngeal samples (Ct values based on the E gene). 13,161 were positive and 1,941 isolates were obtained via culture (Vero E6 cells).	- At Ct = 25, up to 70% of patients remain positive in culture. At Ct = 30 this value drops to 20%. At Ct = 35, the value used to report a positive result for PCR, <3% of cultures are positive.
Kim (2021) (31) LTE Case series South Korea Feb-Jun 2020	Clinical and virological characterization of 21 hospitalized patients. Viral RNA was quantitated using rtRT-PCR (targeting the N gene) and viral cultures were conducted via plaque assay (vero cells) until at least two consecutive cultures showed no growth.	- Viable SARS-CoV-2 was cultured in 29/89 samples. - Viral culture was positive only in samples with a CT ≤ 28.4. - Median time from symptom onset to viral clearance in culture was 7 days. - The incidence of culture positivity decreased with an increasing time from symptom onset and with an increasing cycle-threshold value.
Vetter (2020) (35) Case series Switzerland Feb 2020	Clinical, virological, and immunological characterization of the first five patients assessed at the Geneva University Hospital (HUG), from the day of diagnosis until convalescence. SARS-CoV-2 was detected by rtRT-PCR in both the oropharyngeal swabs (OPS) and the nasopharyngeal swabs (NPS) of each patient. Viral culture was conducted using Vero E6 cells.	- Isolation of virus in culture was successful from both NPS and OPS during the first week of illness for four mild cases. - The mean viral load in samples affording successful isolation was $1.2x10^9$ copies/ml. SARS-CoV-2 could not be isolated in clinical specimens containing less than $1.4x10^6$ viral RNA copies/ml.
Lewis (2020) (39)	Investigated household transmission in 5 households with daily specimen collection.	- In multiple patients, low Ct values (<20) on days 2-4 post symptom onset coincided with onset of additional symptoms (chest pain, myalgia, and loss

Contact tracing study USA Apr 2020	During days 1–4, if a household contact had an inconclusive result (1 of 2 target gene regions positive for SARS-CoV-2 by rRT-PCR) or positive result (both target gene regions positive) the associated specimen and all subsequent daily specimens from the person were submitted for viral culture to evaluate infectiousness. Specimens positive by rRT-PCR that were collected on day 14 with Ct values<35 were also cultured. Gene targets for rRT-PCR and methods for culture were not described.	of taste and smell) and positive viral cultures on both days. - Culture was not successful among specimens collected 14 days post symptom onset, despite positive rRT-PCR and Ct values <35.
Subgenomic RNA Studies (n=3)		
Rodríguez-Grande (2021) (32) Case series Spain Jan 2021*	Assessed samples of persistent RT-PCR positive cases (n=60) with >21 days since the first diagnostic RT-PCR for evidence of replicative virus as determined by subgenomic E gene RNA (SG RNA).	- SG RNA was detected in 12/60 cases (20%). Collection dates ranged from 28-79 days after onset in these samples. - In all cases with detectable SG RNA, Ct values for genomic RNA were <30, consistent with the values expected for an active virus. - The age range of subjects with prolonged viral shedding and SG viral RNA was quite wide and equally distributed between males and females. Seven were immunosuppressed. The severities of the COVID-19 episodes were mild (40%), intermediate (20%), and severe (40%). One case with SG RNA at day 25 was asymptomatic.
Marot (2021) (27) LTE Cross-sectional study France Aug-Sept 2020	Conducted real-time RT-PCR assays to detect the presence of the viral E (envelope) subgenomic RNA and E negative-strand RNA in clinical samples. Also attempted to isolate virus via culture (Vero CCL-81 cells, incubated 2-7 days) from samples to associate the presence of positive-stranded replicative intermediate RNAs (RIs) with	- No RIs were detectable in samples when the Ct > 33 (viral load below 4.34 $\log_{10}$ copies/mL) - The ratios of mean normalized RIs per genome indicate a high level of viral replication during the first 5 days from symptom onset, followed by a significant decline.

	the detection of viable virus. Data were obtained from 61 immunocompetent healthcare workers (HCWs) diagnosed with SARS-CoV-2 infection by RT-PCR on nasopharyngeal samples.	
Hogan (2021) (33) Prospective and retrospective cohort studies USA Mar-Apr 2020 & July-Sep 2020	Developed a novel 2-step rRT-PCR specific to the minus strand of the envelope gene (actively replicating virus produces minus-strand RNA intermediates thus can be used as a proxy for potential infectiousness). Retrospectively collected a convenience set of longitudinal upper respiratory specimens with a broad range of Ct values. For the prospective phase of the study, they collected upper respiratory samples from 53 consecutive patients with confirmed SARS-CoV-2 infection. Samples were collected a median of 9 days (IQR: 4–18 days) after symptom onset.	- Minus-strand RNA was detected in 41 (28.1%) patients. - The median Ct value was significantly lower in samples with detected minus-strand RNA (20.7) than those in which the minus strand was not detected (33.2, $p<0.01$). - Minus-strand RNA was detected in two immunocompentent inpatients >10 days post symptom onset with high Ct values (~39). Minus-strand SARS-CoV-2 RNA was detected up to 30 days after symptom onset in an immunocompromised patient.

LTE= letter to editor

ASSOCIATION BETWEEN VIRAL LOAD AND TRANSMISSION RISK

- Viral loads appear to peak on average 5 days post expsoure and 1-2 days post symptom onset, with a short period (<2 days) of high transmission risk and transmission potential being greatly diminished by 7-10 days post symptom onset (40-42). During peak viral load, highly infectious cases can shed tens to thousands of SARS-CoV-2 virions/min (24).

- Several observational studies were conducted that investigated household/cluster transmission. In line with the culture findings from the section above, cases with higher viral loads (i.e., lower Ct values) were more likely to transmit SARS-CoV-2.
    - Index cases with high viral load (>10^6 copies/uL) were more likely to transmit SARS-CoV-2 to close contacts (OR 4.9, 95% CI: 1.3-18, p=0.02) (43). The secondary attack rate was reported to range from 12% when the index case had a viral load ≤1x10^6 copies/mL to 24% when the index

case had a viral load of ≥1x10^{10} copies/mL (adjusted odds ratio per $\log_{10}$ increase in viral load=1.3, 95% CI: 1.1-1.5) (44).

- Regression models demonstrated that cases resulting in secondary transmission had higher median viral loads than that of cases that did not transmit SARS-CoV-2 (45). Two retrospective cohort studies conducted in US university residences also found that index cases resulting in secondary transmission had higher viral loads (up to 6.5 fold) than cases that did not cause secondary transmission (46, 47). Although both symptomatic and asymptomatic cases exhibited average Ct peaks around Ct 19-22, the Ct values were significantly lower in symptomatic cases (range: 12-36 vs. 14-37), indicative of reduced viral load among asymptomatic cases (47).
- A cross-sectional study comprising the full population of Denmark found that index cases with a Ct <20 had a transmission risk 1.89 times higher than an index case with a Ct >25 (48). The index case had a Ct value of >30 in 39% of secondary cases, but transmission risk was significantly higher if the Ct values were <28. Index cases with high Ct values (>35) did occur, but the transmission risk was much lower (8%).
- The majority of secondary household cases were detected within 10 days post symptom onset of the index case, aligning with the timing of recovery of replicative virus findings noted in section above (43).
- One study found that clusters with high viral loads (>10^6 copies/mL) were considerably larger than clusters with subjects showing a lower viral load (17 infected individuals vs 3 within cluster, p<0.001) (49).

- There were few studies that reported on how the relationship between viral load and transmission risk varied by presence of symptoms, severity of symptoms, or risk factors (e.g., age, chronic health conditions).
  - A systematic review found that adult, pediatric, symptomatic/presymptomatic and asymptomatic COVID-19 cases show similar respiratory viral load distributions during the infectious period (24). Interestingly, a larger population study found that older age was positively associated with transmission risk, even after controlling for viral load (i.e., age was a better predictor of transmission risk than viral load) (48).
  - High viral loads (Ct<20) prior to symptom onset among cases that transmitted SARS-CoV-2 presymptomatically have been reported (50). The longer the incubation period, the larger the fraction of presymptomatic viral load, and thus a higher likelihood of presymptomatic transmission (41).
  - High viral loads have been reported both in the pre-symptomatic period and up to 8-10 post-symptom onset. It is during this time when Ct values are low (<30) that there is a high probability of transmission.

Table 2: Studies that investigate association between viral load and transmission risk (n=12).

STUDY	METHOD	KEY OUTCOMES
Chen (2020) (24) *Preprint* Systematic review and modelling study Canada* Dec 2020*	A systematic review was conducted to capture studies published up to August 7, 2020 (n=64) in order to develop a comprehensive dataset of respiratory viral loads (rVLs) of SARS-CoV-2. A meta-analysis and model was then conducted to investigate individual infectiousness by shedding viable virus via respiratory droplets and aerosols. SARS-CoV-2 rVLs was analyzed across age and symptomatology subgroups as well as disease course.	- At the 90th case percentile (cp) throughout the infectious period, the estimated rVL was 8.91 (95% CI: 8.83-9.00) log10 copies/ml. - Age and symptomatology minimally influenced case variation in SARS-CoV-2 rVL during the infectious period. Adult, pediatric, symptomatic/presymptomatic and asymptomatic COVID-19 cases showed similar rVL distributions, with standard deviations of 2.03, 2.06, 2.00 and 2.01 log10 copies/ml, respectively. - The mechanistic model showed that SARS-CoV-2 rVL increased exponentially after infection, peaked around 1 day post symptom onset and then diminished exponentially. Highly infectious cases can shed tens to thousands of SARS-CoV-2 virions/min, especially between 1-5 days post symptom onset.
Cerami 2021 (43) *Preprint* Prospective cohort study USA Apr-Oct 2020	Enrolled COVID-positive persons (n=102) and their household members (n=213) to study SARS-CoV-2 transmission within households. Households were enrolled a median of 6 days from onset of symptoms in the index case. Secondary cases were detected either by RT-qPCR (targeting N1, N2, and RNase P) of a nasopharyngeal swab on study day 1 and weekly nasal swabs (days 7, 14, 21), or based on seroconversion by day 28.	- The majority of secondary household cases were detected within 10 days post symptom onset of the index case. - Index cases with high viral load (>10^6 viral copies/ul) at enrollment were more likely to transmit virus to household contacts during the study (OR 4.9, 95% CI 1.3-18, p=0.02). - Viral load was correlated within families, meaning persons in the same household were more likely to have similar viral loads, suggesting an inoculum effect. These differences were not attributable to the D614G mutation in the SARS-CoV-2 spike protein, as the vast majority of isolates genotyped contained this mutation (98%).
Bjorkman (2021) (46) Retrospective cohort study USA	Analyzed the transmission of COVID-19 in residence halls based on the weekly RT-qPCR (targeting the E gene) screening of residential	- The average viral load was 6.5-fold higher in rooms with likely transmission (mean Ct=26.2) than in rooms without transmission (mean Ct=28.9).

Aug-Nov 2020	students. Each Ct whole unit is a factor of 2 in RNA copies per ml. Investigated the extent to which the timing of cases supported inter-roommate transmission.	- These cases spanned a range of over 7 orders of magnitude in viral load, with the highest load found in the likely transmission group (Ct=15.4) and the lowest found in the unlikely transmission group (Ct=40.6). The only cases with Ct greater than 34 (22 cases) were found in the unlikely transmission group.
Tian (2021) (47) *Preprint* Retrospective cohort study USA Sept-Oct 2020	Performed a total of 61,982 tests of 7,440 undergraduate students to determine whether the Ct value could differentiate the spreader from the non-spreader. Students were tested multiple times via RT-PCR (targeting the N, S and ORF1ab genes) over the study period and 602 cases were identified.	- 48.2% (94/195) of index cases had at least one contact who became SARS-CoV-2-positive, whereas 51.8% of the index cases (n=101) did not spread SARS-CoV-2 to their contacts. - Mean Ct values of the spreader and the non-spreader were nearly identical (peak at Ct = 18-21) but their median Ct values differed by almost one cycle, suggesting that spreaders had a lower Ct value than the non-spreaders (see Figure 1B&C in article). Ct range was slightly broader for the spreader (12-36) than that for the non-spreader (14-36). - Although both groups exhibited Ct peaks around Ct 19-22, the Ct values were significantly lower in symptomatic than those in asymptomatic cases (range: 12-36 vs. 14-37), indicative of reduced viral load among asymptomatic cases.
Shrestha (2021) (42) Retrospective cohort study USA Mar-Apr 2020	Evaluated transmission potential by examining viral load with respect to time since onset of symptoms in healthcare professionals infected with SARS-CoV-2 (n=230). Nasopharyngeal swabs were tested by RT-PCR (targeting the N1, N2, and N3 genes). The mean of the 3 Ct values from the three gene targets was considered the Ct for the test. Viral loads since symptom onset were predicted using the	- SARS-CoV-2 viral RNA load is very high within 2–3 days post onset of symptoms and falls rapidly by orders of magnitude within a few days (see Figure 1 in article). - Transmission potential of COVID-19 is greatly diminished by 7–10 days post onset of symptoms (see Figure 3 in article). Of the AUC spanning the interval from onset of symptoms to 30 days, 86.3% lie within the first 5 days, 96.9% within the first 7 days, and 99.7% within the first 10 days.

	regression model, with the area under the curve (AUC) representing the distribution of transmission potential over time.	
Marks (2020) (44) Retrospective cohort study Spain Mar-Apr 2020	This study was a post-hoc analysis of data collected in a cluster randomised trial that included individuals with qPCR confirmed COVID-19 and their close contacts. Factors associated with transmission were assessed by linear regression using all clusters of an index case for which quantitative viral load from nasopharyngeal swabs was available.	- The overall secondary attack rate was 17% (125/753 contacts) with a range of 12% when the index case had a viral load $\leq 1x10^6$ copies/mL to 24% when the index case had a viral load of $\geq 1x10^{10}$ copies/mL. - According to multivariate analysis, the odds of transmission were higher when the index case had a high viral load (adjusted odds ratio per $\log_{10}$ increase in viral load=1.3 (95%CI: 1.1-1.5). - 90% of transmission events occurred when the index case had a high viral load (≥5.1 $\log_{10}$ copies/mL). 50% occurred in clusters where the index case had a viral load of ≥8.8 $\log_{10}$ copies/mL. - Other factors associated with an increased risk of transmission were household contact and age of the contact. No association was observed with mask usage, age or sex of index case, or with presence of respiratory symptoms in index case.
Kawasuji (2020) (45) Case-control study Japan Apr-May 2020	COVID-19 patients who transmitted the disease to at least one other patient were analysed as "cases" (index patients, n=14) and compared with patients who were not the cause of secondary transmission (non-index patients, n=14, analysed as "controls"). Cases were confirmed and viral load quantified via RT-qPCR (targeting the N2 gene). The nasopharyngeal viral load time courses were assessed between the index and non-index symptomatic patients using non-linear	- Viral loads peaked soon after symptom onset, and then gradually decreased. Median time to viral clearance did not significantly differ between index and non-index patients: 21 days (IQR: 15–31) vs. 17 days (9-26), p=0.34. - The viral load at the time of initial sample collection was significantly higher in symptomatic vs. asymptomatic patients and in adult vs. children. - Regression models of symptomatic cases only (n=18) demonstrated that the median viral load of the index patients at onset was higher than that of the non-index patients: 6.6 log copies/µL (95%CI: 5.2-8.2) vs. 3.1 (1.5-4.8). This trend continued until 10 days post onset. When asymptomatic cases were also included in this model (n=10), the

	regression employing a standard one-phase decay model.	overall trend stayed the same: 3.3 log copies/µL (95% CI: 1.6-5.2) vs. 1.8 (-0.4-4.6), p=0.015.
Lyngse (2021) (48) *Preprint* Cross-sectional study Denmark Aug 25-Feb 10, 2021	Used comprehensive administrative register data from Denmark, comprising the full population and all SARS-CoV-2 tests, to estimate household transmission risk. RT-PCR (targeting the E-gene) was used and a test for SARS-CoV-2 was defined as positive if the Ct value was ≤38. 66,602 primary cases were identified, from which 99.6% had available Ct values. 103,389 secondary cases were identified.	- 25% of primary cases had a Ct value ≤25, 50% had a Ct value ≤28, and 75% had a Ct value ≤32. Ct value was similar across age groups. - There was an approximately linear decreasing relationship between Ct values and transmission risk. - The index case had a Ct value of >30 in 39% of secondary cases (but this is day of testing vs. an unknown peak viral load point- they did not have data to adjust for this). Primary cases with a Ct value of 38 had a transmission risk of 8% within the household. - Transmission risk was significantly higher if Ct values were <28. - A primary case with a Ct value of 18-20 has a transmission risk 1.89 higher than a primary case with a Ct value of 36-38. - Transmission risk had a negative association with age in children <20 and a positive association with age for those >20 yrs.
Ladoy (2021) (49) *Preprint* Surveillance study Switzerland Jan-Jun 2020	Characterized the dynamics of the first wave of SARS-CoV-2 infection in the canton of Vaud (western Switzerland) through the detection and the location of clusters using the results of SARS-CoV-2 RT-PCR tests (n= 33,651 tested, n=3,317 positive). A spatial scan approach was used to assess the importance of viral load in the evolution of the clusters and a Modified Space-Time DBSCAN algorithm was used to	- 1,684 space-time clusters were identified. - The majority of clusters had at least one person with a high viral load (>1 billion copies/ml). Clusters with such high viral loads were considerably larger (median of 17 infected individuals) than clusters with subjects showing a viral load lower >1 million copies/ml (median of 3 infected individuals, p<0.001). - Clusters involving younger individuals had the highest viral loads, while clusters composed of older individuals had low to medium viral loads. - There were 20 clusters in which the viral load of the three first cases were all below 100,000 copies/ml, suggesting that in some

	characterize the diffusion dynamics of transmission clusters.	instances, even subjects with less than 100,000 copies/ml may still be contagious.
Park (2020) (50) Case series South Korea -> Israel Feb 2020	An outbreak of SARS-CoV-2 among 39 pilgrim travelers was investigated. Ten confirmed cases without symptoms at the first sampling dates (2 post-symptomatic, 4 pre-symptomatic, and 4 asymptomatic) were selected for follow-up respiratory tract sample RT-PCR tests (targeting the E gene).	- Available Ct values from specimens of the lower respiratory tract were significantly lower in cases without symptoms (median, 22.8; IQR, 20.1–25.4) than in cases with symptoms at the first sampling dates (median, 27.9; IQR, 23.4–30.4). The viral loads gradually decreased over time and were not different between symptomatic and asymptomatic cases. - The highest viral load (Ct<20) was observed from the first sample of a case collected 7 days before symptom onset. Transmission occurred from this case to a close contact during the presymptomatic period.
Goyal 2021 (40) Modelling study USA* Feb 2021*	Developed a transmission simulation framework to analyze the contribution of viral load to observed epidemiologic transmission metrics SARS-CoV-2. This process included within-host modeling of viral loads, simulations of exposures and possible transmissions based on various transmission dose response curves, testing of various parameter sets against epidemiologic data and exploratory analyses with the best fitting model.	- Simulations demonstrated an upper airway viral load $<10^4$ SARS-CoV-2 RNA copies is very unlikely (~0.00005%) to lead to transmission. Transmission is much more likely (39%) given an exposure to an infected person who is shedding $>10^7$ RNA copies, and 75% given an exposure to an infected person with a viral load of $>10^8$ RNA copies. - There is an inflection point between 10^6 and 10^7 RNA copies, after which multiple transmission events becomes much more likely from a single person (i.e., super spreading event). - Infected persons are likely to be most infectious (viral load above TD50) for a 0.5–1.0 day period between days 2 and 6 post infection. This variability is likely attributable to heterogeneity in incubation period rather than timing of peak viral load.
Ke (2020) (41) *Preprint* Modelling study USA*	Developed data-driven within-host models of SARS-CoV-2 infection. Analyzed the relationship between viral load in the lower and upper respiratory trans (LRT & URT) and potential	- Respiratory viral load peak on average 5.2 days (SD: ±1.3 days) and 5.4 days (±1 day) post infection in the URT and the LRT, respectively, and on average 2 days (±0.2 day) and 2.1 days (±1.2 days) post symptom onset.

Sep 2020	infectiousness via a probabilistic model using existing epidemiological evidence (from 8 cases). Develop several more models to explain the prolonged period of virus infection in the LRT.	- The longer the incubation period, the larger the fraction of presymptomatic viral load (See Fig. 2; $p<0.001$), and thus leads to a higher fraction of presymptomatic transmission. - Model demonstrates that the logarithm of viral load (rather than absolute viral load) is an appropriate surrogate for infectiousness (i.e., viral growth is a better predictor of presymptomatic transmission than viral load measurement alone). - Spatial dissemination in the lungs is an important process in sustaining prolonged high viral loads in the LRT.

Methods:

A daily scan of the literature (published and pre-published) is conducted by the Emerging Sciences Group, PHAC. The scan has compiled COVID-19 literature since the beginning of the outbreak and is updated daily. Searches to retrieve relevant COVID-19 literature are conducted in Pubmed, Scopus, BioRxiv, MedRxiv, ArXiv, SSRN, Research Square and cross-referenced with the COVID-19 information centers run by Lancet, BMJ, Elsevier, Nature and Wiley. The daily summary and full scan results are maintained in a refworks database and an excel list that can be searched. Targeted keyword searching is conducted within these databases to identify relevant citations on COVID-19 and SARS-COV-2. Search terms used included: Shedding, Viral dynamics, Viral RNA dynamics, Viral clearance, Viral RNA clearance, Viable, Culture, Infectivity, Infectious Period, Communicability period, Period of communicability, Viral load, Viral RNA load, Infectiousness. This review contains research published up to March 31, 2021. Each potentially relevant reference was examined to confirm it had relevant data and relevant data is extracted into the review.

Nouveaux éléments de preuve sur la COVID-19

Synthèse en bref sur la charge virale et la probabilité de transmission pendant la période infectieuse du SRAS-CoV-2

Introduction

Quel est le lien entre la charge virale et la probabilité de transmission pendant la période infectieuse du SRAS-CoV-2? Varie-t-il selon la présence des symptômes, la gravité des symptômes, les facteurs de risque (p. ex., âge, problèmes de santé chroniques) ou selon l'infection découlant des variants du SRAS-CoV-2 qui circulent actuellement et qui sont préoccupants?

La corrélation entre la charge virale et la probabilité de transmission a été étudiée pendant toute la durée de la pandémie afin de caractériser le moment où, pendant une infection au SRAS-CoV-2, une personne peut être plus infectieuse et plus susceptible de transmettre le virus. La recherche a également tenté de caractériser les attributs des personnes ou les caractéristiques de l'infection qui peuvent être associés à un risque plus élevé de transmission. Pendant l'hiver 2021, de nouvelles recherches ont indiqué que les variants préoccupants (p. ex., B.1.1.7, B.1.351 et P.1) peuvent avoir une dynamique de transmission et une virulence différentes des souches de type sauvage qui circulaient plus tôt pendant la pandémie. Cela pourrait être attribuable à une multitude de facteurs entrelacés (p. ex., persistance plus longue de l'excrétion de l'ARN viral, diminution de la réponse immunitaire ou énergie de liaison plus faible entre la protéine de pointe du SRAS-CoV-2 et les récepteurs humains). La base de données probantes actuelle est contradictoire en ce qui concerne la question de savoir si les variants préoccupants ont une charge virale plus élevée. Certaines études ont signalé des charges virales plus élevées dans les cas de variants (B.1.1.7 et P.1) comparativement aux cas de type sauvage (1 à 5), tandis que trois nouvelles études n'ont signalé aucune différence significative (6 à 8). D'autres études sont nécessaires pour déterminer les facteurs qui contribuent à l'augmentation de la transmission observée avec les variants préoccupants actuellement en circulation. Des études récentes sur la vaccination indiquent par ailleurs que la vaccination peut prévenir les infections symptomatiques et réduire la charge virale de 1,6 fois à 20 fois dans les infections qui se produisent après avoir reçu la première dose du vaccin (9 à 11). Ainsi, même si les vaccins ne préviennent pas entièrement l'infection, la réduction de la charge virale pendant l'infection réduira probablement aussi la transmission. La présente synthèse en bref sur la recherche qui examine le lien entre la charge virale et la probabilité de transmission pendant la période infectieuse du SRAS-CoV-2, publié jusqu'au 31 mars 2021.

La mesure de substitution la plus courante de la charge virale du SRAS-CoV-2 est la valeur de cycle seuil (Ct), qui est le nombre de cycles pendant la réaction en chaîne de la polymérase (RT-PCR) à transcription inversée nécessaire pour atteindre un seuil de détection pour une certaine cible génétique. Dans ce modèle, des valeurs Ct plus faibles indiquent une charge virale plus élevée et, lorsqu'elles sont fournies, une estimation de

la charge virale, copies/ml, peut alors être calculée. Ce calcul nécessite un processus de normalisation basé sur la cible d'amplification dans l'extrait et la valeur Ct. L'utilisation des valeurs Ct comme indicateur de la charge virale comporte plusieurs inconvénients. Premièrement, l'efficacité de l'amplification est influencée par le dosage lui-même et les facteurs associés au prélèvement de l'échantillon (p. ex., quantité de matériel d'échantillonnage prélevé) (12, 13). Les études sont souvent très hétérogènes dans les méthodes d'échantillonnage, les essais de détection et les cibles génétiques utilisées. Deuxièmement, le seuil de la limite supérieure de la valeur Ct qui détermine un résultat PCR positif n'était pas uniforme dans les différentes études, bien que la plupart aient rapporté des valeurs positives à la valeur Ct 35. Il est recommandé d'utiliser une courbe standard avec des matériaux de référence ou des témoins internes du plasmide avec des nombres de copies virales connus pour interpréter les valeurs de Ct comme des charges virales pour ainsi obtenir une quantification appropriée (p. ex., copies/ml) (14). Comme il y a toutefois eu une grande hétérogénéité et une incohérence dans les courbes types calculées entre les différentes études, il faut donc faire preuve de prudence lorsqu'on interprète les résultats de la charge virale dans la documentation sur la COVID-19.

La détection de l'ARN viral par RT-PCR ne fournit pas de preuve d'infectiosité, puisque ce test donne également des résultats positifs en présence de particules de virus non infectieux. La récupération d'un virus capable de se répliquer a été utilisée comme mesure de l'infectiosité (c.-à-d. du potentiel de transmission). Cela se fait le plus souvent au moyen de la culture cellulaire. La détection de l'ARN subgénomique a également été recommandée comme substitut potentiel pour l'élimination du virus capable de se répliquer (15), bien qu'il n'y ait pas de consensus à cet égard (16). Bien que l'excrétion de l'ARN viral soit souvent observée dans les échantillons respiratoires prélevés plus de 15 à 17 jours après l'apparition des symptômes (17), le virus réplicatif n'a pas été isolé au cours des 10 derniers jours dans les formes légères (18 à 22). La corrélation entre les charges virales du SRAS-CoV-2 et les valeurs Ct avec isolement du virus réplicatif est un sujet d'intérêt important dans l'étude du potentiel de transmission et est explorée dans cette synthèse.

Points clés

- L'exposé sur les données probantes a permis de cerner 27 études, dont 2 revues systématiques, 5 cohortes prospectives, 5 cohortes rétrospectives, 1 étude cas-témoin, 7 études transversales, 1 étude de surveillance, 4 séries de cas, 1 étude de dépistage des contacts et 2 études de modélisation.

- Dans toutes les études, la transmission était plus probable lorsque les échantillons contenaient un virus réplicatif, ce qui s'est produit lorsque les valeurs Ct étaient faibles (< 30) et que l'échantillon avait été prélevé moins de 8 à 10 jours après l'apparition des symptômes.

Études qui examinent l'association entre la charge virale et les preuves d'un virus réplicatif (culture/ARN subgénomique) (n = 15) :

- Le virus réplicatif était le plus susceptible d'être isolé à partir d'échantillons dont les valeurs Ct étaient inférieures à 30 ou dont la charge virale était supérieure à 1 x 106 copies/ml. Les échantillons dont la valeur Ct est ≤ 25 ont montré la présence d'un virus réplicatif à un taux supérieur à 90 %.

- La revue systématique la plus récemment publiée sur ce sujet a fait état d'une corrélation importante entre la valeur Ct et les taux de positivité de la culture. La probabilité de récupération du virus dans les spécimens dont la valeur Ct est supérieure à 35 était de 8,3 % (IC à 95 % : 2,8 % à 18,4 %). On a en outre indiqué que les probabilités de propagation du virus réplicatif diminuaient de 0,64 pour chaque augmentation d'une unité de la valeur Ct (IC à 95 % : 0,49 à 0,84, p < 0,001).

- Il était peu probable que l'on récupère un virus réplicatif dans les échantillons prélevés plus de 8 à 10 jours après l'apparition des symptômes, et ce, même dans les échantillons dont les valeurs Ct étaient inférieures à 35. Ainsi, la valeur Ct et le nombre de jours après l'apparition des symptômes évalués en tandem peuvent être une méthode efficace pour déterminer la probabilité qu'une personne soit toujours contagieuse.

- Les cas de culture positive identifiés après plus de 8 à 10 jours ou grâce à des valeurs Ct supérieures à 35 étaient plus susceptibles d'être des cas graves ou immunodéprimés.

- Les méthodes d'échantillonnage et de détection utilisées dans les études étaient hétérogènes. L'association globale entre la valeur Ct et l'isolement du virus réplicatif ne semblait pas différer selon la cible génétique du SRAS-CoV-2 (p. ex., nucléocapside (N), enveloppe (E), protéine de spicule (S)) utilisée pour le test PCR.

Études qui examinent l'association entre la charge virale et la probabilité de transmission (n = 12) :

- Des études de modélisation ont démontré que la charge virale atteignait un sommet en moyenne cinq jours après l'exposition et un à deux jours après l'apparition des symptômes, avec une courte période (< 2 jours) de risque de transmission élevé, après quoi la probabilité de transmission diminue rapidement de 7 à 10 jours après l'apparition des symptômes. Les formes hautement infectieuses peuvent excréter des dizaines à des milliers de virions SARS-CoV-2/min, particulièrement de 1 à 5 jours après l'apparition des symptômes.

- Les cas index présentant une charge virale élevée (> 10^6 copies/ml ou une valeur Ct inférieure à 30) étaient plus susceptibles de transmettre le SRAS-CoV-2 aux contacts du ménage.

- La transmission à partir de cas index ayant des valeurs Ct élevées (> 35) s'est produite, mais le risque de transmission était beaucoup plus faible (8 %).

- La majorité des cas dans des ménages secondaires ont été détectés dans les 10 jours suivant l'apparition des symptômes du cas index.

- Des charges virales élevées ont été signalées pendant la période présymptomatique et jusqu'à 8 à 10 jours après l'apparition des symptômes. C'est pendant cette période où les valeurs Ct sont faibles (< 30) qu'il y a une forte probabilité de transmission.

Vue d'ensemble des éléments de preuve

Au total, 27 études ont été incluses dans la présente synthèse, y compris plusieurs études d'observation. Bon nombre d'études sont des préimpressions et n'ont donc pas fait l'objet d'un processus d'évaluation par les pairs. Les cohortes prospectives présentent un risque plus faible de biais que les cohortes rétrospectives et les analyses transversales des données des dossiers médicaux ou les données de surveillance recueillies régulièrement sur la COVID-19. Certaines de ces études semblaient cependant avoir une bonne capacité de généralisation, car elles utilisaient de grandes bases de données nationales. Toutefois, les cohortes rétrospectives et les études transversales présentent un risque plus élevé de biais en raison de leur nature rétrospective, ainsi que du risque accru de données manquantes et confusionnelles. Les séries de cas comprennent un petit échantillon, en plus de présenter un biais de sélection et un biais de rappel (p. ex., apparition de symptômes autodéclarés) et un manque de généralisable. Des modèles prédictifs ont également été inclus dans cette synthèse en bref, et leurs analyses représentent une approximation d'une situation réelle et peuvent donc être utilisées pour comparer des options ou des scénarios, en gardant à l'esprit les limites des modèles utilisés. Les rapports de cas et les études ou revues publiées avant les plus récentes revues systématiques pertinentes sur ce sujet (recherche effectuée jusqu'en septembre 2020) ont été exclus de cet examen, car on s'attendait à ce qu'ils soient inclus dans les revues systématiques (23, 24).

Les études étaient souvent très hétérogènes dans les méthodes d'échantillonnage, les tests de détection et les cibles génétiques utilisées. Par conséquent, les résultats ne peuvent pas être comparés directement entre les études. Les résultats du test RT-PCR dépendent de la qualité de l'échantillon ainsi que du matériel utilisé (c.-à-d., les amorces, les ensembles de réactifs et le gène ciblés) qui déterminent la précision du test. Ces différences techniques dans la façon dont les tests ont été effectués ont également rendu plus difficiles les comparaisons entre les études.

Bien que de nombreuses études aient indiqué que les charges virales différaient selon les symptômes ou les facteurs de risque, très peu d'entre elles faisaient état de ce lien dans le contexte du potentiel de transmission. De même, les données probantes obtenues jusqu'à maintenant sur le lien potentiel entre la charge virale et la transmissibilité accrue des variants préoccupants du SRAS-CoV-2, comme le B.1.1.7 et le P.1, sont actuellement présumées être liées, comme l'indiquent les données de surveillance qui indiquent des valeurs Ct plus faibles parmi les infections (1 à 5) et les modèles récents portant sur l'augmentation des cas de variants préoccupants (25). Les éléments de preuve sont actuellement contradictoires quant à savoir si les variants B.1.1.7 et P.1 entraînent en fait une charge virale plus élevée que le SARS-CoV-2 de type sauvage (6 à 8). Les données primaires n'ont pas encore permis de déterminer si d'autres variants préoccupants, comme B.1.351, pourraient être associés à des charges virales plus élevées. Nous espérons que les recherches empiriques futures aideront à combler ces lacunes. Aucune étude n'a analysé directement comment variait le lien entre la charge virale et la probabilité de transmission en fonction du type d'infection associé aux variants préoccupants du SRAS-CoV-2 actuellement en circulation. Ainsi, la preuve présentée ci-dessous reflète les souches de type sauvage par opposition aux variants préoccupants.

TABLE DES MATIÈRES

ASSOCIATION ENTRE LA CHARGE VIRALE ET LA PREUVE D'UN VIRUS RÉPLICATIF

- Treize études ont mentionné avoir détecté un virus reproductif par la culture cellulaire alors que trois autres ont fait état de la détection par l'ARN subgénomique.
- Dans toutes les études, le virus réplicatif était plus susceptible d'être isolé dans des échantillons ayant des valeurs Ct plus faibles que dans des échantillons ayant des valeurs Ct élevées. La détection du virus reproductif variait selon la charge virale et le moment de la collecte de l'échantillon après l'apparition des symptômes. Aucune étude n'a permis de déterminer si l'association entre la charge virale et les preuves d'un virus reproductif variait en fonction des facteurs de risque (p. ex., âge, sexe) ou de l'infection par les variants préoccupants du SRAS-CoV-2.
    - Le virus réplicatif était le plus susceptible d'être isolé à partir d'échantillons dont les valeurs Ct étaient inférieures à 30 (26 à 34) ou dont la charge virale était supérieure à 1 x 10^6 copies/ml (23, 35).
        - Une revue systématique a estimé que la probabilité de récupération du virus dans les spécimens dont la valeur Ct était supérieure à 35 était de 8,3 % (IC à 95 % : 2,8 % à 18,4 %) (23). On a en outre indiqué que les probabilités de propagation du virus vivant diminuaient de 0,64 pour chaque augmentation d'une unité de la valeur Ct (IC à 95 % : 0,49 à 0,84, p < 0,001)(0,001) (23).
        - Lorsque Ct = 25, jusqu'à 70 % des patients obtiennent des résultats de culture positifs. Lorsque Ct = 30, ce pourcentage chute à 20 %. Lorsque Ct = 35, seuls < 3 % des cultures sont positives (30).
        - Dans les groupes ayant eu une forme légère et grave de l'infection, la réplication virale était beaucoup plus susceptible d'être détectée pour les échantillons ayant des valeurs Ct plus faibles (p < 0,001) (36). Les échantillons dans lesquels les valeurs de Ct ≤ 25 incluaient un virus réplicatif à un taux supérieur à 90 % (36).
- Il était peu probable que l'on récupère un virus réplicatif dans les échantillons prélevés plus de 8 à 10 jours après l'apparition des symptômes, et ce, même dans les échantillons dont les valeurs Ct étaient inférieures à 35(34, 37 à 39). Ainsi, la probabilité d'isoler le virus réplicatif sera la plus élevée dans les 8 à 10 jours qui suivent l'apparition des symptômes alors que les niveaux de Ct sont faibles.
- Des signes de virus reproductif ont été détectés dans des cas asymptomatiques ou bénins immunocompétents ayant des valeurs Ct élevées (> 35) (26, 33, 36), mais ces cas semblent rares. De façon générale, les cas dans lesquels la culture a donné des résultats positifs après plus de 8 à 10 jours

ou grâce à des valeurs Ct supérieures à 35 étaient plus susceptibles d'être des cas graves ou immunodéprimés (36, 39).

- Les méthodes d'échantillonnage et de détection utilisées dans les études étaient hétérogènes.
    - Les cibles génétiques détectées dans les tests RT-PCR mentionnés dans les études comprenaient le gène N du SARS-CoV-2 (28, 29, 31, 37), le gène E (27, 28, 30, 32, 36), le gène S (26, 29) et le gène ORF1ab (29). L'association globale entre la charge virale et l'isolement du virus réplicatif ne semblait pas différer selon la cible génétique.
    - La majorité des études ont été réalisées à l'aide de sécrétions rhinopharyngées prélevées par écouvillonnage (26-30, 30, 33 à 38, 38). Toutefois, des écouvillons oropharyngés (34, 35, 37), des expectorations (34, 37), des aspirations bronchiques (36), du sérum (37), de l'urine (37) et des selles (37) ont également été signalés. La culture était plus susceptible d'être positive dans les écouvillons nasopharyngés, oropharyngés et dans les expectorations que dans les autres types de spécimens (37).

Tableau 1 : Études qui examinent l'association entre la charge virale et les preuves d'un virus réplicatif (n = 15)

ÉTUDE	MÉTHODOLOGIE	PRINCIPAUX RÉSULTATS
Études portant sur les cultures (n = 13)		
Jefferson (2020) (23) Revue systématique Royaume-Uni* Décembre 2020*	Recherche dans des bases de données afin de trouver des études publiées jusqu'au 10 septembre 2020 qui tentaient de cultiver ou d'observer le SRAS-CoV-2 dans des spécimens ayant obtenu des résultats positifs au test RT-PCR. Vingt-neuf études ont été trouvées, dont dix ont analysé le lien entre les valeurs Ct et la culture du virus.	- Cinq études ont indiqué une croissance nulle des spécimens lorsque les seuils de Ct variaient entre 24 et 35. La probabilité estimative de récupération du virus dans les spécimens dont la valeur Ct est supérieure à 35 était de 8,3 % (IC à 95 % : 2,8 % à 18,4 %). Tous les donneurs dont la valeur Ct était supérieure à 35 (n = 5) a permis d'obtenir une culture vivante étaient symptomatiques. - Une étude a signalé que les probabilités de culture du virus vivant diminuaient de 0,64 pour chaque augmentation d'une unité de la valeur Ct (IC à 95 % de 0,49 à 0,84, p < 0,001). - Une étude a fait état de résultats similaires, en harmonie avec les preuves empiriques d'une augmentation de la valeur Ct de 0,58 par jour depuis le début des symptômes. - Une étude a révélé que les échantillons ayant une charge virale inférieure à 1 x 10^6 copies/ml n'avaient permis de réussir à créer une culture virale.

		- La charge virale et la probabilité de faire croître un virus SRAS-CoV-2 vivant atteignent un sommet beaucoup plus tôt que pour le SRAS-CoV-1 ou le MERS-CoV.
Killerby (2021) (37) Étude de cohorte prospective ÉTATS-UNIS Mars 2021*	Des écouvillons nasopharyngés (NP), des écouvillons oropharyngés (OP), des expectorations (si disponibles), ainsi que des échantillons de sérum, d'urine et de selles ont été prélevés tous les 2 à 3 jours sur les 14 premiers patients symptomatiques détectés aux États-Unis et ayant subi un test rRT-PCR (ciblant le gène N1, N2 ou N3). Pour qu'un échantillon soit positif, le test devait détecter les trois gènes cibles. Les résultats non concluants étaient ceux qui avaient permis de détecter deux gènes cibles. Une culture virale (cellules Vero CCL-81) a été tentée sur des spécimens non concluants ayant donné un résultat positif au test rRT-PCR (n = 131) recueillis pendant les jours 0 à 29 après l'apparition de la maladie.	- Aucun virus n'a pu être récupéré dans les spécimens respiratoires prélevés plus de 8 jours après l'apparition des symptômes. - Une culture réussie a été observée dans 14 % (8 sur 57) des écouvillons NP, 10 % (4 sur 92) des écouvillons OP et 14 % (2 sur 14) des spécimens d'expectorations avec nucléocapsides (N)1, N2 et N3 SEC allant entre 16,5 et 32,5, 17,7 et 32,6 et 16,7 et 31,4 respectivement. - Les valeurs Ct étaient toutes beaucoup plus faibles ($p < 0,0001$ pour les trois gènes cibles) parmi les spécimens dont le virus a pu être récupéré dans les cultures. - Le virus vivant n'a pas été récupéré dans les spécimens de sérum ou de selles, les spécimens respiratoires non concluants ou les spécimens prélevés après la guérison des symptômes, malgré la détection continue de l'ARN viral.
Antar (2021) (34) *Prépublication* Étude de cohorte prospective ÉTATS-UNIS Avril à juillet 2020	Les patients externes (n = 95) ont effectué une autocollecte de liquides nasaux, oropharyngés (OP) et oraux à moyenne turbulence à six reprises en moyenne, en 1 à 3 mois. Les échantillons ont été testés pour détecter l'ARN viral à l'aide de la plateforme ciblée RT-PCR Abbott M2000. Les valeurs Ct inférieures à 31,5 ont été jugées positives. Des échantillons positifs d'OP nasal évalués par RT-PCR ont	- Aucun échantillon prélevé plus de 11 jours après l'apparition des symptômes n'a donné de résultats positifs pour la culture virale, même dans un cas immunodéprimé ayant obtenu un résultat positif au test RT-PCR avec des valeurs Ct faibles deux mois après l'apparition des symptômes. - La culture virale n'était positive que dans les échantillons dont la valeur Ct était inférieure à 17. - Les valeurs Ct moyennes étaient toutes beaucoup plus faibles dans les spécimens dont le virus avait pu être récupéré dans la culture que dans les échantillons négatifs en culture ($p < 0,00001$). - 14 résultats sur 15 positifs pour l'IgG anti-S-RBD dans la salive, avec des valeurs Ct inférieures à 20,

	été testés pour déterminer la propagation du SRAS-CoV-2 dans la culture cellulaire (méthodes non décrites). On a également analysé si l'IgG anti-SARS-CoV-2 présent dans le liquide buccal pouvait être utilisé pour prédire quels échantillons ayant de faibles valeurs Ct seraient négatifs dans la culture virale.	ont donné des résultats négatifs pour ce qui est de la culture virale. Un échantillon de culture positif a été prélevé le 11e jour après l'apparition des symptômes, soit à peu près au moment prévu de la première détection de cet anticorps.
Owusu (2021) (38) Étude de cohorte prospective ÉTATS-UNIS Mars à mai 2020	Prélèvement de spécimens nasopharyngés en série à divers moments chez des personnes (n = 109) dont la COVID-19 a été confirmée par rRT-PCR. Une culture virale (cellules Vero CCL-81) a été tentée sur des spécimens nasopharyngés ayant donné un résultat positif au test rRT-PCR (n = 35) recueillis pendant dix jours et plus après l'apparition des symptômes. Les participants ont été répartis en trois catégories selon la durée d'excrétion d'ARN viral : Persistant (≥ 14 jours), non persistant (< 14 jours) ou indéterminé.	- Les valeurs Ct des 35 spécimens prélevés ≥ 10 jours après l'apparition des symptômes variaient de 26,3 à 38,4. - La culture n'a réussi pour aucun de ces spécimens.
Folgueira (2021) (36) Étude transversale Espagne Février 2021*	Des échantillons de voies respiratoires (186 exsudats nasopharyngés et 7 aspirations bronchiques) provenant de patients asymptomatiques (n = 11), atteints de la forme légère (n = 91) et grave (n = 87), obtenus à divers moments, du diagnostic clinique jusqu'au suivi, ont été traités par rRT-PCR (ciblant le gène E) et par	- Dans les groupes atteints de la forme légère et grave, les échantillons qui montraient une réplication virale présentaient des valeurs Ct médianes beaucoup plus faibles que les échantillons sans virus viable : 23,3 (EI : 20,5 à 28,0) par rapport à 36,4 (EI : 31,8 à 39,1), respectivement, pour la forme légère de la COVID-19 et 27,7 (EI : 23,2 à 30,0) par rapport à 33,0 (EI : 30,4 à 38,0), respectivement, pour la forme grave de la COVID-19 (p < 0,001). - Les échantillons avec valeur Ct ≤ 25 des deux groupes de patients présentaient un virus viable à un taux supérieur à 90 %. Cependant, même les

	culture cellulaire (cellules Vero E6).	échantillons ayant une valeur Ct ≥ 35 pourraient contenir un virus viable (5 % pour la forme légère et 15 % pour la forme grave de la COVID-19).
Felix (2021) (26) *Prépublication* Étude transversale Brésil Février 2021*	Les patients atteints de la forme légère confirmée de la COVID-19 ont été invités à participer en fournissant des échantillons nasopharyngés (NP) au jour 10 de leur maladie (n = 53). Résultat positif au test RT-PCR (ciblant le gène S) (n = 29) pour la culture cellulaire de SARS-COV-2 obtenue 10 jours après l'apparition des symptômes dans les cellules VeroE6. Après deux passages, l'effet cytopathique et un seuil du cycle inférieur à celui obtenu dans l'échantillon original ont été utilisés pour déterminer la positivité de la culture.	- Quarante patients (79 %) présentaient un résultat positif au SRAS-CoV-2 obtenu par test par RT-PCR effectué le jour 10 (79 %), avec une valeur Ct médiane de 25,7 (plage de 12 à 32). De ce nombre, 29 ont été soumis à des cultures microbiennes. - La culture a réussi pour 24 % (7 sur 29) des échantillons analysés. - La positivité de la culture cellulaire était fortement associée à de faibles valeurs Ct dans les échantillons cliniques. La valeur Ct moyenne était de 20 (EI 16,5 à 21) dans les échantillons positifs après la culture par rapport à 29 (EI, 24 à 32,3) dans les échantillons négatifs après la culture, $p < 0,0001$. - Deux patients pour lesquels la culture a réussi ont déclaré n'avoir aucun symptôme le jour 10.
Marot (2021) (27) Lettre à la rédaction Étude transversale France Août et septembre 2020	Exécution de tests RT-PCR en temps réel pour détecter la présence de l'ARN subgénomique viral (enveloppe) et de l'ARN négatif de la chaîne E dans les échantillons cliniques. On a également tenté d'isoler le virus par culture (cellules Vero CCL-81, incubées de 2 à 7 jours) à partir d'échantillons afin d'associer la présence d'ARN intermédiaires réplicatifs à chaînes positives avec la détection d'un virus viable. Les données ont été obtenues auprès de 61 travailleurs de la santé immunocompétents ayant reçu un diagnostic d'infection au SRAS-CoV-2 par RT-PCR	- Aucun isolat n'a été récupéré par culture lorsque la valeur Ct était supérieure à 28 (c.-à-d. charge virale inférieure à 5,83 $\log_{10}$ copies/ml).

	sur des échantillons nasopharyngés.	
Piralla (2020) (28) Étude transversale Italie Avril à août 2020	Une série d'écouvillonnage de sécrétions nasales prélevées sur des patients en convalescence positifs pour l'ARN du SRAS-CoV-2 détecté par rRT-PCR (ciblant les gènes E ou N) avec une valeur Ct supérieure à 30 a été incluse dans l'étude (n = 387). Une culture cellulaire (cellules Vero E6 incubées jusqu'à 7 jours) a été effectuée pour étudier le potentiel infectieux des échantillons. Remarque : Aucun point temporel (c.-à-d. jour de la maladie) n'a été fourni pour le moment où les échantillons ont été prélevés, mais il est précisé que tous les échantillons ont été prélevés sur des patients qui se sont rétablis au niveau clinique.	- La valeur Ct médiane des échantillons des convalescents était de 36,8 (plage de 30,0 à 39,4). Pour le gène E, la valeur Ct médiane était de 36,9 (plage de 30,0 à 39,4) tandis qu'elle était de 35,5 (plage de 32,0 à 39,4) pour le gène N. - La culture de spécimens de convalescents n'a réussi que pour 9 échantillons (2,3 %, 9 sur 387). - La valeur Ct médiane des échantillons positifs pour la culture n'était pas significativement différente de celle observée dans les échantillons négatifs pour la culture (35,6 par rapport à 36,9, p = 0,37).
Romero-Gómez (2020) (29) Lettre à la rédaction Étude transversale Espagne Février à juin 2020	Échantillons prélevés chez des patients atteints du SRAS-CoV-2. L'examen a comparé les résultats obtenus par RT-PCR à la capacité de croissance du virus par culture cellulaire (cellules Vero E6, incubées pendant 4 jours). 72 spécimens nasopharyngés prélevés à différentes étapes de l'infection chez 66 patients ont été analysés dans le cadre de cette étude. 17 échantillons ont été isolés avec succès.	- Les valeurs Ct des échantillons pouvant être mis en culture étaient significativement inférieures (< 30) à celles des échantillons qui ne pouvaient être mis en culture (> 30) (p < 0,0001, voir les figures 1 et 2 de l'article). - L'isolement du virus en culture a été réussi dans les échantillons dont la Ct se situait entre 21,54 et 37,73. - Les valeurs Ct les plus élevées dans les échantillons cultivés ayant obtenu un résultat positif étaient de 36,08, 37,73 et 37,41 pour les gènes ORF1ab, N et S, respectivement, prélevés un jour après l'apparition des symptômes chez un patient qui avait une toux et de la fièvre.
Jaafar (2020) (30)	Réalisation de 250 566 tests RT-PCR pour le SRAS-CoV-2 sur des échantillons	- Lorsque Ct = 25, jusqu'à 70 % des patients ont obtenu des résultats de culture positifs. Lorsque Ct = 30, ce pourcentage chute à 20 %. Lorsque

Lettre à la rédaction Étude transversale France* Mai 2020	nasopharyngés (valeurs Ct basées sur le gène E). 13 161 de ces tests étaient positifs et 1 941 isolats ont pu être obtenus par culture (cellules Vero E6).	Ct = 35, la valeur utilisée pour déclarer un résultat positif pour le test PCR, < 3 % des cultures obtenaient un résultat positif.
Kim (2021) (31) Lettre à la rédaction Série de cas Corée du Sud Février à juin 2020	Caractérisation clinique et virologique de 21 patients hospitalisés. L'ARN viral a été quantifié à l'aide du test rRT-PCR (ciblant le gène N) et les cultures virales ont été réalisées avec la méthode des plages de lyse (cellules Vero) jusqu'à ce qu'au moins deux cultures consécutives n'affichent aucune croissance.	- Du SRAS-CoV-2 viable a pu être mis en culture dans 29 échantillons sur 89. - La culture virale a été positive seulement dans les échantillons ayant une valeur Ct de 28,4. - Le temps médian entre l'apparition des symptômes et la clairance virale en culture était de 7 jours. - L'incidence de positivité de la culture diminuait avec le temps écoulé depuis l'apparition des symptômes et avec l'augmentation de la valeur du seuil de cycle.
Vetter (2020) (35) Série de cas Suisse Février 2020	Caractérisation clinique, virologique et immunologique des cinq premiers patients évalués à l'Hôpital universitaire de Genève (HUG), du jour du diagnostic jusqu'à la convalescence. Le SARS-CoV-2 a été détecté par rRT-PCR dans les écouvillons oropharyngés (OP) et nasopharyngés (NP) de chacun des patients. La culture virale a été effectuée à l'aide de cellules Vero E6.	- L'isolement du virus en culture a réussi tant pour les OP que les NP pendant la première semaine de la maladie pour quatre personnes atteintes d'une forme légère de l'infection. - La charge virale moyenne dans les échantillons ayant permis de réussir l'isolement était de $1,2 \times 10^9$ copies/ml. Le SARS-CoV-2 n'a pas pu être isolé dans des spécimens cliniques contenant moins de $1,4 \times 10^6$ copies virales d'ARN/ml.
Lewis (2020) (39) Étude de recherche des contacts ÉTATS-UNIS	Enquête sur la transmission aux ménages dans cinq ménages ayant participé à une collecte quotidienne de spécimens. Pendant les jours 1 à 4, si un contact avec un ménage a eu un résultat non concluant (1 des 2 régions du	- Chez plusieurs patients, les faibles valeurs de Ct (< 20) les jours 2 à 4 après l'apparition des symptômes coïncidaient avec l'apparition de symptômes supplémentaires (douleur thoracique, myalgie et perte de goût et d'odeur) et de cultures virales positives les deux jours. - La culture n'a rien donné pour les spécimens recueillis 14 jours après l'apparition des

Avril 2020	gène cible est positive pour le SRAS-CoV-2, comme indiqué par le rRT-PCR) ou un résultat positif (les deux régions du gène cible sont positives), le spécimen associé et tous les spécimens quotidiens subséquents de la personne ont été soumis à une culture virale pour en évaluer l'infectiosité. Les spécimens positifs par rRT-PCR recueillis le jour 14 et ayant des valeurs Ct inférieures à 35 ont également été cultivés. Les cibles génétiques pour le rRT-PCR et les méthodes de culture n'ont pas été décrites.	symptômes, malgré des valeurs positives au test rRT-PCR et une valeur Ct inférieure à 35.
Études de l'ARN subgénomique (n = 3)		
Rodríguez-Grande (2021) (32) Série de cas Espagne Janvier 2021*	On a évalué des échantillons de cas persistants avec tests RT-PCR positifs (n = 60) après plus de 21 jours depuis le premier résultat positif au test RT-PCR pour obtenir des preuves de virus réplicatif déterminé par l'ARN du gène E subgénomique (ARN SG).	- L'ARN SG a été détecté dans 12 cas sur 60 (20 %). Les dates de prélèvement de ces échantillons variaient de 28 à 79 jours après l'apparition des symptômes. - Dans tous les cas où l'ARN SG était détectable, les valeurs Ct pour l'ARN génomique étaient inférieures à 30, ce qui correspond aux valeurs attendues pour un virus actif. - L'éventail d'âge des sujets présentant une excrétion virale prolongée et un ARN viral SG était assez large et réparti également entre les hommes et les femmes. Sept personnes étaient immunodéprimées. Les formes de COVID-19 étaient légères (40 %), intermédiaires (20 %) et graves (40 %). Un cas d'ARN SG au jour 25 était asymptomatique.
Marot (2021) (27) Lettre à la rédaction Étude transversale	Exécution de tests RT-PCR en temps réel pour détecter la présence de l'ARN subgénomique viral (enveloppe) et de l'ARN négatif de la chaîne E dans les échantillons cliniques. On a également tenté d'isoler le virus par culture (cellules	- Aucun ARN intermédiaire n'a été détecté dans les échantillons lorsque la valeur Ct était supérieure à 33 (charge virale inférieure à 4,34 $\log_{10}$ copies/ml). - Les rapports de risques normalisés moyens par génome indiquent un niveau élevé de réplication virale au cours des cinq premiers jours suivant

France Août et septembre 2020	Vero CCL-81, incubées de 2 à 7 jours) à partir d'échantillons afin d'associer la présence d'ARN intermédiaires réplicatifs à chaînes positives avec la détection d'un virus viable. Les données ont été obtenues auprès de 61 travailleurs de la santé immunocompétents ayant reçu un diagnostic d'infection au SRAS-CoV-2 par RT-PCR sur des échantillons nasopharyngés.	l'apparition des symptômes, suivi d'une baisse significative.
Hogan (2021) (33) Études de cohorte prospectives et rétrospectives ÉTATS-UNIS Mars et avril 2020 et juillet à septembre 2020	Développement d'un nouveau rRT-PCR à 2 étapes spécifique à la chaîne négative du gène de l'enveloppe (le virus réplicateur activement produit des intermédiaires d'ARN à chaîne négative et peut donc être utilisé comme indicateur d'infectiosité potentielle). Nous avons recueilli rétrospectivement un ensemble pratique d'échantillons longitudinaux des voies respiratoires supérieures avec une large gamme de valeurs Ct. Pour la phase prospective de l'étude, nous avons prélevé des échantillons des voies respiratoires supérieures chez 53 patients consécutifs atteints d'une infection confirmée au SRAS-CoV-2. Les échantillons ont été prélevés sur une période médiane de 9 jours (EI : 4 à 18 jours) après l'apparition des symptômes.	- L'ARN à chaîne négative a été détecté chez 41 patients (28,1 %). - La valeur Ct médiane était significativement plus faible dans les échantillons où l'ARN à chaîne négative a été détecté (20,7) que dans ceux où la chaîne négative n'a pas été détectée (33,2, $p < 0,01$). - L'ARN à chaîne négative a été détecté chez deux patients hospitalisés immunocompétiteurs plus de 10 jours après l'apparition des symptômes avec des valeurs Ct élevées (~39). L'ARN à chaîne négative du SRAS-CoV-2 a été détecté jusqu'à 30 jours après l'apparition des symptômes chez un patient immunodéprimé.

LTE = lettre à la rédaction

ASSOCIATION ENTRE LA CHARGE VIRALE ET LE RISQUE DE TRANSMISSION

- Les charges virales semblent atteindre un sommet en moyenne cinq jours après l'exposition et un à deux jours après l'apparition des symptômes, avec une courte période (< 2 jours) de risque de transmission élevé et un potentiel de transmission grandement réduit de 7 à 10 jours après l'apparition des symptômes (40 à 42). En période de charge virale maximale, les cas hautement infectieux excrètent des dizaines à des milliers de virions SARS-CoV-2/min (24).

- Plusieurs études d'observation ont été effectuées sur la transmission dans les ménages et dans les grappes. Conformément aux constatations culturelles de la section ci-dessus, les cas présentant une charge virale plus élevée (c.-à-d. des valeurs Ct plus faibles) étaient plus susceptibles de transmettre le SRAS-CoV-2.
    - Les cas index ayant une charge virale élevée (plus de 10^6 copies/uL) étaient plus susceptibles de transmettre le SRAS-CoV-2 à des contacts étroits (RC 4,9, IC à 95 % : 1,3 à 18, p = 0,02) (43). Le taux d'attaque secondaire variait de 12 % lorsque le cas index avait une charge virale de 1×10^6 copies/ml à 24 % lorsque ce cas avait une charge virale de 1×10^{10} copies/ml (rapport de cotes ajusté par $\log_{10}$ augmentation de la charge virale = 1,3, IC à 95 % : 1,1 à 1,5) (44).
    - Les modèles de régression ont démontré que les cas entraînant une transmission secondaire présentaient une charge virale médiane plus élevée que les cas qui ne transmettaient pas le SRAS-CoV-2 (45). Deux études de cohorte rétrospectives effectuées dans des résidences universitaires aux États-Unis ont également révélé que les cas index entraînant une transmission secondaire présentaient une charge virale plus élevée (jusqu'à 6,5 fois) que les cas qui n'ont pas causé de transmission secondaire (46, 47). Même si les cas symptomatiques et asymptomatiques présentaient des sommets pour les valeurs Ct moyennes se rapprochant de 19 à 22, les valeurs Ct étaient beaucoup plus faibles dans les cas symptomatiques (plage de 12 à 36 par rapport à 14 à 37), ce qui indique une réduction de la charge virale chez les cas asymptomatiques (47).
    - Une étude transversale portant sur l'ensemble de la population du Danemark a permis de constater que les cas index ayant une valeur Ct inférieure à 20 présentaient un risque de transmission 1,89 fois plus élevé que celui d'un cas index ayant une valeur Ct supérieure à 25 (48). Le cas index avait une valeur Ct supérieure à 30 dans 39 % des cas secondaires, mais le risque de transmission était significativement plus élevé si les valeurs Ct étaient inférieures à 28. Des cas index avec des valeurs Ct élevées (> 35) se sont produits, mais le risque de transmission était beaucoup plus faible (8 %).
    - La majorité des cas associés à des ménages secondaires ont été détectés dans les 10 jours suivant l'apparition des symptômes chez le cas index, ce qui correspond au moment du rétablissement des résultats du virus réplicatif mentionnés à la section précédente (43).

- Une étude a révélé que les grappes ayant une charge virale élevée (supérieure à 10^6 copies/ml) étaient considérablement plus grandes que les grappes dont les sujets présentaient une charge virale plus faible (17 personnes infectées contre 3 au sein de la grappe, $p < 0,001$) (49).

- Peu d'études ont fait état de la façon dont le lien entre la charge virale et le risque de transmission variait selon la présence de symptômes, la gravité des symptômes ou les facteurs de risque (p. ex., âge, problèmes de santé chroniques).
  - Un examen systématique a révélé que les cas de COVID-19 chez les adultes, les enfants, les patients symptomatiques/présymptomatiques et les patients asymptomatiques présentaient des distributions semblables de la charge virale respiratoire pendant la période infectieuse (24). Fait intéressant, une étude sur une population plus importante a révélé qu'un âge plus avancé était associé positivement au risque de transmission, même après contrôle de la charge virale (c.-à-d. que l'âge était un meilleur prédicteur du risque de transmission que la charge virale) (48).
  - Des charges virales élevées (Ct inférieure à 20) avant l'apparition des symptômes parmi les cas qui ont transmis le SRAS-CoV-2 de façon présymptomatique ont été signalées (50). Plus la période d'incubation est longue, plus grande est la fraction de la charge virale présymptomatique, ce qui augmente la probabilité de transmission présymptomatique (41).
  - Des charges virales élevées ont été signalées tant pendant la période présymptomatique que jusqu'à 8 à 10 jours après l'apparition des symptômes. C'est pendant cette période où les valeurs Ct sont faibles (< 30) qu'il y a une forte probabilité de transmission.

Tableau 2 : Études qui étudient l'association entre la charge virale et le risque de transmission (n = 12).

ÉTUDE	MÉTHODOLOGIE	PRINCIPAUX RÉSULTATS
Chen (2020) (24) *Prépublication* Revue systématique et étude de modélisation Canada* Décembre 2020*	Une revue systématique a été effectuée pour tenir compte des études publiées jusqu'au 7 août 2020 (n = 64) et élaborer un ensemble complet de données sur les charges virales respiratoires (CVR) du SRAS-CoV-2. Une méta-analyse et un modèle ont ensuite été utilisés pour étudier l'infectiosité individuelle en excrétion d'un virus viable par des gouttelettes respiratoires et	- Au 90e centile de cas pendant toute la période infectieuse, la CVR estimée était de 8,91 copies/ml (IC à 95 % : 8,83-9,00). - L'âge et la symptomatologie ont eu une influence minimale sur la variation des cas de CVR du SRAS-CoV-2 pendant la période infectieuse. Les cas de COVID-19 adultes, pédiatriques, symptomatiques ou présymptomatiques et asymptomatiques ont montré des distributions de la valeur de référence semblables, avec des écarts-types de 2,03, de 2,06, de 2,00 et de 2,01 copies/ml, respectivement. - Le modèle mécaniste a montré que la valeur de la CVR du SRAS-CoV-2

	des aérosols. Les CVR du SRAS-CoV-2 ont été analysées dans l'ensemble des sous-groupes d'âge et de symptomatologie, ainsi que dans l'évolution de la maladie.	augmentait de façon exponentielle après l'infection, atteignait un sommet environ un jour après l'apparition des symptômes, puis diminuait de façon exponentielle. Les formes hautement infectieuses peuvent excréter des dizaines à des milliers de virions SARS-CoV-2/min, particulièrement de 1 à 5 jours après l'apparition des symptômes.
Cerami 2021 (43) *Prépublication* Étude de cohorte prospective ÉTATS-UNIS Avril à octobre 2020	Inscription de personnes séropositives à la COVID (n = 102) et de membres de leur ménage (n = 213) pour étudier la transmission du SRAS-CoV-2 dans les ménages. Les ménages ont été inscrits en moyenne six jours après l'apparition des symptômes chez le cas index. Des cas secondaires ont été détectés soit par test RT-qPCR (ciblant N1, N2 et RNase P) à la suite d'un écouvillon nasopharyngé effectué le jour 1 de l'étude et d'écouvillons nasaux hebdomadaires (jours 7, 14, 21), ou par séroconversion le jour 28.	- La majorité des cas dans des ménages secondaires ont été détectés dans les 10 jours suivant l'apparition des symptômes du cas index. - Les cas index ayant une charge virale élevée (supérieure à 10^6 copies virales/uL) au moment de l'inscription étaient plus susceptibles de transmettre le virus aux contacts du ménage pendant l'étude (RC 4,9, IC à 95 %, 1,3 à 18, p = 0,02). - La charge virale était corrélée au sein des familles, ce qui signifie que les personnes du même ménage étaient plus susceptibles d'avoir une charge virale semblable, ce qui suggère un effet d'inoculum. Ces différences n'étaient pas attribuables à la mutation D614G dans la protéine spicule SARS-CoV-2, puisque la grande majorité des isolats génotypés contenaient cette mutation (98 %).
Bjorkman (2021) (46) Étude de cohorte rétrospective ÉTATS-UNIS Août à novembre 2020	Analyse de la transmission de la COVID-19 dans les salles de résidence en fonction du dépistage hebdomadaire du RT-qPCR (ciblant le gène E) chez les élèves dans les résidences. Chaque unité Ct complète est un facteur de 2 copies d'ARN par ml. Enquête sur la mesure dans laquelle le moment des cas a favorisé la transmission entre camarades.	- La charge virale moyenne était 6,5 fois plus élevée dans les pièces où la transmission était probable (Ct moyenne = 26,2) que dans les pièces sans transmission (Ct moyenne = 28,9). - Ces cas s'étendaient sur une plage de plus de 7 ordres de grandeur de la charge virale, la charge la plus élevée se trouvant dans le groupe de transmission probable (Ct = 15,4) et la charge la plus faible se trouvant dans le groupe de transmission improbable (Ct = 40,6). Les seuls cas avec Ct supérieur à 34 (22 cas) ont été découverts dans le groupe de transmission improbable.

Tian (2021) (47) *Prépublication* Étude de cohorte rétrospective ÉTATS-UNIS Septembre et octobre 2020	Exécution d'un total de 61 982 tests sur 7 440 étudiants de premier cycle afin de déterminer si la valeur Ct pouvait différencier le propagateur de celui qui ne l'était pas. Les étudiants ont été testés à plusieurs reprises par des tests RT-PCR (ciblant les gènes N, S et ORF1ab) au cours de la période de l'étude et 602 cas ont été déterminés.	- 48,2 % (94 sur 195) des cas index ont eu au moins un contact qui est devenu positif pour le SRAS-CoV-2, tandis que 51,8 % des cas index (n = 101) n'ont pas transmis le SRAS-CoV-2 à leurs contacts. - Les valeurs Ct moyennes du propagateur et de la personne qui n'est pas un propagateur étaient presque identiques (pic de Ct = 18 à 21), mais leurs valeurs Ct médianes différaient de presque un cycle, ce qui suggère que les propagateurs avaient une valeur Ct inférieure à celle des autres (voir les figures 1B et C dans l'article). La plage des Ct était légèrement plus large pour le propagateur (12 à 36) que pour la personne qui n'avait rien propagé (14 à 36). - Même si les deux groupes présentaient des sommets pour les valeurs Ct se rapprochant de 19 à 22, les valeurs Ct étaient beaucoup plus faibles dans les cas symptomatiques que dans les cas asymptomatiques (plage de 12 à 36 par rapport à 14 à 37), ce qui indique une réduction de la charge virale chez les cas asymptomatiques.
Shrestha (2021) (42) Étude de cohorte rétrospective ÉTATS-UNIS Mars et avril 2020	Évaluation du potentiel de transmission obtenue en examinant la charge virale selon le temps qui s'est écoulé depuis l'apparition des symptômes chez les professionnels de la santé infectés par le SRAS-CoV-2 (n = 230). Des tests RT-PCR (ciblant les gènes N1, N2 et N3) ont été effectués sur des écouvillons nasopharyngés. La moyenne des 3 valeurs Ct pour les trois gènes cibles a été jugée être la valeur Ct du test. Les charges virales depuis l'apparition des symptômes ont été prédites à l'aide du modèle de	- La charge virale d'ARN du SRAS-CoV-2 est très élevée dans les 2 à 3 jours suivant l'apparition des symptômes et chute rapidement d'un ordre de grandeur en quelques jours (voir la figure 1 dans l'article). - Le potentiel de transmission de la COVID-19 est grandement réduit de 7 à 10 jours après l'apparition des symptômes (voir la figure 3 dans l'article). Parmi la zone sous la courbe qui couvre l'intervalle entre l'apparition des symptômes et 30 jours, 86,3 % ont eu lieu dans les 5 premiers jours, 96,9 % dans les 7 premiers jours et 99,7 % dans les 10 premiers jours.

	régression, la zone sous la courbe représentant la distribution du potentiel de transmission au fil du temps.	
Marks (2020) (44) Étude de cohorte rétrospective Espagne Mars et avril 2020	Cette étude a consisté en une analyse ponctuelle des données recueillies dans le cadre d'un essai randomisé en grappe auquel ont participé des personnes atteintes de COVID-19 dont le résultat a été confirmé par un test qPCR et leurs contacts étroits. Les facteurs associés à la transmission ont été évalués par régression linéaire à l'aide de toutes les grappes d'un cas index pour lequel la charge virale quantitative provenant des écouvillons nasopharyngés était disponible.	- Le taux d'attaque secondaire global était de 17 % (125 contacts sur 753) avec une plage de 12 % lorsque le cas index avait une charge virale de 1 x 10^6 copies/ml à 24 % lorsque le cas de l'indice avait une charge virale de 1 x 10^{10} copies/ml. - Selon une analyse multivariée, les probabilités de transmission étaient plus élevées lorsque le cas index présentait une charge virale élevée (rapport de cotes ajusté par augmentation par $\log_{10}$ de la charge virale = 1,3 (IC à 95 % : 1,1 à 1,5). - 90 % des événements de transmission se sont produits lorsque le cas index avait une charge virale élevée (≥ 5,1 $\log_{10}$ copies/ml). 50 % se sont produits dans des grappes où le cas index avait une charge virale de ≥ 8,8 $\log_{10}$ copies/ml. - D'autres facteurs associés à un risque accru de transmission étaient le contact avec le ménage et l'âge du contact. Aucun lien n'a été observé avec l'utilisation du couvre-visage, l'âge ou le sexe du cas index, ou avec la présence de symptômes respiratoires dans le cas index.
Kawasuji (2020) (45) Étude cas/témoin Japon Avril et mai 2020	Les patients atteints de COVID-19 qui ont transmis la maladie à au moins un autre patient ont été analysés comme des « cas » (patients de référence, n = 14) et comparés aux patients qui n'étaient pas la cause de la transmission secondaire (patients autres qu'index, n = 14, analysés comme des « témoins »). Les cas ont été confirmés et la charge virale quantifiée par RT-qPCR (ciblant le	- Les charges virales ont atteint un sommet peu après l'apparition des symptômes, puis ont diminué graduellement. Le temps médian avant la clairance virale ne différait pas de façon significative entre les patients index et autres qu'index : 21 jours (EI : 15 à 31) par rapport à 17 jours (9 à 26), p = 0,34. - La charge virale au moment du prélèvement initial de l'échantillon était beaucoup plus élevée chez les patients symptomatiques et asymptomatiques, ainsi que chez les adultes et les enfants. - Les modèles de régression des cas symptomatiques seulement (n = 18) ont démontré que la charge virale médiane des

	gène N2). Les parcours temporels de la charge virale nasopharyngée ont été évalués entre le cas index et les patients non symptomatiques à l'aide d'une régression non linéaire utilisant un modèle standard de désintégration en une phase.	patients index au début était plus élevée que celle des patients autres qu'index : 6,6 copies log/µL (IC à 95 % : 5,2 à 8,2) c. 3,1 (1,5 à 4,8). Cette tendance s'est poursuivie jusqu'à 10 jours après l'apparition des symptômes. Lorsque des cas asymptomatiques ont également été inclus dans ce modèle (n = 10), la tendance globale est demeurée la même : 3,3 copies log/µL (IC à 95 % : 1,6 à 5,2) c. 1,8 (-0,4 à 4,6), p = 0,015.
Lyngse (2021) (48) *Prépublication* Étude transversale Danemark Du 25 août au 10 février 2021	On a utilisé des données complètes du registre administratif du Danemark, comprenant l'ensemble de la population et tous les tests SARS-CoV-2, pour estimer le risque de transmission des ménages. Le test RT-PCR (ciblage du gène E) a été utilisé et un test pour le SARS-CoV-2 a été défini comme positif si la valeur Ct était ≤ 38. 66 602 cas primaires ont été cernés, dont 99,6 % avaient des valeurs Ct disponibles. 103 389 cas secondaires ont été identifiés.	- 25 % des cas primaires avaient une valeur Ct de 25, 50 % avaient une valeur Ct de 28 et 75 % avaient une valeur Ct de 32. La valeur Ct était similaire pour tous les groupes d'âge. - Il y avait un lien décroissant à peu près linéaire entre les valeurs Ct et le risque de transmission. - Le cas index avait une valeur Ct supérieure à 30 dans 39 % des cas secondaires (mais c'est le jour du test par rapport à un point de charge virale de pointe inconnu - ils n'avaient pas de données pour le modifier). Les cas primaires dont la valeur Ct était de 38 présentaient un risque de transmission de 8 % au sein du ménage. - Le risque de transmission était significativement plus élevé si les valeurs Ct étaient inférieures à 28. - Un cas primaire avec une valeur Ct de 18 à 20 présente un risque de transmission de 1,89 plus élevé qu'un cas primaire avec une valeur Ct de 36 à 38. - Le risque de transmission présentait un lien négatif avec l'âge chez les enfants de moins de 20 ans et un lien positif avec l'âge chez ceux de plus de 20 ans.
Ladoy (2021) (49) *Prépublication* Étude de surveillance	Caractérisation de la dynamique de la première vague d'infection par le SRAS-CoV-2 dans le canton	- 1 684 grappes spatio-temporelles ont été identifiées. - La majorité des grappes comptaient au moins une personne ayant une charge

Suisse Janvier à juin 2020	de Vaud (Suisse occidentale) grâce à la détection et à l'emplacement de grappes à l'aide des résultats des tests RT-PCR pour le SARS-CoV-2 (n = 33 651 testés, n = 3 317 positifs). Une approche d'acquisition spatiale a été utilisée pour évaluer l'importance de la charge virale dans l'évolution des grappes et un algorithme DBSCAN espace-temps modifié a été utilisé pour caractériser la dynamique de diffusion des grappes de transmission.	virale élevée (>1 milliard de copies/ml). Les grappes ayant une charge virale aussi élevée étaient considérablement plus importantes (médiane de 17 personnes infectées) que les grappes dont la charge virale était inférieure à plus d'un million de copies/ml (médiane de 3 personnes infectées, p < 0,001). - Les grappes contenant des individus plus jeunes avaient la charge virale la plus élevée, tandis que les grappes composées d'individus plus âgés avaient une charge virale faible à moyenne. - Il y avait 20 grappes dans lesquelles la charge virale des trois premiers cas était inférieure à 100 000 copies/ml, ce qui suggère que dans certains cas, même les sujets ayant moins de 100 000 copies/ml peuvent encore être contagieux.
Park (2020) (50) Série de cas Corée du Sud -> Israël Février 2020	Une éclosion de SRAS-CoV-2 parmi 39 pèlerins a fait l'objet d'une enquête. Dix cas confirmés sans symptômes aux premières dates d'échantillonnage (2 post-symptomatiques, 4 pré-symptomatiques et 4 asymptomatiques) ont été sélectionnés pour les tests RT-PCR de suivi des voies respiratoires (ciblant le gène E).	- Les valeurs Ct disponibles pour les spécimens des voies respiratoires inférieures étaient beaucoup plus faibles dans les cas sans symptômes (médiane, 22,8; EI, 20,1 à 25,4) que dans les cas avec symptômes aux premières dates d'échantillonnage (médiane, 27,9; EI, 23,4 à 30,4). La charge virale a diminué graduellement au fil du temps et n'était pas différente entre les cas symptomatiques et asymptomatiques. - La charge virale la plus élevée (Ct < 20) a été observée à partir du premier échantillon d'un cas prélevé 7 jours avant l'apparition des symptômes. La transmission s'est produite entre ce cas et un contact étroit pendant la période présymptomatique.
Goyal 2021 (40) Étude de modélisation États-Unis* Février 2021*	Élaboration d'un cadre de simulation de la transmission pour analyser la contribution de la charge virale aux paramètres de transmission épidémiologique observée SARS-CoV-2. Ce processus comprenait la	- Les simulations ont démontré qu'une charge virale supérieure des voies aériennes inférieure à 104 copies d'ARN SARS-CoV-2 est très peu probable (~0,00005 %) pour entraîner la transmission. La transmission est beaucoup plus probable (39 %) étant donné l'exposition d'une personne infectée qui

	modélisation des charges virales à l'intérieur de l'hôte, des simulations des expositions et des transmissions possibles en fonction de diverses courbes de la dose-réponse de la transmission, l'essai de divers ensembles de paramètres par rapport aux données épidémiologiques et des analyses exploratoires avec le meilleur modèle d'ajustement.	perd plus de 107 copies d'ARN, et 75 % étant exposée à une personne infectée ayant une charge virale de plus de 108 copies d'ARN. - Il y a un point d'inflexion entre 106 et 107 copies d'ARN, après quoi des événements de transmission multiples deviennent beaucoup plus probables d'une seule personne (c.-à-d. un événement de super propagation). - Les personnes infectées sont susceptibles d'être les plus infectieuses (charge virale supérieure à la dose TD50) pendant une période de 0,5 à 1 jour entre les jours 2 et 6 après l'infection. Cette variabilité est probablement attribuable à l'hétérogénéité de la période d'incubation plutôt qu'au moment du pic de la charge virale.
Ke (2020) (41) *Prépublication* Étude de modélisation États-Unis* Septembre 2020	Élaboration de modèles d'infection au SRAS-CoV-2 à l'intérieur de l'hôte fondés sur des données. Analyse de la relation entre la charge virale dans les voies respiratoires inférieures et supérieures trans (TLR et URT) et l'infectiosité potentielle au moyen d'un modèle probabiliste utilisant les données épidémiologiques existantes (provenant de 8 cas). Élaboration de plusieurs autres modèles pour expliquer la période prolongée d'infection virale dans les VRI.	- Pic de la charge respiratoire virale 5,2 jours en moyenne (ET : ± 1,3 jour) et 5,4 jours (± 1 jour) après l'infection dans les VRS et les VRI, respectivement, et en moyenne 2 jours (± 0,2 jour) et 2,1 jours (± 1,2 jour) après l'apparition des symptômes. - Plus la période d'incubation est longue, plus grande sera la fraction de la charge virale présymptomatique (voir fig. 2; $p < 0,001$), ce qui entraîne une fraction plus élevée de transmission présymptomatique. - Le modèle démontre que le logarithme de la charge virale (plutôt que la charge virale absolue) est un substitut approprié pour l'infectiosité (c.-à-d. que la croissance virale est un meilleur prédicteur de la transmission présymptomatique que la mesure de la charge virale seule). - La dissémination spatiale dans les poumons est un processus important pour maintenir des charges virales élevées prolongées dans les VRI.

Méthodologies :

Une analyse documentaire quotidienne (ouvrages publiés et en prépublication) est effectuée par le Groupe des sciences émergentes de l'ASPC. L'analyse a compilé les ouvrages sur la COVID-19 depuis le début de l'éclosion et est mise à jour quotidiennement. Les recherches visant à extraire les ouvrages pertinents sur la COVID-19 sont menées dans Pubmed, Scopus, BioRxiv, MedRxiv, ArXiv, SSRN et Research Square, et les résultats sont recoupés avec les ouvrages figurant sur la liste de la documentation sur la COVID de l'Organisation mondiale de la Santé et des centres d'information sur la COVID-19 gérés par Lancet, BMJ, Elsevier, Nature et Wiley. Le résumé quotidien et les résultats complets de l'analyse sont conservés dans une base de données RefWorks et dans une liste Excel consultable. Une recherche ciblée par mot-clé a été effectuée dans ces bases de données pour recenser les citations pertinentes sur la COVID-19 et le SRAS-CoV-2. Les termes de recherche utilisés comprenaient : Shedding, Viral dynamics, Viral RNA dynamics, Viral clearance, Viral RNA clearance, Viable, Culture, Infectivity, Infectious Period, Communicability period, Period of communicability, Viral load, Viral RNA load, Infectiousness. La présente revue contient des recherches publiées jusqu'au 31 mars 2021. Chaque référence potentiellement pertinente a été examinée pour confirmer qu'elle comportait des données pertinentes, qui ont été extraites dans la revue.

Examen par les pairs

Ce document a fait l'objet d'un examen par les pairs dirigé par un expert en la matière et d'un examen en ce qui concerne la rédaction et la science par le Bureau de la Conseillère scientifique en chef.

Evidence Snapshot:

Evidence Brief on the Therapeutic use of Vitamin D Supplementation for COVID-19

Context

This evidence brief summarizes the evidence of the efficacy of therapeutic or prophylactic supplementation of vitamin D in the treatment or prevention of COVID-19. The immunomodulating effects of vitamin D are complex and not fully understood and research conducted prior to COVID-19 suggested there was limited evidence of vitamin D benefit in lowering risk of acute respiratory infections.

Key Findings

This evidence brief includes five systematic reviews and reports that summarize three randomized controlled trials (RCTs) and one prospective cohort conducted in adults and 2 quasi-experimental conducted in geriatric populations up to May 26, 2021.

The key findings were:

- One of three RCTs found that vitamin D treatment in COVID-19 patients may reduce the risk of severe disease progression (admittance to ICU) (RR 0.04, 95%CI 0.01- 0.29, 1 RCT, 76 observations). A small prospective cohort reported reduced ICU admission (unadjusted OR = 0.13, 95%CI 0.03–0.6) among those that received 1000 IU vitamin D3 per day.
- Two RCTs found that vitamin D treatment did not significantly reduce mortality across 2 RCTs compared to the standard of care control group (RR 0.56; 95%CI 0.05 – 5.85, 2 RCTs, 313 observations), but a significant reduction in mortality was reported across two quasi-experimental studies and one RCT (OR 0.26; 95%CI 0.10-0.71).
- No association was reported with vitamin D treatment and adverse reactions. Across all studies only one trial recorded a single adverse event, vomiting, following a large bolus treatment of 200 000IU of cholecalciferol treatment (RR 2.98; 95%CI 0.12-72.30).
- None of the systematic reviews identified studies on supplementation of vitamin D to prevent COVID-19, although there are on-going trials registered to address this question.
- The overall confidence in these results is low as there was a lot of heterogeneity in the treatment regime, study design and imprecision in outcomes. Several trials have been initiated to further explore this question, which may change the conclusions of this review.

Considerations

There is insufficient evidence at present to determine the benefits and any potential harms of vitamin D supplementation as a treatment of COVID-19 and no evidence on prevention.

Aperçu des éléments de preuve :

Synthèse en bref sur l'utilisation thérapeutique d'une supplémentation en vitamine D contre la COVID-19

Contexte

Ce document résume les éléments de preuve en ce qui concerne l'efficacité de la prophylactique supplémentation thérapeutique en vitamine D pour le traitement ou la prévention de la COVID-19. Les effets immunomodulateurs de la vitamine D sont complexes et mal compris, et les recherches effectuées avant la COVID-19 ont indiqué qu'il y avait peu d'éléments de preuve sur les bienfaits de la vitamine D pour réduire le risque d'infections respiratoires aiguës.

Principales constatations

Ce résumé des éléments de preuve comprend cinq revues systématiques et des rapports qui résument trois essais cliniques randomisés (ECR) et une cohorte prospective formée d'adultes, ainsi que deux quasi-expériences effectuées auprès de populations gériatriques jusqu'au 26 mai 2021.

Les principales conclusions sont les suivantes :

- L'un des trois ECR a révélé que le recours à un régime de vitamine D chez les patients atteints de COVID-19 pouvait permettre de réduire le risque de progression plus sévère de la maladie (admission aux SI) (RR = 0,04, IC à 95 % : 0,01 à 0,29, 1 ECR, 1 ECR, 76 observations). Une petite cohorte prospective a indiqué une réduction des admissions aux SI (RC non ajusté = 0,13, IC à 95 % : 0,03 à 0,6) chez les personnes qui ont reçu 1 000 UI de vitamine D3 par jour.
- Deux ECR ont révélé que l'apport d'un régime de vitamine D ne réduisait pas significativement la mortalité comparativement au groupe témoin standard ayant obtenu des soins habituels (RR 0,56; IC à 95 % : 0,05 à 5,85, 2 ECR, 313 observations) (5, 8 à 11). Une réduction importante de la mortalité a cependant été signalée dans deux quasi-expériences et dans un ECR (RC = 0,26; IC à 95 % : 0,10 à 0,71) (11).
- Aucun lien n'a été signalé avec le traitement à la vitamine D et les effets indésirables. Dans toutes les études, un seul essai a enregistré un événement indésirable, soit des vomissements, à la suite d'un important traitement avec bolus de 200 000 UI de cholécalciférol (RR 2,98; IC à 95 % : 0,12 à 72,30).
- Aucune des revues systématiques n'a relevé d'études sur la supplémentation en vitamine D pour prévenir la COVID-19, bien qu'il y ait des essais en cours enregistrés pour répondre à cette question.

- La confiance globale dans ces résultats est faible, car il y avait beaucoup d'hétérogénéité dans le régime de traitement, la conception de l'étude et l'imprécision des résultats. Plusieurs essais ont été entrepris pour approfondir cette question, ce qui pourrait modifier les conclusions de la présente revue systématique.

Facteurs dont il faut tenir compte

À l'heure actuelle, il n'y a pas suffisamment d'éléments de preuve pour déterminer les bienfaits et les méfaits potentiels de la supplémentation en vitamine D comme traitement de la COVID-19, et il n'y a pas non plus d'éléments de preuve en ce qui concerne la prévention.

Nouveaux éléments de preuve sur la COVID-19

Synthèse en bref sur la supplémentation thérapeutique en vitamine D pour des cas de la COVID-19

Introduction

Y a-t-il des preuves de l'efficacité d'une supplémentation thérapeutique en vitamine D pour traiter ou prévenir la COVID-19?

La vitamine D est une prohormone, soit un élément important que l'organisme convertit en hormone avant de l'utiliser dans l'homéostasie du calcium et la santé des os. Cette vitamine joue également un rôle dans d'autres systèmes, y compris la fonction immunitaire (1). Les fonctions immunomodulatrices de la vitamine D sont cependant complexes et mal comprises. Parmi les recherches effectuées avant la pandémie de COVID-19, peu ont montré l'avantage potentiel d'une supplémentation en vitamine D pour réduire le risque de développer des infections respiratoires aiguës (2, 3).

Les normes nutritionnelles canadiennes incluent des recommandations alimentaires sur la vitamine D pour chacun des groupes d'âge, recommandations qui visent à aider à répondre aux besoins nutritionnels habituels et à maintenir des taux sériques de 25-hydroxyvitamine D [25(OH)D] supérieurs à 40 nmol/l pour permettre la santé osseuse (4). Le taux sérique de 25(OH)D est utilisé comme indicateur afin de savoir si la personne a en une quantité suffisante dans son sang (1). Au Canada, une supplémentation en vitamine D est recommandée chez les adultes de plus de 50 ans (4). Les lignes directrices des États-Unis, du Royaume-Uni et de l'Irlande ont, quant à elles, tenu compte des éléments de preuve sur la COVID-19 et recommandent une supplémentation en vitamine D pour la santé des os, mais non pour traiter la COVID-19 ou en prévenir l'apparition (5 à 7).

Les chercheurs ont postulé qu'une carence en vitamine D pourrait augmenter le risque d'infection à la COVID-19, accélérer la progression de la maladie ou entraîner des effets plus sévères. Bien que cette question ne relève pas de la portée de la présente recherche, de nombreuses études d'observation ont porté sur le lien entre l'état nutritionnel en vitamine D et le risque d'infection par la COVID-19, les effets graves et la mortalité. Nous avons relevé dix revues systématiques de qualité faible à élevée qui résument chacune entre 10 et 43 études portant sur les liens entre les effets cliniques de la COVID-19 et l'état nutritionnel en vitamine D (tableau en annexe). Les constatations figurant dans les études incluses dans les revues systématiques n'étaient cependant pas toujours significatives. Les résultats généralement cohérents tirés des revues systématiques ont révélé que la carence en vitamine D était plus importante chez les personnes ayant eu la COVID-19 et que plus le niveau moyen de vitamine D était faible, plus la sévérité de l'infection était grande. En ce qui concerne les résultats associés aux effets de la COVID-19, des associations avec un faible taux sérique en vitamine D ont été mentionnées dans certaines études, notamment en lien avec les hospitalisations, l'admission aux soins intensifs, la ventilation mécanique, l'oxygénothérapie et la mortalité. Les groupes susceptibles de présenter une carence en vitamine D étaient les mêmes à risque d'être atteints

d'une forme grave de COVID-19. La relation entre ces deux éléments est complexe et il est donc difficile d'extrapoler et de trouver une relation de cause à effet entre un faible taux de vitamine D et les effets plus sévères de la COVID-19 (8).

La présente synthèse en bref porte sur les éléments de preuve résumant la recherche sur le lien entre la supplémentation en vitamine D et le traitement ou la prévention de la COVID-19. Les études concernant le traitement ont été effectuées sur des patients atteints de la COVID-19 et incluent généralement des doses élevées de vitamine D (un bolus de grande taille avec un maximum de 200 000 UI ou des doses pouvant aller jusqu'à 60 000 UI par jour pris une fois par semaine, plusieurs fois par semaine ou de façon hebdomadaire) afin de voir si cela permet d'obtenir de meilleurs résultats. Les études concernant la prévention ont porté soit sur une population en santé, soit sur des personnes asymptomatiques ou ayant une forme bénigne de COVID-19 et incluent des doses modérées de vitamine D (entre 1 000 et 9 600 UI par jour pendant 2 à 24 semaines) afin de déterminer si la vitamine prévient la COVID-19 ou en réduit la gravité des effets. Des revues systématiques portant sur le traitement ou sur la prévention de la COVID-19 avec supplémentation en vitamine D ont été recensées. Lorsque de nouvelles données sur les essais ont été publiées depuis les revues systématiques les plus récentes, la recherche primaire ayant été publiée ou en prépublication a également été prise en compte si sa date de publication était postérieure à la plus récente revue systématique, soit jusqu'au 26 mai 2021. À ce jour, aucune étude à ce sujet n'a été réalisée au Canada.

Points clés

- Cinq revues systématiques (deux ayant été publiées, une prépublication et deux rapports inclus dans la littérature grise) sur le traitement avec la vitamine D ont été recensées, ce qui incluait la documentation disponible jusqu'au mars 2021, dont l'une indiquait la date du 15 mai 2021 comme date de vérification des nouvelles recherches. Aucune autre recherche primaire portant sur l'efficacité thérapeutique de la vitamine D pour la COVID-19 n'a été recensée (tableau 1).
- Les schémas posologiques de vitamine D utilisés dans les études étaient hétérogènes, variant d'un bolus unique de 200 000 UI de cholécalciférol à des traitements répartis sur plusieurs jours (jusqu'à 14 jours) comprenant entre 1 000 et 60 000 UI de cholécalciférol ou 532 à 266 µg de calcifédiol par jour (5, 8 à 11).
- Les cinq revues systématiques comprenaient trois essais cliniques randomisés (ECR) publiés, une cohorte prospective effectuée chez des adultes et deux expériences semi-expérimentales menées auprès de populations gériatriques afin d'évaluer la vitamine D comme traitement pour les patients atteints de COVID-19 (tableau 1).
    - L'un des trois ECR a révélé que le recours à un régime de vitamine D chez les patients atteints de COVID-19 pouvait permettre de réduire le risque de progression plus sévère de la maladie (admission aux SI) (RR = 0,04, IC à 95 % : 0,01 à 0,29, 1 ECR, 76 observations) (5, 8 à 11). Une petite cohorte prospective a indiqué une réduction des admissions aux SI (RC non

ajusté = 0,13, IC à 95 % : 0,03 à 0,6) chez les personnes qui ont reçu 1 000 UI de vitamine D3 par jour (10).

  - Deux ECR ont révélé que l'apport d'un régime de vitamine D ne réduisait pas significativement la mortalité comparativement aux résultats du groupe témoin ayant obtenu des soins habituels (RR 0,56; IC à 95 % : 0,05 à 5,85, 2 ECR, 313 observations) (5, 8 à 11). Une réduction importante de la mortalité a cependant été signalée dans deux quasi-expériences sur les populations gériatriques et dans un ECR effectué chez des adultes (RC = 0,26; IC à 95 % : 0,10 à 0,71) (11).
  - Aucun lien n'a été signé entre des événements indésirables et le régime de vitamine D. Dans l'un des essais (n = 237), on a enregistré un épisode de vomissements à la suite d'un grand bolus de 200 000 UI de cholécalciférol, mais aucun lien direct avec le traitement (RR = 2,98; IC à 95 % : 0,12 à 72,30) n'ait pu être établi (9).

- Aucune revue systématique ou étude sur la supplémentation en vitamine D pour prévenir la COVID-19 ou en réduire la gravité n'a été trouvée.
- On trouve 38 essais cliniques inscrits sur clinicaltrials.gov qui incluent une forme de supplémentation en vitamine D (dose de 1 000 à 9 600 UI par jour pendant 2 à 24 semaines chez des populations en santé et des personnes atteintes de la forme bénigne de COVID-19) ou un traitement (fortes doses quotidiennes pouvant aller jusqu'à 60 000 UI par jour dans le cadre de traitements durant une journée, plusieurs jours ou une semaine). Au 28 mai 2021, six de ces études étaient terminées, mais aucun des résultats n'était encore disponible. Ce secteur constitue donc un domaine de recherche actif, et les résultats tirés de ces nouvelles études pourraient modifier les conclusions présentées dans cette synthèse en bref.

Vue d'ensemble des éléments de preuve

Pour ce qui est de la vitamine D utilisée comme traitement contre la COVID-19, quatre revues systématiques avec cote AMSTAR 2 de qualité élevée à faible (ci-après appelés AMSTAR) comprenant trois ECR et deux études semi-expérimentales ont été sélectionnées. Chacune comportait des risques de biais et de l'information manquante en ce qui concerne les protocoles utilisés (12). On pouvait aussi voir des variations dans le traitement en vitamine D et dans les normes de soins (soins donnés au groupe témoin) entre les études. Aucune revue systématique n'a permis de cerner des études sur le lien entre la supplémentation en vitamine D et les effets de la COVID-19. Par conséquent, à l'heure actuelle, il n'y a pas suffisamment d'éléments de preuve pour déterminer les avantages et les inconvénients potentiels de la supplémentation en vitamine D comme traitement de la COVID-19, et on ne retrouve aucune étude publiée sur les avantages et les inconvénients potentiels de la supplémentation en vitamine D pour la prévention de la COVID-19. D'autres essais contrôlés, qui peuvent déjà avoir été entrepris à la suite de l'inscription des essais cliniques dans le registre, seront nécessaires pour évaluer en toute confiance les avantages de la supplémentation en vitamine D pour le traitement ou la prévention de la COVID-19. La confiance globale dans les résultats actuels

des études est faible et des recherches supplémentaires sont susceptibles de modifier les conclusions présentées dans cette revue.

TABLE DES MATIÈRES

SUPPLÉMENTATION EN VITAMINE D OU USAGE THÉRAPEUTIQUE CONTRE LA COVID-19

Tableau 1. Supplémentation en vitamine D ou utilisation comme traitement contre la COVID-19 (n = 5 revues systématiques)

ÉTUDE	PRINCIPAUX RÉSULTATS
Stroehlein (Cochrane) (8) *nouvelle* Revue systématique évolutive (AMSTAR haute qualité) Allemagne* 24 mai 2021 (données de recherche au 11 mars 2021)	- Vitamine D comme traitement contre la COVID-19, évaluée dans des ECR : o Trois ECR avec 356 participants, dont 183 ont reçu un traitement à la vitamine D. Deux études comprenaient des personnes atteintes d'une forme modérée ou grave de COVID-19 et une étude comprenait des personnes asymptomatiques ou atteintes de la forme bénigne de la COVID-19. Un ECR présentait un faible risque de biais et deux étaient associés à des préoccupations en raison des rapports sélectifs. Les traitements consistaient en une seule dose élevée de cholécalciférol par voie orale ou en des doses multiples de calcifédiol par voie orale. o Deux ECR ont constaté que la supplémentation en vitamine D ne faisait aucune différence pour l'ensemble des causes de mortalité alors qu'un ECR n'a trouvé aucune différence dans le besoin de ventilation mécanique. o On pouvait également voir des éléments de preuve contradictoires (RR protecteur de 0,04, RR non significatif de 0,75) en ce qui concerne l'effet protecteur possible contre l'admission aux soins intensifs dans deux ECR.

	○ Une étude sur les cas bénins de COVID-19 n'a signalé aucun effet dont la gravité était jugée prioritaire, mais a plutôt abordé la clairance virale, les marqueurs inflammatoires et les changements des taux sériques de vitamine D. ○ La revue systématique (RS) a cerné 21 essais terminés ou en cours pour lesquels aucun résultat n'avait encore été publié, mais dont le domaine d'étude était pertinent pour la présente revue et pourront donc, une fois publiés, modifier les conclusions présentées dans toute mise à jour de la présente revue. - Les traitements comprenaient : ○ Murai : Cholécalciférol 200 000 UI en une dose ○ Rustogi : Cholécalciférol 60 000 UI par jour pendant 7 jours ○ Castillo : calcifédiol 0,532 mg le jour 1, 0,266 mg les jours 3 et 7, puis une fois par semaine jusqu'au congé ou à l'admission aux SI. - Conclusion : il n'y avait pas suffisamment d'éléments de preuve pour déterminer les bienfaits et les méfaits de la supplémentation en vitamine D comme traitement contre la COVID-19.
Bassatne (Metabolism) (10) *nouvelle* Revue systématique et méta-analyse (cote AMSTAR de qualité faible) Liban* 24 mars 2021 (données de recherche au 18 décembre 2020)	- 31 études d'observation de basse qualité et avec un faible niveau de certitude et 3 ECR ont été inclus. - Études concernant le traitement : ○ Les trois ECR n'ont montré aucune amélioration en ce qui concerne la gravité des effets ou la mortalité, sauf que Castillo a déclaré que la vitamine D était associée à un taux d'admission plus faible aux SI (RC = 0,03 (IC à 95 % : 0,003 à 0,25)). Il s'agissait cependant d'un petit essai comportant un risque incertain de biais. ○ La présente RS a permis de cerner 32 essais en cours qui pourraient être pertinents pour cette revue. ○ Une petite cohorte prospective a constaté qu'un régime de vitamine D3 avec une dose de 1 000 IU par jour pendant 14 jours était associé à un risque plus

	faible d'admission aux SI en raison de la COVID-19 (RC non ajusté = 0,13, IC à 95 % : 0,03 à 0,6). - Liens avec de faibles niveaux de vitamine D : o Le risque de mortalité était plus élevé chez les personnes ayant de faibles taux de vitamine D (RR 2,1, IC à 95 % [0,9 à 4,8]; I^2 = 76 %, 7 études) et trois études utilisant un seuil de 25(OH)D < 30 ng/ml ont montré un risque de mortalité encore plus élevé (RR = 3,1, IC à 95 % [1,4 à 6,8]; I^2 = 0 %, 3 études). o Le risque d'admission aux soins intensifs était plus élevé chez les personnes ayant un faible taux de vitamine D (RR 4,89, IC à 95 % [0,54 à 44,26]; I^2 = 85 %, trois études). o Le risque d'hospitalisation était plus élevé chez les personnes ayant de faibles niveaux de vitamine D dans 2 études sur 3. o Le risque de positivité au SRAS-CoV-2 chez les personnes ayant de faibles taux de vitamine D était significatif pour 25(OH)D < 30 ng/ml (RR = 1,5, IC à 95 % [1,3, 1,8], I^2 = 0 %, 2 études).
National Institute for Health and Care Excellence (NICE), COVID-19 rapid guideline for practitioners on Vitamin D and evidence review (5) (cote AMSTAR de qualité élevée) ROYAUME-UNI 17 décembre 2020 (données de recherche au 29 octobre 2020)	- Supplémentation en vitamine D : o Cette ligne directrice précise que la vitamine D ne devrait pas être recommandée dans le seul but de prévenir la COVID-19, car il n'y avait pas suffisamment de preuves à l'appui. o Les recommandations relatives à la supplémentation pour la population en général portaient sur le maintien de la santé des os et des muscles. L'exposition insuffisante à la lumière du soleil a été associée à des niveaux de vitamine D sous-optimaux, et une supplémentation a été recommandée, particulièrement pendant les mois d'hiver. - Utilisation de la vitamine D pour traiter l'infection à la COVID-19 : o Un ECR (Castillo et coll.) a ajouté du calcifédiol (0,532 mg) au moment de l'admission, puis les jours 3 et 7, ainsi que chaque semaine en plus de la norme de

	soins habituelle. Cette étude présentait un risque élevé de biais et a été jugée comme une preuve très faible. Résultats : 1 personne sur 50 dans le groupe de traitement ayant reçu du calcifédiol et 13 personnes du groupe-témoin sur 26 ont été admis aux SI (RC = 0,03 IC à 95 % : 0,003 à 0,25). La mortalité dans les groupes a touché 0 personne sur 50 et 2 personnes sur 26 respectivement dans le groupe expérimental et dans le groupe témoin (RC = 0,097, IC à 95 % : 0,004 à 2,099). - Lien entre la vitamine D et les effets de la COVID-19 : o 12 études ont été incluses dans cet examen (12 autres n'ont pas été incluses parce qu'elles étaient encore en préimpression). Le lien entre l'infection à la COVID-19 (qu'elle soit ou non présente) et les niveaux de vitamine D était contradictoire (lien négatif et non significatif) et les analyses étaient très variables. Les résultats en ce qui concerne la gravité de l'atteinte étaient également contradictoires pour les soins intensifs, la ventilation mécanique ou l'oxygénothérapie. Une étude a indiqué un lien de protection entre la forme grave de la COVID-19 et la supplémentation en vitamine D.
Nikniaz et coll. (prépublication MedRxiv) (11) Revue systématique et méta-analyse (cote AMSTAR de qualité moyenne) 5 janvier 2021 (données de recherche au 16 décembre 2020)	- Cette revue a examiné 4 essais cliniques (2 ECR (Castillo et Rastogi) et 2 quasi-expériences (Annweiler) ayant porté sur 259 cas de COVID-19 ayant ou non été hospitalisés. Supplémentation orale en vitamine D, y compris avec du cholécalciférol et du calcifédiol (n = 139). - Les études quasi expérimentales ont été effectuées sur des populations de personnes âgées dans les unités de soins de longue durée et de gériatrie de l'hôpital. Le traitement consistait en une dose unique de 80 000 UI de vitamine D3 pour les cas positifs à la COVID-19. L'ECR de Rastogi a porté sur des cas atteints de la forme bénigne de COVID-19 qui ont reçu 60 000 UI par jour de cholécalciférol pendant 7 jours alors que dans l'ECR de Castillo, les personnes hospitalisées en raison de la COVID-19 ont reçu 0,532 mg de calcifédiol le jour 1, 0,266 mg les jours 3 et 7, puis une fois par semaine par la

	suite, jusqu'à ce que la personne obtienne son congé ou soit admise aux soins intensifs. *(Remarque : dans ces études, la dose donnée était supérieure aux limites maximales sécuritaires prévues pour la supplémentation en vitamine D.)* - Dans trois études (deux quasi-expériences et l'ECR de Castillo), les probabilités de mortalité parmi les groupes d'intervention étaient significativement plus faibles comparativement aux groupes témoins (RC = 0,264, IC à 95 % : 0,099 à 0,708, p = 0,008). Les deux quasi-expériences sur les populations gériatriques ont indiqué un effet important sur la survie. - Castillo et coll. a indiqué un taux d'admission aux SI plus faibles, un rapport de cotes (RC) de 0,03 (IC à 95 % : 0,003 à 0,25), alors que deux autres études ont montré une amélioration importante de l'état clinique avec la supplémentation en vitamine D.
COVID-NMA Project (9) Synthèse évolutive (non évaluée) France Mise à jour le 11 mai 2021	- Trois ECR (Castillo, Rastogi et Murai) ont été résumées et le sommaire des constatations indique que la preuve était de très faible qualité. o Le traitement avec vitamine D peut avoir un lien protecteur en ce qui concerne la gravité de l'atteinte (RR : 0,04, IC à 95 % : 0,01 à 0,29, étude (76 observations), très faible certitude). o À ce moment-ci, aucun lien n'a été établi avec la mortalité (très faible certitude) ou les événements indésirables (faible certitude).

Méthodologies :

Une analyse quotidienne de la littérature (publiée et prépubliée) est effectuée par le groupe des sciences émergentes de l'ASPC. L'analyse a permis de compiler la littérature sur la COVID-19 depuis le début de l'épidémie et est mise à jour quotidiennement. Les recherches visant à extraire les ouvrages pertinents sur la COVID-19 sont menées dans Pubmed, Scopus, BioRxiv, MedRxiv, ArXiv, SSRN et Research Square, et les résultats sont recoupés avec les ouvrages figurant sur la liste de la documentation sur la COVID de l'Organisation mondiale de la Santé et des centres d'information sur la COVID-19 gérés par Lancet, BMJ, Elsevier, Nature et Wiley. Le résumé quotidien et les résultats complets de l'analyse sont conservés dans une base de données RefWorks et dans une liste Excel consultable. Une recherche ciblée par mot-clé a été

effectuée dans ces bases de données pour recenser les citations pertinentes sur la COVID-19 et le SRAS-CoV-2. Les termes de recherche utilisés comprenaient : (vitamin D, 25(OH)D, 25hydroxyvitaminD, dihydroxyvitamin, calcif*, cholecalcif*) ou (zinc), un filtre supplémentaire pour les revues systématiques a aussi été utilisé pour sélectionner les premières revues.
Une recherche effectuée dans la littérature grise ciblait les principaux sites web des gouvernements et des entreprises de synthèse de données probantes pour obtenir des éléments de preuve à jour sur ces sujets.
La présente revue contient des recherches publiées jusqu'au 26 mai 2021.
Chaque référence potentiellement pertinente a été examinée pour confirmer qu'elle portait sur la question à l'étude et les conclusions clés qui ont été extraites et présentées dans des tableaux, dans la revue.

Examen par les pairs

Ce document a fait l'objet d'un examen par les pairs dirigé par un expert en la matière et d'un examen en ce qui concerne la rédaction et la science par le Bureau de la Conseillère scientifique en chef.

Préparée par : Lisa Waddell, LNM. Groupe des sciences émergentes, ASPC.

ANNEXE : VITAMINE D ET LIENS AVEC LES EFFETS CLINIQUES DE LA COVID-19

Tableau dans l'annexe. Niveaux de vitamine D ou supplémentation quotidienne et liens avec les effets cliniques de la COVID-19 (n = 10 revues systématiques)

ÉTUDE	PRINCIPAUX RÉSULTATS
Dramé (Nutrients) (13) *nouvelle* Revue systématique (cote AMSTAR de qualité moyenne) 13 avril 2021 (données de recherche au 5 novembre 2020)	- Comprend 11 études d'observation sur le lien entre les effets associés à la COVID-19 et la vitamine D chez des personnes âgées de plus de 60 ans. Les études ont été évaluées comme étant de qualité élevée à moyenne. o Les quatre études comparant les effets de la COVID-19 dans les groupes qui ont pris une supplémentation en vitamine D et ceux qui n'en ont pas reçu ont indiqué que les groupes qui avaient reçu la supplémentation présentaient des effets moins graves. Aucune description quant à l'importance n'est indiquée. o Sept études ont examiné le lien entre la carence en vitamine D et la gravité des effets et révélé que la fréquence des effets graves était plus basse chez les personnes ayant un taux suffisamment élevé de vitamine D. Aucune description quant à l'importance n'est indiquée.. - Ces données confirment que la supplémentation quotidienne en vitamine D peut avoir un effet protecteur sur le système immunitaire contre les infections respiratoires.
Petrelli (J Steroid Biochem Mol Biol, courte communication) (14) *nouvelle*	- 43 études d'observation (612 601 patients) ont été incluses et ont examiné le lien entre la vitamine D et le risque, la gravité et la mortalité associés à la COVID-19.

Revue systématique et méta-analyse (cote AMSTAR de qualité faible) Italie* 29 mars 2021 (données de recherche au 31 janvier 2021)	○ Une carence en vitamine D était associée à un risque plus élevé de COVID-19 (RC = 1,26; IC à 95 % : 1,19 à 1,34; P < 0,01). Le risque d'infection était plus élevé lorsque les taux de vitamine D étaient inférieurs à 20 ng/ml (RC = 1,5). ○ Une carence en vitamine D a été associée à une forme plus grave de COVID-19 (RC = 2,6; IC à 95 % : 1,84 à 3,67; P < 0,01) ○ Une carence en vitamine D a été associée à un risque plus élevé de COVID-19 (RC = 1,22; IC à 95 % : 1,04 à 1,43; P < 0,01) ○ La supplémentation en vitamine D a été associée à une réduction de la gravité de la COVID-19 (n = 6 études) et du risque de mortalité (n = 7 études) (RC = 0,27; IC à 95 % : 0,11 0,66; P < 0,01 et RC = 0,41; IC à 95 % : 0,21 0,81; P = 0,01).
Bassatne (Metabolism) (10) *nouvelle* Revue systématique et méta-analyse (cote AMSTAR de qualité faible) Liban* 24 mars 2021 (données de recherche au 18 décembre 2020)	- 31 études d'observation de basse qualité et avec un faible niveau de certitude et 3 ECR ont été inclus. - Études concernant le traitement : ○ Les trois ECR n'ont pas montré une amélioration de la gravité ou de la mortalité, sauf que Castillo a déclaré, dans son étude, que la vitamine D protégeait contre l'admission aux SI (RC 0,03, IC à 95 % : 0,003 à 0,25) dans un petit essai comportant un risque incertain de biais. ○ 32 essais en cours ont été recensés dans les registres des essais (janvier 2021). ○ Le traitement avec la vitamine D3 à 1 000 IU par jour pendant 14 jours a eu un effet protecteur (RC non ajusté = 0,13, IC à 95 % [0,03–0,6], 1 étude). - Liens avec de faibles niveaux de vitamine D : ○ Le risque de mortalité était plus élevé chez les personnes ayant de faibles taux de vitamine D (RR 2,1, IC à 95 % [0,9 à 4,8]; I^2 = 76 %, 7 études) et trois études utilisant un seuil de 25(OH)D < 30 ng/ml ont montré un risque de mortalité encore plus élevé (RR = 3,1, IC à 95 % [1,4 à 6,8]; I^2 = 0 %, 3 études).

	○ Le risque d'admission aux soins intensifs était plus élevé chez les personnes ayant un faible taux de vitamine D (RR 4,89, IC à 95 % [0,54 à 44,26]; I^2 = 85 %, trois études). ○ Le risque d'hospitalisation était plus élevé chez les personnes ayant de faibles niveaux de vitamine D dans 2 études sur 3. - Le risque de positivité au SRAS-CoV-2 chez les personnes ayant de faibles taux de vitamine D était significatif pour 25(OH)D < 30 ng/ml (RR = 1,5, IC à 95 % [1,3, 1,8], I^2 = 0 %, 2 études).
Teshome (Frontiers in Public Health) (15) *nouvelle* Revue systématique et méta-analyse (cote AMSTAR de qualité moyenne) Éthiopie* 5 mars 2021 (données de recherche au 20 décembre 2020)	- 14 études (91 120 participants) ont examiné les niveaux de vitamine D et le risque d'infection à la COVID-19. 5 études de cohorte, 5 comparaisons avec témoins et 4 études de prévalence ont été incluses. ○ Une carence en vitamine D était associée à un risque d'infection à la COVID-19 plus élevé (RC = 1,80; IC à 95 % : 1,72 à 1,88, I^2 de 79,1 %, 8 études).
Akbar (Frontiers in Nutr) (16) *nouvelle* Revue systématique et méta-analyse (cote AMSTAR de haute qualité) Indonésie* 29 mars 2021 (données de recherche au 9 décembre 2020)	- De faibles taux sériques de 25-hydroxyvitamine D (25-DHO) associés à la susceptibilité à la COVID-19, à la gravité et à la mortalité liées à la COVID-19 ont été étudiées dans 14 études (999 179 participants) : ○ Un faible taux sérique de vitamine D a été associé à des taux d'infection à la COVID-19 plus élevés (RC = 2,71 [1,72, 4,29], p < 0,001; I^2 : 92,6 %) et à l'âge et au sexe masculin, ce qui augmentait considérablement le lien. ○ Un faible taux sérique de vitamine D a été associé à une forme plus grave de COVID-19 (RC = 1,90 [1,24, 2,93], p = 0,003; I^2 : 55,3 %). ○ Un faible taux sérique de vitamine D a été associé à un taux de mortalité plus élevé (RC = 3,08 [1,35, 7,00], p = 0,011; I^2 : 80,3 %). Les facteurs de risque de mortalité connexes étaient le sexe masculin et le diabète, qui nécessitent un examen plus poussé pour déterminer le lien.

	- Une relation de causalité ne peut être établie avec les études d'observation incluses.
Ghasemian (prépublication MedRxiv) (17) *nouvelle* Revue systématique et méta-analyse (cote AMSTAR de qualité faible) Iran* 3 février 2021 (données de recherche au 18 décembre 2020)	- 23 études (11 901 participants) ont été incluses. o Les probabilités de contracter la COVID-19 étaient plus élevées chez les personnes ayant une carence en vitamine D (RC 3,3., IC à 95 % : 2,5 à 4,3, 3 études). o Les probabilités de contracter une forme grave de COVID-19 étaient plus élevées chez les personnes ayant une carence en vitamine D (RC 5,1, IC à 95 % : 2,6 à 10,3, 13 études). o Selon sept études, il n'y avait aucun lien entre la mortalité et la carence en vitamine D. - Il a été démontré que la positivité du SRAS-CoV-2 était inversement proportionnelle aux concentrations sériques de 25(OH)D.
National Institute for Health and Care Excellence (NICE), COVID-19 rapid guideline for practitioners on Vitamin D and evidence review (5) (AMSTAR high quality) ROYAUME-UNI 17 décembre 2020 (données de recherche au 29 octobre 2020)	- Supplémentation en vitamine D : o Cette ligne directrice précise que la vitamine D ne devrait pas être recommandée dans le seul but de prévenir la COVID-19, car il n'y avait pas suffisamment de preuves à l'appui. o Les recommandations relatives à la supplémentation pour la population en général portaient sur le maintien de la santé des os et des muscles. L'exposition insuffisante à la lumière du soleil a été associée à des niveaux de vitamine D sous-optimaux, et une supplémentation a été recommandée, particulièrement pendant les mois d'hiver. - Utilisation de la vitamine D pour traiter l'infection à la COVID-19 : o Un ECR (Castillo et coll.) a ajouté du calcifédiol (0,532 mg) au moment de l'admission, puis les jours 3 et 7, ainsi que chaque semaine en plus de la norme de soins habituelle. Cette étude présentait un risque élevé de biais et a été jugée comme une preuve très faible. Résultats : 1 personne sur 50 dans le groupe de traitement ayant reçu le calcifédiol et 13 personnes sur 26 dans le groupe-témoin ont été admises aux SI

	(RC = 0,03 IC à 95 % : 0,003 à 0,25). La mortalité dans les groupes a touché 0 personne sur 50 et 2 personnes sur 26 respectivement dans le groupe expérimental et dans le groupe témoin (RC = 0,097, IC à 95 % : 0,004 à 2,099). - Lien entre la vitamine D et les effets de la COVID-19 : o 12 études ont été incluses dans cet examen (12 autres n'ont pas été incluses parce qu'elles étaient encore en préimpression). Les liens entre l'infection à la COVID-19 (présente ou non) et les niveaux de vitamine D étaient contradictoires (lien négatif et non significatif) et les analyses étaient très variables. Les résultats en ce qui concerne la gravité de l'atteinte étaient également contradictoires pour les soins intensifs, la ventilation mécanique ou l'oxygénothérapie. Une étude a indiqué un lien de protection entre la forme grave de la COVID-19 et la supplémentation en vitamine D.
Liu (IJID) (18) Revue systématique et méta-analyse (cote AMSTAR de haute qualité) Chine* 2 janvier 2021 (données de recherche au 25 septembre 2020)	- Dans 10 études d'observation (cotées de qualité moyenne à élevée par l'auteur de la revue) qui comprenaient 361 934 participants (4 178 cas de COVID-19), la carence en vitamine D était associée à un risque accru de contracter l'infection à la COVID-19 (RC = 1,43, IC à 95 % : 1,00 à 2,05) et les personnes atteintes de COVID-19 présentaient des niveaux de vitamine D considérablement plus bas. Il y avait une hétérogénéité importante.
Pereira (Crit Rev Food Sci Nutr) (19) Revue systématique et méta-analyse (cote AMSTAR de qualité faible) Brésil* 2 novembre 2020 (données de recherche au 9 octobre 2020)	- Rapport sur le lien entre la carence en vitamine D et la gravité de la COVID-19 dans une analyse de la prévalence portant sur la carence et l'insuffisance en vitamine D chez les personnes atteintes de la maladie. - On a inclus 27 études d'observation jugées comme présentant un risque de biais faible (n=4) et élevé (n=23). - La probabilité d'une carence en vitamine D était plus élevée dans les formes graves de COVID-19 (RC 1,65 IC à 95 % : 1,30 à 2,09, I^2 35,7 %) et les niveaux de vitamine D étaient beaucoup plus faibles chez les personnes atteintes de la forme grave.

	- Dans le cas d'une carence grave, on a signalé une augmentation de l'hospitalisation (RC 1,81, IC à 95 % : 1,41 à 2,21, I^2 0,0 %) et de la mortalité (RC 1,82, IC à 95 % : 1,06 à 2,58, I^2 59,0 %).
Das (prepublication MedRxiv) (20) Revue systématique (cote AMSTAR de qualité faible) Multiple* 3 décembre 2020 (données de recherche au 3 novembre 2020)	- Onze études d'observation publiées et jugées être de qualité moyenne à élevée selon l'auteur de la revue ont été incluses. Toutes les études ont examiné le lien possible entre la carence en vitamine D et l'incidence ou la gravité de la COVID-19 et ont été incluses. L'analyse est descriptive, aucune méta-analyse n'a été prévue. - Les résultats de chacune des études figurent dans les tableaux. Il y avait constamment des liens entre la carence en vitamine D et la forme plus grave de la COVID-19 ou la mortalité découlant de cette infection.

Emerging Evidence on COVID-19

Evidence Brief on the Therapeutic use of Vitamin D Supplementation for COVID-19

Introduction

Is there evidence of the efficacy of therapeutic supplementation of vitamin D in the treatment or prevention of COVID-19?

Vitamin D is a prohormone, a substance the body converts to a hormone, important for calcium homeostasis and bone health. It is also implicated in other systems including immune function (1). The immunomodulating functions of vitamin D are complex and not fully understood. Research conducted prior to the COVID-19 pandemic suggests there is limited evidence of a potential benefit of vitamin D supplementation to lower risk of developing acute respiratory infections (2, 3).

Nutrition standards in Canada include dietary recommendations for vitamin D for all age groups to help meet usual nutrient requirements and maintain 25-hydroxyvitamin D [25(OH)D] serum levels above 40 nmol/L in support of bone health (4). Serum 25(OH)D is used as an indicator of vitamin D status (1). In Canada, Vitamin D supplementation is advised for adults over 50 y of age (4). Guidelines from the United States, United Kingdom and Ireland have considered the evidence for COVID-19 and recommend Vitamin D supplementation for bone health, but not for treatment or prevention of COVID-19 (5-7).

Researchers have postulated that vitamin D deficiency could put individuals at higher risk of developing COVID-19 infection or having more serious disease progression/outcomes. Although outside of the scope of this research question, many observational studies have been conducted on the association between Vitamin D status and risk of COVID-19 infection, severe outcomes and mortality. We identified ten systematic reviews of low to high quality that each summarize 10-43 studies related to associations with COVID-19 clinical outcomes and vitamin D status (Appendix Table). Across studies within the systematic reviews, findings were not consistently significant. Overall consistent findings from the systematic reviews identified that vitamin D deficiency was higher among COVID-19 cases, and mean vitamin D levels were lower with increasing severity of COVID-19. For outcomes of COVID-19 severity, associations with low serum vitamin D were reported in some studies for hospitalizations, ICU admittance, mechanical ventilation or oxygen therapy as well as mortality. The groups likely to be vitamin D deficient were the same groups at risk of severe COVID-19. This relationship is complex, and finding an association of low vitamin D levels and more severe COVID-19 outcomes cannot be extrapolated to mean causation (8).

This evidence brief focuses on systematic reviews that summarize research on COVID-19 and vitamin D supplementation for treatment or prevention. Treatment studies are on COVID-19 patients and generally include high doses of vitamin D (large bolus up to 200 000 UI or doses up to 60 000 IU/day as single day, multi-day or weekly treatment) to see if this improves outcome. Prevention studies are either on a healthy

population or asymptomatic/mild cases of COVID-19 and include moderate doses of vitamin D (1000-9600 IU/day for 2-24 weeks) to see if it prevents COVID-19 or reduces the severity outcomes of COVID-19 infection. Systematic reviews on COVID-19 treatment or prevention with vitamin D supplementation were identified and where new trial data have been published since the most recent systematic reviews, primary research in published or prepublication format was also considered for inclusion if it had been published following the most recent systematic review, up to May 26, 2021. To date, no studies have been done in Canada on this topic.

Key Points

- Five systematic reviews (two published, one prepublication and two grey literature reports) on vitamin D treatment were identified and included literature up to March 2021, with one reporting they last checked for new research May 15, 2021. No additional primary research was identified on the therapeutic efficacy of vitamin D for COVID-19 (Table 1).
- Across the studies there was a lot of heterogeneity in treatment regimes from large single bolus of 200 000 IU Cholecalciferol to multi-day treatments (up to 14d) of 1000-60 000 IU cholecalciferol to 532-266 mcg calcifediol per day (5, 8-11).
- The five systematic reviews included three published randomized controlled trials (RCT) and one prospective cohort conducted in adults and 2 quasi-experiments conducted in geriatric populations evaluating Vitamin D as a treatment for patients with COVID-19 (Table 1).
    - One of three RCTs found that vitamin D treatment in COVID-19 patients may reduce the risk of severe disease progression (admittance to ICU) (RR 0.04, 95%CI 0.01- 0.29, 1RCT, 76 observations) (5, 8-11). A small prospective cohort reported reduced ICU admission (unadjusted OR = 0.13, 95%CI 0.03–0.6) among those that received 1000 IU vitamin D3 per day (10).
    - Two RCTs found that vitamin D treatment did not significantly reduce mortality compared to the standard care control group (RR 0.56; 95%CI 0.05 – 5.85, 2 RCTs, 313 observations) (5, 8-11), but a significant reduction in mortality was reported in two quasi-experimental studies on geriatric populations and one RCT on adults (OR 0.26; 95%CI 0.10-0.71) (11).
    - No association with adverse events and vitamin D treatment were reported. In one trial (n=237) one vomiting event was recorded following a large single bolus of 200 000 IU cholecalciferol, however an association with treatment was not found (RR 2.98; 95%CI 0.12-72.30) (9).
- No systematic reviews or studies were found on supplementation of vitamin D to prevent COVID-19 or reduce COVID-19 severity.
- There were 38 clinical trials registered on clinicaltrials.gov that included a form of vitamin D supplementation (dosing 1000-9600 IU/day for 2-24 weeks in healthy population and mild COVID-19

cases) or treatment (large bolus or high daily doses up to 60 000 IU/day as single day or multi-day or weekly treatments) and COVID-19 outcomes, six indicated they were completed as of May 28, 2021, but have not yet posted results. This remains an area of active research and the results of new studies may change the conclusions of this evidence brief.

Overview of the Evidence

For vitamin D as a treatment for COVID-19, four systematic reviews with AMSTAR 2 rating of high to low quality (herein referred to as AMSTAR) included three RCTs and two quasi-experiments, each with some risk of bias concerns and missing information in the study protocols (12). There were also variations in the vitamin D treatment and standard of care (control group care) across studies. No systematic reviews identified studies on supplementation of vitamin D and COVID-19 outcomes. Thus, at present there is insufficient evidence to determine the benefits and any potential harms of vitamin D supplementation as a treatment of COVID-19 and no published evidence on the benefits and potential harms of vitamin D supplementation for prevention of COVID-19. Additional controlled trials, which may already be initiated based on the trials registered, are needed to confidently evaluate whether there are benefits to vitamin D supplementation for treatment or prevention. The overall confidence in the current results is low and additional research is likely to change the conclusions of this review.

CONTENTS

VITAMIN D SUPPLEMENTATION OR THERAPEUTIC USE FOR COVID-19

Table 1. Vitamin D Supplementation or Use as a Therapeutic for COVID-19 (n= 5 systematic reviews)

STUDY	KEY OUTCOMES
Stroehlein (Cochrane) (8) *new* Living Systematic Review (AMSTAR high quality) Germany* May 24, 2021 (search date Mar 11, 2021)	- Vitamin D as a treatment for COVID-19 assessed by RCTs: o 3 RCTs with 356 participants of whom 183 received vitamin D treatment. 2 studies included moderate/severe COVID-19 and 1 included asymptomatic/mild COVID-19. 1 RCT was at low risk of bias and 2 had some concerns due to selective

	reporting. Treatments were a single high dose of oral cholecalciferol or multiple doses of oral calcifediol. o 2 RCTs found vitamin D supplementation made no difference to all cause mortality and 1 RCT found no difference in the need for mechanical ventilation. o There was conflicting evidence (protective RR 0.04, not significant RR 0.75) for a possible protective effect against ICU admission in 2 RCTs. o One study on mild COVID-19 cases did not report any of the prioritized severity outcomes, instead they report on viral clearance, inflammatory markers and changes in vitamin D serum levels. o The SR identified 21 completed or on-going trials without published results that would be relevant to this review, thus future results may change the conclusions of any updates to this review. - The treatments included: o Murai: Cholecalciferol 200 000IU in 1 dose o Rustogi: Cholecalciferol 60 000IU/ day for 7 days o Castillo: Calcifediol 0.532 mg on day 1, 0.266 mg on days 3 and 7, and then weekly until discharge or ICU admission. - Conclusion: there was insufficient evidence to determine the benefits and harms of vitamin D supplementation as a treatment of COVID-19.
Bassatne (Metabolism) (10) *new* Systematic review and meta-analysis (AMSTAR rating low quality) Lebanon* Mar 24, 2021 (search date Dec 18, 2020)	- 31 observational studies, low quality and certainty in the evidence, and 3 RCTs were included. - Treatment studies: o The 3 RCTs did not show an improvement in severity outcomes or mortality except Castillo reported Vitamin D was associated with lower ICU admission OR 0.03 (95% CI: 0.003–0.25), however, this was a small trial with uncertain risk of bias. o This SR identified 32 on-going trials that may be relevant to this review.

	○ 1 small prospective cohort found treatment with vitamin D3 1000IU/day for 14 days was associated with lower risk of COVID-19 ICU admission (unadjusted OR = 0.13, 95% CI 0.03–0.6). - Associations with low Vitamin D levels: ○ Mortality risk was higher for those with low vitamin D levels (RR 2.1, 95% CI [0.9–4.8]; I^2 = 76%, 7 studies) and three studies using a 25(OH)D <30ng/ml cut-off showed a even higher risk of mortality (RR = 3.1, 95% CI [1.4–6.8]; I^2 = 0%, 3 studies). ○ ICU risk was higher for those with low vitamin D levels (RR 4.89, 95%CI [0.54 - 44.26]; I^2 = 85%, 3 studies). ○ Risk of hospitalization was higher for those with low vitamin D levels in 2/3 studies. ○ Risk of SARS-CoV-2 positivity for those with low vitamin D levels was significant for 25 (OH)D <30ng/ml (RR = 1.5, 95% CI [1.3, 1.8], I2 = 0%, 2 studies).
National Institute for Health and Care Excellence (NICE), COVID-19 rapid guideline for practitioners on Vitamin D and evidence review (5) (AMSTAR high quality) UK Dec 17, 2020 (search date Oct 29, 2020)	- Vitamin D supplementation: ○ The guideline states vitamin D should not be recommended for the sole purpose of preventing COVID-19, as there was insufficient evidence to support this. ○ The recommendations for general population supplementation were related to maintenance of bone and muscle health. Insufficient exposure to sunlight has been linked to suboptimal vitamin D levels, and supplementation was recommended, particularly during the winter months. - Vitamin D for treating COVID-19 infection: ○ One RCT (Castillo et al) added Calcifediol (0.532mg) on admission, day 3 and 7 and then weekly in addition to standard of care. This study had serious risk of bias and was considered very low evidence. Results: 1/50 from the calcifediol treatment group and 13/26 controls were admitted to the ICU (OR 0.03 (95%CI 0.003-0.25).

	Mortality occurred in 0/50 and 2/26 in the treatment and control arms (OR 0.097, 95%CI 0.004-2.099). - Vitamin D status associations with COVID-19 outcomes: o 12 studies were included in their review (an additional 12 were not included because they were still in preprint). The association between COVID-19 status and vitamin D levels was conflicting (non-significant and negative association) and analyses were highly variable. Outcomes of severity were also conflicting for ICU, mechanical ventilation or oxygen therapy. One study reported a protective association with severe COVID-19 and supplementing with Vitamin D.
Nikniaz et al (prepublication MedRxiv) (11) Systematic Review and Meta-analysis (AMSTAR moderate quality) Jan 5, 2021 (search date Dec 16, 2020)	- This review included 4 clinical trials (2 RCTs (Castillo and Rastogi) and 2 quasi-experiments (Annweiler x2)), of 259 COVID-19 cases, hospitalized and not-hospitalized. Oral vitamin D supplementation, including cholecalciferol and calcifediol (n=139). - The quasi-experimental studies were conducted on elderly populations in long-term care and geriatric unit in the hospital. The treatment was a single 80 000IU dose of Vitamin D_3 for COVID-19 positive cases. Rastogi RCT was conducted on mild COVID-19 cases and received Cholecalciferol 60 000IU/ day for 7 days and Castillo was on hospitalized COVID-19 cases that received Calcifediol 0.532 mg on day 1, 0.266 mg on days 3 and 7, and then weekly until discharge or ICU admission. *(Note: Dosing in these studies is above upper limits of supplement safety for vitamin D.)* - Across 3 studies (two quasi-experiments and Castillo RCT), a significantly lower odds of mortality among the intervention groups compared with the control groups (OR = 0.264, 95% CI = 0.099–0.708, p-value = 0.008) was reported. Both quasi-experiments on geriatric populations reported a significant impact on survival. - Castillo et al. reported lower ICU admissions, odds ratio (OR) of 0.03 (95% CI: 0.003 - 0.25) and two studies showed significant improvement in clinical status with vitamin D treatment.

COVID-NMA Project (9) Living Synthesis (Not evaluated) France Updated May 11, 2021	- Three RCTs (Castillo, Rastogi, and Murai) were summarized and the summary of findings table indicates the evidence was very low quality. o Treatment with vitamin D may have a protective association with disease severity (RR: 0.04, 95%CI 0.01 - 0.29, 1 study (76 obs),very low certainty). o No association was identified for mortality (very low certainty) or adverse events at this time (low certainty).

Methods:

A daily scan of the literature (published and pre-published) is conducted by the Emerging Science Group, PHAC. The scan has compiled COVID-19 literature since the beginning of the outbreak and is updated daily. Searches to retrieve relevant COVID-19 literature are conducted in Pubmed, Scopus, BioRxiv, MedRxiv, ArXiv, SSRN, Research Square and cross-referenced with the COVID-19 information centers run by Lancet, BMJ, Elsevier, Nature and Wiley. The daily summary and full scan results are maintained in a refworks database and an excel list that can be searched. Targeted keyword searching was conducted within these databases to identify relevant citations on COVID-19 and SARS-COV-2. Search terms used included: (vitamin D, 25(OH)D, 25hydroxyvitaminD, dihydroxyvitamin, calcif*, cholecalcif*) or (zinc), an additional filter for systematic reviews was used to identify reviews initially.
A grey literature search was conducted targeting key government websites and evidence synthesis organizations for current evidence syntheses on these topics.
This review contains research published up to May 26, 2021.
Each potentially relevant reference was examined to confirm it addressed the review question and key findings were extracted into tables in the review.

Peer-review
This document underwent peer-review by a subject matter expert, and editorial and science to policy review by the Office of the Chief Science Officer.

APPENDIX: VITAMIN D AND ASSOCIATIONS WITH COVID-19 CLINCIAL OUTCOMES

Appendix Table. Vitamin D Levels or Daily Supplementation and Association with COVID-19 Clinical Outcomes (n=10 systematic reviews)

STUDY	KEY OUTCOMES
Dramé (Nutrients) (13) *new* Systematic review (AMSTAR rating moderate quality) Apr 13, 2021 (search date Nov 5, 2020)	- Includes 11 observational studies on the association between COVID-19 outcomes and vitamin D in populations aged >60 years old. Studies were assessed to be of high – moderate quality. ○ 4 studies comparing COVID-19 outcomes in groups who supplement with vitamin D and those who don't found the supplementation groups had fewer severe outcomes in all 4 studies. Significance not described.

	○ 7 studies looked at the association between vitamin D deficiency and severity outcomes and found lower frequency of severe outcomes among those with sufficient vitamin D. Significance not described. - These data support that daily supplementation of vitamin D may have a protective effect via a positive impact on the immune system against respiratory infections.
Petrelli (J Steroid Biochem Mol Biol, short communication) (14) *new* Systematic review and meta-analysis (AMSTAR rating low quality) Italy* Mar 29, 2021 (search data Jan 31. 2021)	- 43 observational studies (612601 patients) were included and examined the association between vitamin D and risk, severity and mortality from COVID-19. ○ Vitamin D deficiency was associated with higher risk of COVID-19 (OR = 1.26; 95 % CI, 1.19–1.34; P < .01). Infection risk was higher with vitamin D values <20 ng/mL, (OR 1.5). ○ Vitamin D deficiency was associated with more severe COVID-19 (OR = 2.6; 95 % CI, 1.84–3.67; P < .01) ○ Vitamin D deficiency was associated with higher risk of COVID-19 mortality (OR = 1.22; 95 % CI, 1.04–1.43; P < .01) ○ Supplementation with Vitamin D was associated with reduced COVID-19 severity (n=6 studies) and mortality risk (n=7 studies) (OR = 0.27; 95 % CI, 0.11−0.66; P < .01 and OR = 0.41; 95 % CI, 0.21−0.81; P = .01).
Bassatne (Metabolism) (10) *new* Systematic review and meta-analysis (AMSTAR rating low quality) Lebanon* Mar 24, 2021 (search data Dec 18, 2020)	- 31 observational studies, low quality and certainty in the evidence, and 3 RCTs were included. - Treatment studies: ○ The 3 RCTs did not show an improvement in severity outcomes or mortality except Castillo reported Vitamin D was protective against ICU admission OR 0.03 (95% CI: 0.003–0.25) in a small trial with uncertain risk of bias. ○ 32 on-going trials were identified across trial registries (Jan 2021). ○ Treatment with vitamin D3 1000IU/day for 14 days was protective (unadjusted OR = 0.13, 95% CI [0.03–0.6], 1 study). - Associations with low Vitamin D levels:

	○ Mortality risk was higher for those with low vitamin D levels (RR 2.1, 95% CI [0.9–4.8]; I^2 = 76%, 7 studies) and three studies using a 25(OH)D <30ng/ml cut-off showed a even higher risk of mortality (RR = 3.1, 95% CI [1.4–6.8]; I^2 = 0%, 3 studies). ○ ICU risk was higher for those with low vitamin D levels (RR 4.89, 95%CI [0.54 - 44.26]; I^2 = 85%, 3 studies). ○ Risk of hospitalization was higher for those with low vitamin D levels in 2/3 studies. - Risk of SARS-CoV-2 positivity for those with low vitamin D levels was significant for 25 (OH)D <30ng/ml (RR = 1.5, 95% CI [1.3, 1.8], I2 = 0%, 2 studies).
Teshome (Frontiers in Public Health) (15) *new* Systematic review and meta-analysis (AMSTAR rating moderate quality) Ethiopia* Mar 5, 2021 (search data Dec 20, 2020)	- 14 studies (91120 participants) looked at Vitamin D levels and the risk of COVID-19 infection. 5 cohort, 5 case control, and 4 cross-sectional studies were included. ○ Vitamin D deficiency was associated with higher infection rates of COVID-19 (OR = 1.80; 95%CI: 1.72, 1.88, I^2 of 79.1%, 8 studies).
Akbar (Frontiers in Nutr) (16) *new* Systematic review and meta-analysis (AMSTAR rating high quality) Indonesia* Mar 29, 2021 (search data Dec 9, 2020)	- Low serum 25-hydroxyvitamin D (25-OHD) levels associated with susceptibility to COVID-19, severity, and mortality related to COVID-19 was investigated in 14 studies (999 179 participants): ○ Low serum Vitamin D was associated with higher infection rates of COVID-19 (OR = 2.71 [1.72, 4.29], p < 0.001; I^2: 92.6%) and age and male gender significantly increased the association. ○ Low serum Vitamin D was associated with higher severe COVID-19 (OR = 1.90 [1.24, 2.93], p = 0.003; I2: 55.3%). ○ Low serum Vitamin D was associated with higher mortality (OR = 3.08 [1.35, 7.00], p = 0.011; I2: 80.3%), intervening risk factors for mortality were male gender and diabetes, which require further exploration to determine the relationship.

	- A causal relationship cannot be established with the included observational studies.
Ghasemian (prepublication MedRxiv) (17) *new* Systematic review and meta-analysis (AMSTAR rating low quality) Iran* Feb 3, 2021 (search date Dec 18, 2020)	- 23 studies (11901 participants) were included. o The odds of getting COVID-19 were higher among vitamin D deficient persons (OR 3.3., 955CI 2.5-4.3, 3 studies). o The odds of developing severe COVID-19 were higher among vitamin D deficient persons (OR 5.1, 95%CI 2.6-10.3, 13 studies). o There was no association with mortality and vitamin D deficiency, 7 studies. - SARS-CoV-2 positivity has been shown to be inversely proportional to 25(OH) D serum levels.
National Institute for Health and Care Excellence (NICE), COVID-19 rapid guideline for practitioners on Vitamin D and evidence review (5) (AMSTAR high quality) UK Dec 17, 2020 (search date Oct 29, 2020)	- Vitamin D supplementation: o The guideline states vitamin D should not be recommended for the sole purpose of preventing COVID-19, as there was insufficient evidence to support this. o The recommendations for general population supplementation were related to maintenance of bone and muscle health. Insufficient exposure to sunlight has been linked to suboptimal vitamin D levels, and supplementation was recommended, particularly during the winter months. - Vitamin D for treating COVID-19 infection: o One RCT (Castillo et al) added Calcifediol (0.532mg) on admission, day 3 and 7 and then weekly in addition to standard of care. This study had serious risk of bias and was considered very low evidence. Results: 1/50 calcifediol treatment group and 13/26 controls were admitted to the ICU (OR 0.03 (95%CI 0.003-0.25). Mortality occurred in 0/50 and 2/26 in the treatment and control arms (OR 0.097, 95%CI 0.004-2.099). - Vitamin D status associations with COVID-19 outcomes: o 12 studies were included in their review (an additional 12 were not included because they were still in preprint). The associations between COVID-19 status

	and vitamin D levels were conflicting (non-significant and negative associations) and analyses were highly variable. Outcomes of severity were also conflicting for ICU, mechanical ventilation or oxygen therapy. One study reported a protective association with severe COVID-19 and supplementing with Vitamin-D.
Liu (IJID) (18) Systematic Review and Meta-analysis (AMSTAR rating high quality) China* Jan 2, 2021 (search date Sept 25, 2020)	- Across 10 observational studies (rated as medium to high quality by the review author) that included 361 934 participants (4178 COVID-19 cases), vitamin D deficiency was associated with increased risk of COVID-19 (OR = 1.43, 95% CI 1.00 to 2.05) and people with COVID-19 were shown to have significantly lower vitamin D levels. There was significant heterogeneity.
Pereira (Crit Rev Food Sci Nutr) (19) Systematic Review and Meta-analysis (AMSTAR rating low quality) Brazil* Nov 2, 2020 (search date Oct 9, 2020)	- Reports on the association between vitamin D deficiency and COVID-19 severity, via an analysis of the prevalence of vitamin D deficiency and insufficiency in people with the disease. - 27 observational studies considered at low (n=4) and high (n=23) risk of bias were included. - Higher odds of vitamin D deficiency was found in severe COVID-19 cases, OR 1.65 95%CI 1.30–2.09, I^2 35.7% and vitamin D levels were significantly lower among severe cases. - For severe deficiency, increased hospitalization OR 1.81 (95%CI 1.41–2.21, I^2 0.0%) and mortality OR 1.82 (95%CI 1.06–2.58, I^2 59.0%) were reported.
Das (prepublication MedRxiv) (20) Systematic Review (AMSTAR rating low quality) Multiple* Dec 3, 2020 (search date Nov 3, 2020)	- 11 published observational studies considered to be moderate to high quality by the review author were included. All studies examined the possible association between vitamin D deficiency and the incidence or severity of COVID-19 disease and were included. Analysis is descriptive, no meta-analysis was planned. - Individual study results were presented in the tables. Consistently there were associations between vitamin D deficiency and more severe COVID-19 and/or mortality.

Emerging Evidence on COVID-19

Evidence Brief of vitamin D and zinc supplementation for therapeutic use on COVID-19 cases

Introduction

Is there evidence of the efficacy of therapeutic or prophylactic supplementation of vitamin D or zinc in the prevention or treatment of COVID-19?

Vitamin D and zinc are micronutrients that play various physiological roles, including a role in the immune system (1). Deficiencies of these micronutrients have been postulated to put individuals at higher risk of developing infection or more serious progression of disease, thus data on the association of deficiencies and COVID-19 disease outcomes are also summarized in this review. This evidence brief highlights the most recent systematic reviews on these micronutrients supplementation or status and COVID-19, where systematic reviews were not identified, primary research in published or prepublication format up to Jan 7, 2021 has been included. To date evidence in the Canadian context is pending.

Key Points

Vitamin D

- Vitamin D is a prohormone, a substance the body converts to a hormone, which is important for calcium homeostasis and bone health and is also implicated in other systems including immune function. The immunomodulating functions of vitamin D are complex and not fully understood. Research conducted prior to the pandemic suggests there is limited evidence of a potential benefit of vitamin D supplementation to lower risk of developing acute respiratory infections (2, 3).
- Nutrition standards in Canada include dietary recommendations for vitamin D for all age groups to help maintain 25-hydroxyvitamin D serum levels above 40 nmol/L in support of bone health (4). Vitamin D supplementation is advised for adults over 50 y of age (4). Other guidelines such as one from the United States and United Kingdom that have considered the evidence for COVID-19 continue to recommend supplementation for bone health, but not for treatment or prevention of COVID-19 (5, 6).
- Seven systematic reviews were identified in bibliographic databases, five of which included literature up to Fall 2020 and are summarized below along with three grey literature reports on the therapeutic efficacy of vitamin D for COVID-19 or acute respiratory tract infections.
- Five systematic reviews reported on observational studies that detailed associations between insufficient and/or deficient levels of vitamin D and increased risk of severe COVID-19 and mortality (Table 1). The associations across studies were not consistently significant, however vitamin D deficiency was shown to be high among COVID-19 cases, and mean vitamin D levels were lower with

increasing severity of COVID-19. For outcomes of severity, associations were reported in some studies for ICU admittance, mechanical ventilation or oxygen therapy as well as mortality. Most studies contributing to these outcomes were considered to have a high risk of bias. The groups at risk of vitamin D deficiency are the same groups at risk of severe COVID-19, this relationship is complex and although some studies have reported associations with low vitamin D and COVID-19 outcomes, these data cannot be extrapolated as a cause of the COVID-19 outcomes.

- Vitamin D as a treatment for patients with COVID-19 was assessed in three systematic reviews that collectively include two published and one prepublished randomized controlled trial (RCT) and 2 quasi-experiments conducted in adults (Table 1).
    - Evidence that vitamin D treatment in COVID-19 patients may reduce the risk of severe disease progression (RR 0.04, 95%CI 0.01 -0.29, 1RCT, 76 observations) (7).
    - Evidence that vitamin D treatment reduces mortality was not significant across 2 RCTs (RR 0.56; 95%CI 0.05 – 5.85, 2 RCT, 313 observations) (7), but was significant across two quasi-experimental studies and one RCT (OR 0.26; 95%CI 0.10-0.71) (8).
    - In one trial (n=237) a single adverse event was recorded (RR 2.98; 95%CI 0.12-72.30) (7).
- Several clinical trials were registered on clinicaltrials.gov. Of 45 on vitamin D, four indicated they were completed, but have not posted results. The objectives of these studies varied across treating COVID-19 with vitamin D (n=33) to exploring vitamin D levels (n=12) along with other micronutrients.

Zinc

- Zinc is an essential micronutrient that is required for adaptive and innate immune response (1). It has been used against other respiratory viruses and diarrhea in children with conflicting results across studies (9). Globally up to 20% of people are deficient in zinc, inadequate intake of zinc is more prevalent in low and middle income countries (9).
- Zinc has demonstrated antiviral properties *in vitro* studies have found that zinc inhibit viral RNA-dependent RNA polymerase against SARS-CoV-1 (1). Cellular uptake of zinc has been shown to increase when zinc is combined with a zinc ionophore such as hydroxychoroquine. Thus, many on-going clinical trials are examining the addition of zinc to existing treatments (1).
- One guidance document from the United States addressed zinc supplementation and COVID-19, the recommendation is against supplementation above the current dietary allowances (10).
- Two systematic reviews were identified. One high quality systematic review includes non-SARS-CoV-2 research and indicates moderate evidence for the role of zinc as a therapeutic in the prevention and reduction of severe disease progression across respiratory tract infection literature. The other review identified one retrospective observational study, also summarized in Table 2.

- A high quality systematic review last updated in August did not identify any RCTs related to the therapeutic use of zinc for COVID-19.
- As a therapeutic, two retrospective cohort studies evaluated the impact of adding zinc sulphate to standard of care treatment for COVID-19 cases:
    - Multivariable analysis showed an increased frequency of being discharged home (OR 1.53, 95 % CI 1.12–2.09) and reduction in mortality or transfer to hospice among patients who did not require ICU level of care remained significant (OR 0.449, 95 % CI 0.271–0.744) (11).
    - Zinc sulfate was not significantly associated with a change in risk of in-hospital mortality (adjusted hazard ratio, 0.66; 95% CI, 0.41 to 1.07; P = .09) in one retrospective cohort (12).
- This is an area of active research, 21 registered trials were identified on clinicaltrials.gov, three were completed, but have not posted results. Most registered trials were looking at supplementing or treating with zinc as a monotherapy or in combination with other compounds, others were exploring zinc levels along with other micronutrients.

Overview of the Evidence

For vitamin D as a therapeutic for COVID-19, three systematic reviews of high to low quality based on AMSTAR 2 criteria (herein referred to as AMSTAR) included three RCTs and two quasi-experiments, each with some risk of bias concerns and missing information in the study protocols (13). There were also variations in the vitamin D treatment and standard of care across studies. Thus, the overall confidence in this evidence was low and the conclusions of this review are likely to change with future research.

Five systematic reviews with an AMSTAR quality rating from high to low examined associations between vitamin D levels and COVID-19 infection, severity or mortality (13). The studies included in these reviews were observational studies, frequently retrospective in design and considered at high risk of bias. The outcomes summarized in each review varied as did the inclusion of prepublications, which meant each review examined a different subset of studies. Thus, the overall confidence in these results is low and additional research is likely to change the conclusions of this review.

Limited evidence was identified on the use of zinc in treatment of COVID-19. Two systematic reviews on zinc were identified; the quality ranged from low to high AMSTAR ratings (13). Two retrospective cohorts at high risk of bias due to their retrospective study design were also included. Thus, the overall confidence in these results is very low and additional research is likely to change the conclusions of this review.

CONTENTS

VITAMIN D

Table 1. Vitamin D and COVID-19

STUDY	KEY OUTCOMES
Effect of Vitamin D supplementation or use as a therapeutic	
National Institute for Health and Care Excellence (NICE), COVID-19 rapid guideline for practitioners on Vitamin D and evidence review (AMSTAR high quality) (5) UK Published December 17, 2020	- Vitamin D supplementation • The guideline states vitamin D should not be recommended for the sole purpose of preventing COVID-19, as there was insufficient evidence to support this. • The recommendations for general population supplementation were related to maintenance of bone and muscle health. Insufficient exposure to sunlight has been linked to suboptimal vitamin D levels, and supplementation was recommended, particularly during the winter months. - Vitamin D for treating COVID-19 infection • One RCT (Castillo et al) added Calcifediol (0.532mg) on admission, day 3 and 7 and then weekly in addition to standard of care. This study had serious risk of bias and was considered very low evidence. Results: 1/50 calcifediol treatment group and 13/26 controls were admitted to the ICU (OR 0.03 (95%CI 0.003-0.25). Mortality occurred in 0/50 and 2/26 in the treatment and control arms (OR 0.097, 95%CI 0.004-2.099) - Vitamin D status associations with COVID-19 outcomes • 12 studies were included in their review (an additional 12 were not included because they were still in preprint). The association between COVID-19 status and vitamin D levels were conflicting (non-significant and negative association) and analyses were highly variable. Outcomes of severity were also conflicting for ICU, mechanical ventilation or oxygen therapy. One study reported a protective association with severe COVID-19 and supplementing with Vitamin-D.

Nikniaz et al (prepublication MedRxiv) (8) Systematic Review and Meta-analysis (AMSTAR moderate quality) Jan 5, 2021 (search date Dec 16, 2020)	- This review included 4 clinical trials (2 RCTs (Castillo and Rastogi) and 2 quasi-experiments (Annweiler x2)), of 259 COVID-19 cases, hospitalized and not-hospitalized. Oral vitamin D supplementation, including cholecalciferol and calcifediol (n=139). The therapeutic protocols ranged from 60,000 to 80,000 IU dosing for a duration range of 7 to 14 days. *(Note: Dosing in these studies is above upper limits of supplement safety for vitamin D.)* - Across 3 studies, a significantly lower odds of mortality among the intervention groups compared with the control groups (OR = 0.264, 95% CI = 0.099–0.708, p-value = 0.008) was reported. Both quasi-experiments on geriatric populations reported a significant impact on survival. - Castillo et al. reported lower ICU admissions, odds ratio (OR) of 0.03 (95% CI: 0.003 - 0.25) and two studies showed significant improvement in clinical status with vitamin D treatment.
COVID-NMA Project (7) Living Synthesis (Not evaluated) France Jan 7, 2021 (Search date Dec 4, 2020)	- Three RCTs (Castillo, Rastogi, and Murai) were summarized and the summary of findings table indicates the evidence was very low quality however, treatment with vitamin D may have a protective association with disease severity (very low certainty), but no association was identified for mortality (very low certainty) or adverse events at this time (low certainty).
Association of vitamin D levels and clinical outcomes	
Liu et al. (IJID) (14) Systematic Review and Meta-analysis (AMSTAR rating high quality) Jan 2, 2021 (search date Sept 25, 2020)	- Across 10 observational studies (rated as medium to high quality by review author) included 361 934 participants (4178 COVID-19 cases), vitamin D deficiency was associated with increased risk of COVID-19 (OR = 1.43, 95% CI 1.00 to 2.05) and people with COVID-19 were shown to have significantly lower vitamin D levels. There was significant heterogeneity.
Pereira et al. (Crit Rev Food Sci Nutr) (15) Systematic Review and Meta-analysis (AMSTAR rating low quality)	- Reports on the association between vitamin D deficiency and COVID-19 severity, via an analysis of the prevalence of vitamin D deficiency and insufficiency in people with the disease.

Nov 2, 2020 (search date Oct 9, 2020)	- 27 observational studies considered at low (n=4) and high (n=23) risk of bias were included. - A higher odds of vitamin D deficiency was found in severe COVID-19 cases, OR 1.65 95%CI 1.30–2.09, I^2 35.7% and vitamin D levels were significantly lower among severe cases. - For severe deficiency, increased hospitalization OR 1.81 (95%CI 1.41–2.21, I^2 0.0%) and mortality OR 1.82 (95%CI 1.06–2.58, I^2 59.0%) were reported.
Das et al. (prepublication MedRxiv) (16) Systematic Review (AMSTAR rating low quality) Dec 3, 2020 (search date Nov 3, 2020)	- 11 published observational studies considered to be moderate to high quality by the review author were included. All studies examined the possible association between vitamin D deficiency and the incidence or severity of COVID-19 disease were included. Analysis is descriptive, no meta-analysis was planned. - Individual study results were presented in the tables. Consistently there were associations between vitamin D deficiency and more severe COVID-19 and/or mortality.
Ghasemian et al (prepublication MedRxiv) (17) Systematic Review (AMSTAR rating low quality) Oct 26, 2020 (search date Oct 10, 2020)	- 16 observational studies, rated by the author as fair quality, on possible associations between vitamin D deficiency and COVID-19 were included. - Across included COVID-19 cases the meta-analysis results indicated 48% (33-63) were vitamin D deficient and 29% (8-65) were insufficient and 25% (8-59) had normal levels of vitamin D. A similar analysis of a comparable control group was not presented in the review. - The other summaries reported in this review do not address the review question.
Not on COVID	
The Scientific Advisory Committee on Nutrition (SACN), rapid review on vitamin D and acute respiratory tract infections (ARTI). (2) UK December 2020	- This rapid review was updated from June to December to support the work of the NICE rapid guideline for practitioners on vitamin D. - This review reports a protective association with daily vitamin D supplementation and ARTIs for dosages >400IU and < 1000IU per day in 1-16 year olds (moderate quality evidence).

	ARTI: refers to any infection of the sinuses, throat, airways or lungs. Upper RTIs (URTI) include tonsillitis, laryngitis and the common cold. Lower RTIs (LRTIs) include bronchitis and pneumonia. Influenza affects both upper and lower respiratory tracts.

ZINC

Table 2: Zinc and COVID-19

Study	Key Outcomes
Hunter et al. (prepublication MedRxiv) (18) Systematic Review (AMSTAR rating high quality) Nov 4, 2020 (search date Aug 2020)	- This living systematic review identified 128 RCTs on zinc as a therapeutic, no RCTs specific to SARS-CoV-2 or COVID-19 met the inclusion criteria. - Studies of respiratory tract infections indicate treatment with zinc may prevent infection, reduce severity, and decrease duration of illness (moderate, low, low quality of evidence for these outcomes respectively). Quantitative outcomes available in text. - Adverse events were not higher than active controls and none were serious (moderate quality evidence). - Overall confidence in the results was very low due to risk of bias and indirectness across studies within outcomes.
James et al. (prepublication MedRxiv) (9) Systematic Review (AMSTAR rating low quality) Oct 19, 2020 (search conducted Aug 11, 2020)	- A systematic review of COVID-19 papers on zinc netted 1 prepublication (Carlucci included below) from 79 potentially relevant citations.
Yao et al (Chest, letter to the editor) (12) Retrospective cohort USA January 2021	- Retrospective study that evaluated mortality in COVID-19 patients (n=242) treated with or without zinc sulphate. - Results: Multivariate Cox regression, zinc sulfate was not significantly associated with a change in risk of in-hospital mortality (adjusted hazard ratio, 0.66; 95% CI, 0.41 to 1.07; P = .09).
Carlucci et al. (J Med Micro) (11)	- Retrospective observational study to compare outcomes among hospitalized COVID-19 patients ordered to receive

Retrospective cohort USA Sept 2020 (conducted Mar-Apr 2020)	hydroxychloroquine and azithromycin plus zinc sulphate (n=411) versus hydroxychloroquine and azithromycin alone (n=521). - The addition of zinc sulphate did not impact the length of hospitalization, duration of ventilation or intensive care unit (ICU) duration. - In univariate analyses, zinc sulphate increased the frequency of patients being discharged home, and decreased the need for ventilation, admission to the ICU and mortality or transfer to hospice for patients who were never admitted to the ICU. - After adjusting for the time at which zinc sulphate was added to our protocol, an increased frequency of being discharged home (OR 1.53, 95 % CI 1.12–2.09) and reduction in mortality or transfer to hospice among patients who did not require ICU level of care remained significant (OR 0.449, 95 % CI 0.271–0.744).

Methods:

A daily scan of the literature (published and pre-published) is conducted by the Emerging Science Group, PHAC. The scan has compiled COVID-19 literature since the beginning of the outbreak and is updated daily. Searches to retrieve relevant COVID-19 literature are conducted in Pubmed, Scopus, BioRxiv, MedRxiv, ArXiv, SSRN, Research Square and cross-referenced with the COVID-19 information centers run by Lancet, BMJ, Elsevier, Nature and Wiley. The daily summary and full scan results are maintained in a refworks database and an excel list that can be searched. Targeted keyword searching was conducted within these databases to identify relevant citations on COVID-19 and SARS-COV-2. Search terms used included: (vitamin D, 25(OH)D, 25hydroxyvitaminD, calcitriol*) or (zinc), an additional filter for systematic reviews was used to identify reviews initially.
A grey literature search was conducted targeting key government websites and evidence synthesis organizations for current evidence syntheses on these topics.
This review contains research published up to January 7, 2021
Each potentially relevant reference was examined to confirm it addressed the review question and key findings were extracted into tables in the review.

Nouveaux éléments de preuve sur la COVID-19

Sommaire des éléments de preuve sur la supplémentation thérapeutique en vitamine D or en zinc pour des cas de la COVID-19

Introduction

Existe-t-il des éléments de preuve sur l'efficacité d'une supplémentation thérapeutique ou prophylactique en vitamine D ou en zinc dans la prévention ou le traitement de la COVID-19 ?

La vitamine D et le zinc sont des micronutriments qui jouent divers rôles physiologiques, notamment un rôle dans le système immunitaire (1). Les carences en ces micronutriments sont présumées exposer les individus à un risque plus élevé de développer une infection ou de faire évoluer la maladie vers une forme plus grave, c'est pourquoi les données sur l'association entre les carences et l'évolution de la maladie COVID-19 sont également résumées dans cette étude. Cette synthèse met en évidence les revues systématiques les plus récentes portant sur le niveau ou les supplémentations en micronutriments et la COVID-19, lorsque des revues systématiques n'ont pas été identifiées, les recherches principales sous forme publiée ou prépubliée jusqu'au 7 janvier 2021 ont été incluses. À ce jour, les éléments de preuve dans le contexte canadien sont en suspens.

Points clés

Vitamine D

- La vitamine D est une prohormone, une substance transformée en hormone par le corps, qui est importante pour l'homéostasie du calcium et la santé des os et qui est également impliquée dans d'autres systèmes, notamment la fonction immunitaire. Les fonctions immunomodulatrices de la vitamine D sont complexes et ne sont pas entièrement comprises. Les recherches menées avant la pandémie suggèrent qu'il existe peu d'éléments de preuve sur un bénéfice potentiel de la supplémentation en vitamine D dans la réduction du risque de développer des infections respiratoires aiguës (2, 3).
- Les normes de nutrition au Canada comprennent des recommandations alimentaires en matière de vitamine D pour tous les groupes d'âge afin de contribuer à maintenir des niveaux sériques de 25-hydroxyvitamine D supérieurs à 40 nmol/L en faveur de la santé des os (4). Une supplémentation en vitamine D est conseillée aux adultes de plus de 50 ans (4). D'autres lignes directrices, comme celle des États-Unis et du Royaume-Uni, qui ont examiné les éléments de preuve sur la COVID-19, continuent de recommander la supplémentation pour la santé osseuse, mais pas pour le traitement ou la prévention de la COVID-19 (5, 6).

- Sept revues systématiques ont été identifiées dans les bases de données bibliographiques, dont cinq comprenaient de la littérature jusqu'à l'automne 2020 et sont résumées ci-dessous, ainsi que trois rapports de littérature grise sur l'efficacité thérapeutique de la vitamine D pour la COVID-19 ou les infections aiguës des voies respiratoires.
- Cinq revues systématiques ont fait état d'études d'observation qui décrivaient des associations entre des niveaux insuffisants et/ou déficients de vitamine D et un risque accru de COVID-19 grave et de mortalité (Tableau 1). Les associations entre les études n'étaient pas toujours significatives, mais le nombre de carences en vitamine D s'est avéré élevé parmi les cas de COVID-19, et les taux moyens de vitamine D diminuaient de manière proportionnelle au niveau de gravité de la COVID-19. En ce qui concerne l'évolution de la gravité, des associations ont été signalées dans certaines études lors de l'admission en USI, la ventilation mécanique ou l'oxygénothérapie ainsi que la mortalité. La plupart des études contribuant à ces résultats ont été considérées comme présentant un risque de biais élevé. Les groupes présentant un risque de carence en vitamine D sont également ceux qui présentent un risque de COVID-19 grave, cette relation est complexe et bien que certaines études aient rapporté des liens entre le niveau peu élevé en vitamine D et la COVID-19, ces données ne peuvent pas être extrapolées comme cause de l'évolution de la COVID-19.
- La vitamine D en tant que traitement pour les patients atteints de COVID-19 a été évaluée dans trois revues systématiques qui comprenaient collectivement deux essais contrôlés randomisés (ECR) publiés et un prépublié, ainsi que deux quasi-expériences menées chez des adultes (Tableau 1).
    - Éléments de preuve confirmant que le traitement à la vitamine D chez les patients atteints de COVID-19 peut réduire le risque d'évolution de la maladie vers une forme grave (RR 0,04, 95 % IC 0,01 -0,29, 1RCT, 76 observations) (7).
    - Les éléments de preuve indiquant que le traitement à la vitamine D réduit la mortalité n'étaient pas significatifs dans 2 ECR (RR 0,56; 95 %CI 0,05 - 5,85, 2 ECR, 313 observations) (7), mais étaient significatifs dans deux études quasi-expérimentales et un ECR (OR 0,26; 95 %CI 0,10-0,71) (8).
    - Dans un essai (n=237), un seul événement indésirable a été enregistré (RR 2,98; 95 %CI 0,12-72,30) (7).
- Plusieurs essais cliniques ont été enregistrés sur clinicaltrials.gov. Sur les 45 personnes sous vitamine D, quatre ont indiqué qu'elles avaient été jusqu'au bout, mais n'ont pas communiqué les résultats. Les objectifs de ces études variaient du traitement de la COVID-19 avec de la vitamine D (n=33) à l'exploration des niveaux de vitamine D (n=12) ainsi que d'autres micronutriments.

Zinc

- Le zinc est un micronutriment essentiel nécessaire à la réponse immunitaire adaptative et innée (1). Il a été utilisé contre d'autres virus respiratoires et contre la diarrhée chez les enfants, avec des résultats

contradictoires d'une étude à l'autre (9). À l'échelle mondiale, jusqu'à 20 % des individus présentent une carence en zinc, l'apport insuffisant en zinc étant plus fréquent dans les pays à faibles et moyens revenus (9).

- Le zinc a démontré des propriétés antivirales; des études *in vitro* ont indiqué que le zinc inhibe l'ARN polymérase virale dépendante de l'ARN contre le SRAS-CoV-1 (1). Il a été démontré que l'absorption du zinc par les cellules augmente lorsque le zinc est combiné avec un ionophore de zinc tel que l'hydroxychoroquine. Ainsi, de nombreux essais cliniques en cours examinent l'ajout de zinc aux traitements existants (1).
- Un document d'orientation américain traite de la supplémentation en zinc et de la COVID-19, la recommandation est contre une supplémentation supérieure aux apports alimentaires actuels (10).
- Deux revues systématiques ont été identifiées. Une revue systématique de haute qualité inclut des recherches ne portant pas sur le SARS-CoV-2 et indique des éléments de preuve modérés sur le rôle du zinc comme thérapeutique dans la prévention et la réduction de l'évolution de la maladie vers une forme grave dans la littérature sur les infections des voies respiratoires. L'autre examen a identifié une étude d'observation rétrospective, également résumée dans le Tableau 2.
- Une revue systématique de haute qualité, mise à jour pour la dernière fois en août, n'a identifié aucun ECR lié à l'utilisation thérapeutique du zinc pour la COVID-19.
- Sur le plan thérapeutique, deux études de cohorte rétrospectives ont évalué l'impact de l'ajout de sulfate de zinc au traitement standard des cas de COVID-19:
    - L'analyse à plusieurs variables a révélé une augmentation de la fréquence des renvois à domicile (OR 1,53, 95 % CI 1,12-2,09) et la réduction de la mortalité ou du transfert dans un centre de soins palliatifs chez les patients qui n'avaient pas besoin du niveau de soins administré par une USI est restée significative (OR 0,449, 95 % CI 0,271-0,744) (11).
    - Le sulfate de zinc n'a pas été associé de manière significative à une modification du risque de mortalité hospitalière (rapport de risque ajusté, 0,66; IC à 95 %, 0,41 à 1,07; P = 0,09) dans une cohorte rétrospective (12).
- Il s'agit d'un domaine de recherche active, 21 essais enregistrés ont été identifiés sur clinicaltrials.gov, trois ont été achevés, mais n'ont pas encore publié de résultats. La plupart des essais enregistrés ont porté sur la supplémentation ou le traitement au zinc en monothérapie ou en association avec d'autres composés, d'autres ont exploré les niveaux de zinc en même temps que d'autres micronutriments.

Vue d'ensemble des éléments de preuve

Concernant la vitamine D en tant que thérapeutique pour COVID-19, trois revues systématiques de haute à basse qualité basées sur les critères AMSTAR 2 (ci-après dénommées AMSTAR) ont inclus trois ECR et deux quasi-expériences, chacune présentant un certain risque de biais et de manque d'informations dans les

protocoles d'étude (13). Dans les études, il existe également des variations dans le traitement à la vitamine D et dans la qualité des soins. Ainsi, le niveau de confiance générale dans ces éléments de preuve était peu élevé et les conclusions de cette étude sont susceptibles de changer selon les recherches futures.

Cinq revues systématiques avec une cote de qualité AMSTAR variant d'élevée à faible ont examiné les associations entre les niveaux de vitamine D et l'infection, la gravité ou la mortalité par COVID-19 (13). Les études incluses dans ces revues étaient des études d'observation, souvent de conception rétrospective et considérées comme présentant un risque élevé de biais. Les résultats résumés dans chaque étude étaient variables, de même que l'inclusion des prépublications, ce qui signifie que chaque étude a examiné un sous-ensemble différent d'études. Ainsi, le niveau de confiance générale dans ces résultats est peu élevé et d'autres recherches sont susceptibles de modifier les conclusions de cette étude.

Des éléments de preuve limités ont été identifiés concernant l'utilisation du zinc dans le traitement du COVID-19. Deux revues systématiques sur le zinc ont été identifiées; la qualité variait de faible à élevée selon le classement AMSTAR (13). Deux cohortes rétrospectives présentant un risque élevé de biais en raison de la conception des études rétrospectives ont également été incluses. Ainsi, le niveau de confiance générale dans ces résultats est très faible et d'autres recherches sont susceptibles de modifier les conclusions de cette étude.

TABLE DES MATIÈRES

VITAMINE D

Tableau 1. Vitamine D et COVID-19

ÉTUDE	PRINCIPAUX RÉSULTATS
Effet d'une utilisation ou d'une supplémentation en vitamine D à des fins thérapeutiques	
National Institute for Health and Care Excellence (NICE), COVID-19 rapid guideline for practitioners on Vitamin D and evidence review (AMSTAR, qualité élevée) (5) ROYAUME-UNI Publié le 17 décembre 2020	- Supplémentation en vitamine D • La directive stipule que la vitamine D ne doit pas être recommandée dans le seul but de prévenir la COVID-19, car il n'y avait pas suffisamment d'éléments de preuve pour l'étayer. • Les recommandations en faveur de la supplémentation de la population générale étaient liées au maintien de la santé des os et des muscles. Une exposition insuffisante au soleil a été liée à des taux de vitamine D

	sous-optimaux, et une supplémentation a été recommandée, en particulier pendant les mois d'hiver. - La vitamine D comme traitement de l'infection par COVID-19 • Un ECR (Castillo et al) a ajouté du Calcifediol (0,532 mg) à l'admission, le troisième et le septième jour, puis chaque semaine, en plus des soins standard. Cette étude présentait un risque sérieux de partialité et a été considérée comme un élément de preuve très peu fiable. Résultats : 1/50 du groupe de traitement au calcifédiol et 13/26 du groupe de contrôle ont été admis en USI (OR 0,03 (95 % IC 0,003-0,25). La mortalité observée était de 0/50 et 2/26 dans les groupes de traitement et de contrôle (OR 0,097, 95 %CI 0,004-2,099) - Associations entre le niveau de vitamine D et l'évolution de la COVID-19 • 12 études ont été incluses dans leur revue (12 autres n'ont pas été incluses, car elles étaient encore en phase de préimpression). L'association entre l'état de la COVID-19 et les taux de vitamine D était contradictoire (association non significative et négative) et les analyses étaient très variables. Les résultats des formes graves étaient également contradictoires pour les soins intensifs, la ventilation mécanique ou l'oxygénothérapie. Une étude a fait état d'une association protectrice entre une forme grave de la COVID-19 et la supplémentation en vitamine D.
Nikniaz et al (prépublication MedRxiv) (8) Revue systématique et méta-analyse (AMSTAR, qualité moyenne) 5 janvier 2021 (date de recherche, 16 décembre 2020)	- Cette revue a porté sur 4 essais cliniques (2 ECR (Castillo et Rastogi) et 2 quasi-expériences (Annweiler x2)), sur 259 cas de COVID-19, hospitalisés et non hospitalisés. Supplémentation orale en vitamine D, y compris cholécalciférol et calcifediol (n=139). Les protocoles thérapeutiques variaient de 60 000 à 80 000 UI de dosage pendant une durée de 7 à 14 jours. *(Note : le dosage dans ces études est supérieur aux limites maximales de sécurité des compléments en vitamine D)*

	- Dans trois études, une probabilité de mortalité significativement plus faible dans les groupes d'intervention que dans les groupes de contrôle (OR = 0,264, 95 % IC = 0,099-0,708, valeur p = 0,008) a été constatée. Les deux quasi-expériences sur des populations gériatriques ont fait état d'un impact significatif sur la survie. - Les essais Castillo et al. ont indiqué une baisse des admissions en USI, avec un rapport de cotes (RC) de 0,03 (IC à 95 %: 0,003 - 0,25) et deux études ont révélé une amélioration significative de l'état clinique avec le traitement à la vitamine D.
Projet COVID-NMA (7) Synthèse vivante (non évaluée) France 7 janvier 2021 (Date de recherche: 4 décembre 2020)	- Trois ECR (Castillo, Rastogi et Murai) ont été résumés et le tableau de synthèse des résultats indique que les éléments de preuve sont de très mauvaise qualité; toutefois, le traitement à la vitamine D peut avoir une association protectrice avec la gravité de la maladie (très faible certitude), mais aucune association n'a été établie concernant la mortalité (très faible certitude) ou les événements indésirables pour le moment (faible certitude).
Association des taux de vitamine D et des résultats cliniques	
Liu et al. (IJID) (14) Revue systématique et méta-analyse (AMSTAR, qualité élevée) 2 janvier 2021 (date de recherche, 25 septembre 2020)	- Dans 10 études d'observation (classées de qualité moyenne à élevée par l'auteur de la revue) portant sur 361 934 participants (4 178 cas de COVID-19), la carence en vitamine D était associée à un risque accru de COVID-19 (OU = 1.43, 95 % IC 1,00 à 2,05) et les personnes atteintes de COVID-19 présentaient des taux de vitamine D significativement plus faibles. Il y avait une forte hétérogénéité.
Pereira et al. (Crit Rev Food Sci Nutr) (15) Revue systématique et méta-analyse (AMSTAR, qualité faible) 2 nov. 2020 (date de recherche, 9 oct. 2020)	- Rapport sur l'association entre la carence en vitamine D et la gravité de la COVID-19, via une analyse de la prévalence de la carence et de l'insuffisance en vitamine D chez les personnes atteintes de la maladie. - 27 études d'observation considérées comme présentant un risque de biais faible (n=4) et élevé (n=23) ont été incluses.

	- Une probabilité plus élevée de carence en vitamine D a été constatée dans les cas graves de COVID-19, OU 1,65 95 %CI 1,30-2,09, I2 35,7 % et les niveaux de vitamine D étaient significativement plus faibles chez les cas graves. - Pour les carences graves, une augmentation du taux d'hospitalisation OU 1,81 (95 % IC 1,41-2,21, I2 0,0 %) et de la mortalité OU 1,82 (95 %CI 1,06–2,58, I2 59,0 %) ont été rapportés.
Das et al. (prépublication MedRxiv) (16) Examen systématique (évaluation AMSTAR, qualité faible) 3 déc. 2020 (date de recherche, 3 nov. 2020)	- 11 études d'observation publiées, considérées comme de qualité moyenne à élevée par l'auteur de la revue, ont été incluses. Toutes les études ayant étudié l'association possible entre une carence en vitamine D et l'incidence ou la gravité de la maladie COVID-19 ont été incluses. L'analyse est descriptive, aucune méta-analyse n'a été prévue. - Les résultats des études individuelles ont été présentés dans les tableaux. Des associations entre la carence en vitamine D et une forme plus grave de COVID-19 et/ou la mortalité ont systématiquement été observées.
Ghasemian et al (prépublication MedRxiv) (17) Examen systématique (évaluation AMSTAR, qualité faible) 26 oct. 2020 (date de recherche, 10 oct. 2020)	- 16 études d'observation, jugées de qualité moyenne par l'auteur, sur les associations possibles entre la carence en vitamine D et la COVID-19 ont été incluses. - Sur l'ensemble des cas COVID-19 inclus, les résultats de la méta-analyse ont indiqué que 48 % (33-63) présentaient une carence en vitamine D, 29 % (8-65) avaient un niveau insuffisant et 25 % (8-59) avaient un taux normal de vitamine D. Aucune analyse similaire d'un groupe témoin comparable n'a été présentée dans la revue. - Les autres résumés présentés dans cette revue ne traitent pas de la question de la revue.
Ne concerne pas la COVID	
Le Scientific Advisory Committee on Nutrition (SACN), rapid review on vitamin D and acute respiratory tract infections (ARTI). (2) ROYAUME-UNI	- Cette revue rapide a été mise à jour entre juin et décembre afin de soutenir le travail de la ligne directrice rapide du NICE sur la vitamine D et destinée aux praticiens. - Cette étude fait état d'une association protectrice entre une supplémentation quotidienne en vitamine D et les

Décembre 2020	ARTI pour les dosages >400 UI et < 1000 UI par jour chez les 1-16 ans (éléments de preuve de qualité modérée). *ARTI : désigne toute infection des sinus, de la gorge, des voies respiratoires ou des poumons. Les infections des voies respiratoires supérieures (IVRS) comprennent l'amygdalite, la laryngite et le rhume. Les infections des voies respiratoires inférieures (IVRI) comprennent la bronchite et la pneumonie. La grippe affecte les voies respiratoires supérieures et inférieures.*

ZINC

Tableau 2: Zinc et COVID-19

Étude	Principaux résultats
Hunter et al. (prépublication MedRxiv) (18) Revue systématique (AMSTAR, qualité élevée) 4 novembre 2020 (date de recherche, août 2020)	- Cette revue systématique vivante a identifié 128 ECR sur le zinc thérapeutique, aucun ECR spécifique au SRAS-CoV-2 ou à la COVID-19 ne remplissait les critères d'inclusion. - Des études sur les infections des voies respiratoires indiquent que le traitement au zinc peut prévenir l'infection, réduire la gravité et diminuer la durée de la maladie (qualité des éléments de preuve respectivement modérée, faible, faible pour ces résultats). Les résultats quantitatifs sont disponibles dans le texte. - Les événements indésirables n'étaient pas plus nombreux que dans le groupe de contrôle actif et aucun n'était grave (éléments de preuve de qualité moyenne). - La confiance générale dans les résultats était très faible en raison du risque de biais et du caractère indirect des études au sein des résultats.
James et al. (prépublication MedRxiv) (9) Examen systématique (évaluation AMSTAR, qualité médiocre) 19 octobre 2020 (recherche effectuée le 11 août 2020)	- Une revue systématique des articles sur la COVID-19 traitant du zinc a identifié 1 prépublication (Carlucci incluse ci-dessous) à partir de 79 citations potentiellement pertinentes.

Yao et al (Chest, letter to the editor) (12) Cohorte rétrospective ÉTATS-UNIS Janvier 2021	- Étude rétrospective ayant évalué la mortalité chez les patients atteints de COVID-19 (n=242) et traités avec ou sans sulfate de zinc. - Résultats : après analyse par régression de Cox à plusieurs variables, le sulfate de zinc n'a pas été associé de manière significative à une modification du risque de mortalité hospitalière (rapport de risque ajusté, 0,66; IC à 95 %, 0,41 à 1,07; P = 0,09).
Carlucci et al. (J Med Micro) (11) Cohorte rétrospective ÉTATS-UNIS Sept 2020 (effectuée en mars-avril 2020)	- Étude d'observation rétrospective visant à comparer les résultats chez les patients hospitalisés pour la COVID-19 à qui on a administré de l'hydroxychloroquine et de l'azithromycine plus du sulfate de zinc (n=411) par rapport à de l'hydroxychloroquine et l'azithromycine seules (n=521). - L'ajout de sulfate de zinc n'a pas eu d'incidence sur la durée de l'hospitalisation, la durée de la ventilation ou la durée du séjour en soins intensifs (USI). - Dans les analyses à variable simple, le sulfate de zinc a augmenté la fréquence des renvois de patients chez eux et a réduit le besoin de ventilation, l'admission en soins intensifs et le taux de mortalité ou le transfert dans un centre de soins palliatifs pour les patients qui n'ont jamais été admis en soins intensifs. - Après ajustement de l'heure à laquelle le sulfate de zinc a été ajouté à notre protocole, l'analyse multivariable a révélé une augmentation de la fréquence des renvois à domicile (OR 1,53, 95 % CI 1,12-2,09) et une réduction de la mortalité ou du transfert dans un centre de soins palliatifs chez les patients qui n'avaient pas besoin du niveau de soins administré par une USI est restée significative (OR 0,449, 95 % CI 0,271-0,744) (11).

Méthodes:

Un balayage quotidien de la littérature (publiée et prépubliée) est effectué par le Groupe des sciences émergentes de l'ASPC. L'analyse a compilé la littérature sur la COVID-19 depuis le début de l'épidémie et est mise à jour quotidiennement. Les recherches pour trouver la littérature pertinente sur la COVID-19 sont effectuées dans Pubmed, Scopus, BioRxiv, MedRxiv, ArXiv, SSRN, Research Square et croisées avec les centres

d'information sur la COVID-19 gérés par Lancet, BMJ, Elsevier, Nature et Wiley. Le résumé quotidien et les résultats complets de l'analyse sont conservés dans une base de données Refworks et une liste excel qui peut être consultée. Une recherche ciblée par mot-clé a été effectuée dans ces bases de données pour identifier les citations pertinentes sur COVID-19 et SARS-COV-2. Les termes de recherche utilisés comprenaient: (vitamin D, 25(OH)D, 25hydroxyvitaminD, calcitriol*) ou (zinc), un filtre supplémentaire pour les revues systématiques a d'abord été utilisé pour identifier les revues.
Une recherche de littérature grise a été effectuée en ciblant les principaux sites web gouvernementaux et les organisations de synthèse des éléments de preuve pour obtenir des synthèses d'éléments de preuve actuels sur ces sujets.
Cette étude contient les recherches publiées jusqu'au 7 janvier 2021
Chaque référence potentiellement pertinente a été examinée pour confirmer qu'elle répondait à la question de la revue et les principales conclusions ont été extraites dans des tableaux la revue.

Emerging Evidence on COVID-19

Rapid Review of Multisystem Inflammatory Syndrome in Children (MIS-C)

INTRODUCTION

What are the epidemiological characteristics of multisystem inflammatory syndrome in children (MIS-C)?

The goal of this review is to summarize the epidemiological characteristics of multisystem inflammatory syndrome in children (MIS-C), which is also referred to as Paediatric Inflammatory Multisystem Syndrome (PIMS). MIS-C is an emerging condition that has been identified during the COVID-19 pandemic. Children presenting with Kawasaki-like illness following positive COVID-19 tests were first reported in the UK on April 27, 2020 (1). Case definitions have since been released by World Health Organization (2), the Centers for Disease Control in the United States (USA) (3), and the Royal College of Paediatrics and Child Health in the United Kingdom (4). As illustrated in the appendix, the three case definitions are similar, but not the same.

In this review, the term MIS-C is used for consistency, but broadly refers to the syndrome known as PIMS or MIS-C. There is no definitive diagnostic test for MIS-C. MIS-C is considered a separate, but related, syndrome to incomplete, complete or atypical Kawasaki disease (KD), Kawasaki disease shock syndrome (KDSS), toxic shock syndrome (TSS), and macrophage activated syndrome (MAS), with many overlapping features (5).This review includes evidence from articles where one of the three definitions were applied, or Kawasaki Disease or an inflammatory syndrome following COVID-19 was diagnosed.

The vast majority of the MIS-C articles were case reports and cohort studies. To give a rough indication of the strength of the evidence, the articles were then organized as large, medium, and small based on the number of MIS-C patients presented in the article ≥50, 6-49, and ≤5, respectively. Outcomes related to the epidemiology of MIS-C were summarized, including: demographics of MIS-C patients (age, sex, ethnicity/race and comorbidities), common severity outcomes (intensive care unit (ICU) admission, mechanical ventilation and extracorporeal membrane oxygenation (ECMO) utilization), mortality and the timing of MIS-C compared to acute COVID-19 infection. Note that similar cases of multisystem inflammatory syndrome have been reported in adults (known as MIS-A), which is the topic of a separate review available upon request: phac.evidence-donnees.probantes.aspc@canada.ca

KEY POINTS

There were 102 articles identified. Eleven articles were large cohort studies, describing more than 50 cases of MIS-C each. Forty-three articles were medium-sized, describing 6-49 cases of MIS-C each. Forty-eight articles were case reports where the number of cases of MIS-C described ranged from one to five.

Prevalence among Paediatric COVID-19 Cases

A large, international, multi-site study estimated that MIS-C affected between 0.5%-3.1% of all diagnosed pediatric COVID-19 patients and between 0.9%-7.6% of hospitalized pediatric COVID-19 patients aged less than 18 years (6). Three other articles looked at the frequency of MIS-C amongst hospitalized pediatric COVID-19 cases, with estimates varied from 6% in Peru (7) to 9% and 11% in the USA (8,9).

Age

MIS-C can affect children of any age as indicated by the ranges across articles. However, the median age of cases was in the range of 7-11 years. This was consistent in the large, medium and small articles.

Sex

In the large, medium and small articles, 57-58% of cases were male.

Comorbidities

In the articles that reported on comorbidities, the definition of comorbidity was inconsistent. The most commonly reported comorbidity was obesity. Obesity rates were consistent, but lower in small articles (8%) compared with medium (22%) and large (24-29%) articles. Another common comorbidity was asthma (6-18%). Patients with at least one comorbidity ranged from 19% when excluding obesity to 29% with obesity included. Few articles made comparisons of the rates of a given comorbidity to the prevalence of that comorbidity in the general pediatric population. One article found that the proportion of MIS-C patients with obesity is slightly higher than reported in the underlying population (10).

No articles attempted to disentangle the relationship between any given condition, COVID-19 infection and the development of MIS-C. For example, children with obesity or asthma could be more likely to contract COVID-19, and would therefore be overrepresented in MIS-C cases, without being specifically predisposed to MIS-C. This relationship is largely unexplored and needs to be studied further.

Ethnicity

Although some articles reported on ethnicity or race, few articles provided comparisons to the composition of the underlying population. However, in 14 medium-sized articles from the USA, Black and Hispanic children were the largest portion of patients at 36% and 29% respectively. A large article from the USA reported similar demographics (33% Hispanic and 27% Black) (10). The USA CDC states that, compared with White people, Black people are 2.6 times more likely and Hispanic people 2.8 times more likely to be infected with COVID-19 (11). This may partially or wholly explain any disproportionately high rates of MIS-C among these populations. This complex relationship needs to be studied further.

Onset of MIS-C relative to SARS-CoV-2 infection

Clinical case data suggests that there is a delay in the onset of MIS-C after acute infection with SARS-CoV-2. In three articles that documented the timing of acute COVID-19 infection for each MIS-C patient, the onset of MIS-C occurred 15-24 days after the onset of acute COVID-19 symptoms. A handful of articles (n=6) determined the time between the peak of MIS-C cases was approximately two to five weeks after the peak of

COVID-19 cases at the state or country level. The delay in onset is further supported by low positivity rates (<50%) using RT-PCR compared to IgG serology (>75%). This suggests that MIS-C is often a post-infection syndrome, having a delayed onset after the acute COVID-19 infection.

Severity Outcomes

The evidence suggests MIS-C patients often need intensive care, but that the overall survival rate is high. Eight large articles reported ICU admission rates of 21-80%; this was consistent with the medium-sized articles reporting 65% and the small articles reporting 74%. In addition, between 25-40% of MIS-C cases were intubated and 5-11% required ECMO. In the large articles, fatality rates ranged from 0 to 2.2% of hospitalized patients and 2.6% of MIS-C patients admitted to the ICU. This was consistent with the medium-sized articles that reported a 2% mortality rate but was lower than the 7% mortality reported in the small articles. There may be duplicate cases and deaths included in these totals, but the number of deaths could also be an underestimation as not all cases were resolved at the time of publication of the papers.

OVERVIEW OF THE EVIDENCE

In a literature search up to November 10, 2020, 102 articles were found that contain information on the epidemiological characteristics of MIS-C. Nearly all of these articles were case reports or retrospective cohorts.

There were 11 large articles that were mostly retrospective cohorts. These included two multi-national studies, four articles from the USA, three from the UK, and two from mainland Europe (Table 1).

There were 43 medium-sized articles (with a total of 861 cases of MIS-C) included in this review. These included both case series and retrospective cohort studies. In total, 18 were from the USA (379 cases), 13 from Europe (314 cases), four were from South America (50 cases), two from the Middle East (53 cases), two from India (42 cases) and one from South Africa (23 cases) (Table 2).

Case reports tend to be published when a new condition has been identified. They are good for generating hypotheses but are generally considered weak evidence. These 48 case reports are keeping with this trend as they capture some of the earlier case reports of MIS-C, prior to official recognition of the syndrome and to highlight the range of countries that have reported cases of MIS-C: 20 were from the USA, 13 from Europe, and the rest were from India (6 articles), the Middle East (5 articles), South America (2 articles), Africa (1 article) and Canada (1 article) (Table 3).

Limitations

- The majority of articles in this review are from the USA and Europe. In contrast, only two articles are from Africa, and only a portion of one review drew data from Asia. There is only one case report from Canada.

- There is an issue with double counting patients, as some articles were drawing from the same hospitals, regions or data sources. This could bias the results. When reported by the author, this is identified in the tables below. To avoid the extensive double counting, systematic and other reviews were not included.
- Many articles had incomplete data, especially co-morbidity and ethnicity data, which were often collected from only a portion of the cases.
- Because this is an emerging syndrome, case definitions and inclusion criteria have evolved over time. Each case may or may not meet one of the three standard case definitions, or the requirements for Kawasaki disease.
- None of the articles provide any follow-up to patients after they recover from acute MIS-C. Therefore, sequelae or further complications are still unknown.

CONTENTS

For each study contained in the evidence tables below, the following information on MIS-C is provided when available: Age, sex, ethnicity/race, comorbidities, severity outcomes (ICU admission, intubation, ECMO and death), PCR and serology testing results for SARS-CoV-2, and interval between acute COVID-19 infection and MIS-C onset. These variables are not included when they were not reported.

LARGE ARTICLES

Table 1: Articles describing 50 or more cases of MIS-C, by descending order of size

Study	Method	Key Findings
Godfred-Cato (2020) (10) Retrospective cohort USA Mar-Jul, 2020	Data on 570 MIS-C cases was collected from 40 state health departments in the District of Columbia and New York City	- Median age = 8 years (range = 2 weeks – 20 years) - 316/570 (55%) male - 187 (33%) were Hispanic, 153 (27%) Black, 61 (11%) White, 13 (2%) Asian, 48 (8%) other ethnicity and 108 (19%) unknown ethnicity. This study finds that the proportion of Hispanic, Black and White MIS-C patients with obesity is slightly higher than reported in the population.

		- 146 (26%) were obese, 48 (8%) had a chronic lung disease - 364 (64%) admitted to ICU, 69 (12%) required mechanical ventilation - 10 (2%) died - All but 5 tested positive for COVID-19 by either or both PCR or serological testing and the other 5 had an epidemiological link to a known COVID-19 case
Feldstein (2020) (12) Retrospective cohort USA Mar-May, 2020	Prospective and retrospective surveillance of 186 patients with MIS-C admitted to participating health centers in 26 states in the USA	- Median age = 8.3 years (IQR = 3.3-12.5 years) - 115/186 (62%) male - 57 (31%) were Hispanic, 46 (25%) Black, 35 (19%) Asian, 9 (5%) other ethnicity, 41 (22%) unknown ethnicity - 45 (24%) were obese. In addition, 51 (27%) had a comorbidity, including 33 (18%) with respiratory conditions, 5 (3%) with cardiac conditions, 10 (5%) with immune-related conditions and 20 (11%) with other conditions. - 148 (80%) admitted to ICU, 37 (20%) required mechanical ventilation, 8 (4%) required ECMO - 4 (2%) died - 131 tested positive for COVID-19 by either or both PCR or serological testing and the other 55 had an epidemiological link to a known COVID-19 case - MIS-C cases occurred a median of 25 days (range = 6-51 days) after acute COVID-19 infection
Deep (2020) (13) Retrospective cohort UK Mar-May, 2020 Note: 78 of the children in this study had been previously reported.	116 children admitted to 24 PICUs in the UK were assessed for acute kidney injury Patients with existing kidney problems were excluded	- Median age = 11 years (IQR = 7-14 years) - 76/116 (66%) male - 51 (45%) were Black, 29 (26%) Asian, 24 (21%) White, 9 (8%) other ethnicity - 20 (17%) had a comorbidity, including 5 (4%) with asthma, 3 (3%) with cystic fibrosis, 1 (1%) with chronic lung disease, 1 (1%) with autism, 10 (9%) others - 116 (100%) admitted to ICU (as required by the study design), 41 (35%) required mechanical ventilation, 3 (3%) required ECMO - 2 (2%) died

Belot (2020) (14) Retrospective cohort France Mar-May, 2020	All paediatric departments in France reported 108 cases of MIS-C diagnosed after March 1, 2020, to estimate the burden of this condition in France	- Median age = 8 years (IQR = 5-11 years) - 53/108 (49%) male - 72 (67%) admitted to ICU, 46 (43%) required mechanical ventilation - 1 (1%) died - 79 tested positive for COVID-19 by either or both PCR or serological testing. 16 had proven contact with COVID-19 cases and 13 were suspected to have had COVID-19 based upon symptoms and history. - MIS-C cases peaked 4-5 weeks after local COVID-19 cases peaked
Dufort (2020) (15) Retrospective cohort USA Mar-May, 2020	Hospitals in New York State that provide pediatric care reported 99 potential cases of MIS-C	- Age categories were given: 31 (31%) were aged 0 to 5 years, 42 (42%) were aged 6 to 12 years, and 26 (26%) were aged 3 to 20 years - 53/99 (54%) male - 31 (31%) were Black, 29 (29%) White, 4 (4%) Asian, 14 (14%) other ethnicity, 21 (21%) unknown ethnicity - 36 (36%) had a comorbidity, including 29 (29%) with obesity and 14 (14%) with chronic lung disease - 79 (80%) admitted to ICU, 10 (10%) required mechanical ventilation, 1 (1%) required ECMO - 2 (2%) died - 76/77 (99%) tested serology positive while 50/99 (56%) tested PCR positive - MIS-C cases peaked 31 days after local COVID-19 cases peaked
Antunez-Montes (2020) (16) Ambidirectional cohort Mexico, Colombia, Peru, Costa Rica and Brazil Jul-Aug, 2020	A physician group in Central and South America collected 95 MIS-C cases from 409 confirmed pediatric SARS-CoV-2 infections	- 95 cases of MIS-C were identified from 409 pediatric patients admitted to hospital with a positive COVID-19 test (23%) - Median age = 7 years (range = 1 month - 17 years). The MIS-C patients were significantly older than non-MIS-C pediatric patients admitted to hospital with COVID-19. - 52/95 (55%) male - 11 (12%) had comorbidities, and had significantly lower socioeconomic status than pediatric patients admitted with acute COVID-19

		- 20 (21%) admitted to ICU, 9 (9%) required mechanical ventilation - 2 (2%) died - All tested positive for COVID-19 by either or both PCR or serological testing
Davies (2020) (17) Retrospective cohort UK Apr-May, 2020 Note: Eight of the children included in this study had been reported previously	A description of 78 PIMS cases, aged 17 and under, admitted to PICUs in the UK	- Prior to COVID-19, historical data for similar inflammatory disease averaged 1 ICU admission per week (95% CI 0.85–1.22). In comparison, there was an average of 14 cases per week for PIMS, and a peak of 32 admissions per week during the study period. - Median age = 11 years (IQR = 8-14 years) - 52/78 (67%) male - 37 (47%) were Black, 22 (28%) Asian, 17 (22%) White, 2 (3%) other ethnicity - 17 (22%) had comorbidities, including 2 (3%) with major pre-existing conditions - 78 (100%) admitted to ICU (as it was required for inclusion in the study), 36 (46%) required mechanical ventilation, 3 (4%) required ECMO - 2 (3%) died - 33/35 (94%) tested serology positive while 17/78 (22%) tested PCR positive
Jonat (2020) (18) Retrospective cohort USA Mar-Jun, 2020	A description of all 54 cases of MIS-C identified in a single hospital in the given date range	- Median age = 7 years (range = 10 months - 20 years) - 25/54 (46%) male - 19 (35%) were White, 10 (19%) Black, 8 (15%) other ethnicity, 17 (31%) unknown ethnicity - 7 had pre-existing conditions (excluding obesity) - 31 (57%) admitted to the ICU. No patients required mechanical ventilation or ECMO - None died - 41/54 (97%) tested serology positive while 20/54 (34%) tested PCR positive
Cattalini (2020) (19) *(preprint)* Retrospective cohort	A survey sent to the Italian Pediatric Society and 53 patients	- Median age of KawaCOVID cases = 7 years (IQR: 4.5-11 years), while the median age of Kawasaki cases = 2 years

Italy Feb-May, 2020	met the diagnosis of "KawaCOVID" (equivalent to MIS-C)	(IQR: 1-4 years). Median age is significantly different (p<0.0001). - There was no significant difference in the sex ratio of KawaCOVID compared to Kawasaki disease - ICU admission was more common in KawaCOVID compared to Kawasaki cases (23.1% vs 1.1%; p<0.0001) - KawaCOVID cases had more serious cardiac involvement than Kawasaki cases - myocarditis (60.4% vs 3.1%; p<0.0001), pericarditis (26.4% vs 7.3%; p=0·0013), heart failure (35.8% vs 1%; p<0.00001) and others - All KawaCOVID patients tested positive for COVID-19 by either or both PCR or serological testing (31 tested serology positive while 14 tested PCR positive) - None died
Whittaker (2020) (20) Retrospective survey UK Mar-May, 2020 Note: Eight of the children included in this study have previously been reported	An online survey with data on 58 children who had been admitted to 8 hospitals in England with PIMS (MIS-C)	- Median age = 9 years (IQR = 5.7-14 years, range = 3 months – 17 years) - 38/58 (66%) male - 7 (12%) had comorbidities, including 3 (5%) with asthma, and 1 each (2%) with neurodisability, epilepsy, sickle cell trait, and alopecia - 29 (50%) of patients were admitted to ICU, 25 (43%) required mechanical ventilation, 2 (3%) required ECMO - 1 (2%) died - 40/46 (87%) tested serology positive while 15/58 (26%) tested PCR positive
Duarte-Salles (2020) (6) *(preprint)* Retrospective cohort US, Spain, France, Germany and South Korea Jan-Jun, 2020	Based on medical records, hospital billing data and insurance claims data from the US, Europe, and Asia, children diagnosed or hospitalized with COVID-19 were compared with a	- This study includes 55,270 children and adolescents diagnosed with COVID-19, including 3,693 hospitalized with COVID-19 and were compared with a historical cohort of 1,952,693 children diagnosed with influenza. - MIS-C was relatively uncommon, affecting between 0.5% and 3.1% of patients diagnosed with COVID-19, and between 0.9% and 7.6% of patients hospitalized with COVID-19. - MIS-C was thought to be linked with COVID-19, as similar syndromes are much less common in the historical influenza cohort.

	previous seasonal influenza cohort	

MEDIUM-SIZED ARTICLES

Table 2: Articles describing 6 to 49 cases of MIS-C, by descending order of size

STUDY	METHOD	KEY OUTCOMES
Mamishi (2020) (21) Retrospective cohort Iran Mar-Jun 2020	45 cases of MIS-C are described	- Median age = 7 years (range = 10 months – 17 years) - 24/45 (46%) male - 6 (13%) had pre-existing conditions - 5 (11%) died - 4 of them had underlying diseases (acute lymphocytic leukaemia, chronic kidney disease, cerebral palsy and Budd–Chiari syndrome) - 35 tested serology positive, 10 tested PCR positive
Miller (2020) (22) Retrospective cohort USA Apr-May 2020	44 cases of MIS-C are described	- Median age = 7.3 years (SD = 4.98 years, range = 7 months – 20 years) - 20/44 (45%) male - 15 (34%) were Hispanic, 9 (20%) Black, 9 (20%) White, 11 (25%) unknown ethnicity - 16 (36%) were overweight - 1 (2%) required mechanical ventilation - None died - 31/32 tested serology positive while 15/44 tested PCR positive
Belhadjer (2020) (23) Retrospective cohort France Mar-Apr 2020	35 cases of MIS-C that had cardiac involvement and required ICU admission are described	- Median age = 10 years (range = 2-16 years) - 18/35 (51%) male - 6 (17%) were overweight, 3 (9%) had asthma, 1 (3%) had lupus - 35 (100%) admitted to ICU, 22 (63%) required mechanical ventilation, 10 (29%) required ECMO - None died - 14 tested PCR positive, while 30 patients tested serology positive (28 IgG positive and 2 IgM positive)

Hameed (2020) (24) Retrospective cohort UK Apr-May 2020 Note: 8 patients were reported in other studies	35 cases of MIS-C under the age of 17 are described	- Median age = 11 (IQR = 8 years) - 27/35 (77%) male - 24 (69%) admitted to ICU, 7 (20%) required mechanical ventilation, 2 (6%) required ECMO - 1 (3%) died - 25 tested IgG positive and 23 IgM positive.
Sethuraman (2020) (25) Retrospective cohort USA Apr-Jul 2020	34 cases of MIS-C are described	- Median age = 6 years (IQR = 8 years) - 16/34 (47%) male - 23 (68%) were Black, other ethnicity/race not reported - 2 (6%) were obese and 9 (26%) had asthma 24 (71%) admitted to ICU, 8 (24%) required mechanical ventilation, 2 (6%) required ECMO - None died - 18/25 tested IgG positive, 8/34 tested PCR positive - MIS-C cases peaked 3 weeks after local COVID-19 cases peaked
Minocha (2020) (26) Retrospective cohort USA Mar-Jun 2020	33 cases of MIS-C are described	- Median age = 2.8 years (IQR = 1.4-9 years) - 19/33 (56%) male - 12 (36%) Hispanic, 10 (30%) White, 7 (21%) Black, 4 (12%) Asian - 7 (21%) were obese, 5 (15%) had asthma, 1 (3%) was born prematurely - 11 (33%) admitted to ICU - None died - 14/23 tested IgG positive, while 11/33 tested PCR positive
Kaushik, Aydin, (2020) (27) Retrospective cohort USA Apr-May 2020	33 cases of MIS-C that were admitted to ICU are described	- Median age = 10 years (IQR = 6-13 years) - 20/33 (61%) male - 15 (45%) were Hispanic, 13 (39%) Black, 3 (9%) White, 1 (3%) Asian, 1 (3%) other ethnicity - 16 (48%) of patients had comorbidities - 4 (12%) were obese, 2 (6%) were overweight, 5 (15%) had asthma, 3 (9%) had allergies/eczema, 2 (6%) had cardiac issues, 2 (6%) had hematological issues

Note: 4 patients were reported in other studies		- 33 (100%) admitted to ICU, 5 (15%) required mechanical ventilation, 1 (3%) required ECMO - 1 (3%) died - 11 tested PCR positive while 27 tested serology positive
Capone (2020) (28) Retrospective cohort USA Apr-May 2020	33 cases of MIS-C are described	- Median age = 8.6 years (IQR = 5.5-12.6 years) - 20/33 (61%) male - 8 (24%) were Black, 3 (9%) White, 3 (9%) Asian, 19 (58%) other/mixed/unknown. The ethnic rates of MIS-C were similar to the ethnic rates of the in-hospital population. - 12 (36%) were obese, 2 (6%) were overweight. The childhood obesity rate in the region is 18%, so obese patients are overrepresented in MIS-C cases in this study. - 26 (79%) admitted to ICU, 6 (18%) required mechanical ventilation - None died - 30 tested IgG positive - MIS-C cases peaked 5 weeks after local COVID-19 hospitalization peaked
Moraleda (2020) (29) Retrospective cohort Spain Mar-Jun 2020	31 cases of MIS-C are described	- Median age = 7.6 years (IQR = 4.5-11.5 years) - 18/31 (58%) male - 3 (10%) were obese, 4 (13%) had asthma, and 1 each (3%) had chronic cardiac disease, hematological disease and cancer - 20 (65%) admitted to ICU, 6 (19%) required mechanical ventilation - 1 (3%) died - 17 tested PCR positive, 10 IgM positive and 19 IgG positive - MIS-C cases peaked 1 month after local COVID-19 hospitalizations peaked
Alders (2020) (30) Retrospective cohort UK Mar-May 2020	31 cases of MIS-C are described	- Median age = 10.1 years (range = 8.7-13.9 years) - 21/31 (68%) male - 14 (45%) were Black, 9 (29%) Asian, 4 (13%) White, 3 (10%) mixed, 1 (3%) unknown ethnicity - 5 (16%) were overweight and 7 (23%) were obese

		- 14 (45%) required mechanical ventilation, 1 (3%) required ECMO - None died - 20 tested PCR positive while 28 tested serology positive
Felsenstein (2020) (31) Retrospective cohort UK Mar-Jun 2020	29 cases of MIS-C are described	- Median age = 6 years (IQR = 3.8-9.9 years) - 20/29 (69%) male - 12 (41%) were Caucasian, 6 (21%) South East Asian, 4 (14%) Black, 2 (7%) East Asian, 5 (17%) unknown ethnicity - None died - 14 tested serology positive, 3 tested PCR positive - MIS-C cases peaked 4 weeks after local COVID-19 cases peaked
Lee (2020) (32) Retrospective cohort USA Mar-Jun 2020	28 cases of MIS-C are described	- Median age = 9 years (range = 1 month - 17 years) - 16/28 (57%) male - 12 (43%) Hispanic, 10 (36%) were White, 5 (18%) Black - 14 (50%) of had comorbidities; 4 (14%) were obese, 3 (11%) had asthma, and 1 (4%) each had congenital heart disease, sickle cell anemia, and mitochondrial disorder - 17 (61%) admitted to ICU, none required mechanical ventilation or ECMO - None died - 17 tested PCR positive while 18 tested serology positive
Matsubara (2020) (33) Retrospective cohort USA Apr-Jun 2020	28 cases of MIS-C are described	- Median age = 11.4 years (IQR = 8-13.7 years) - 14/28 (50%) male - 13 (46%) were Black, 7 (25%) White, 4 (14%) Hispanic, 1 (4%) Asian, 3 (11%) unknown ethnicity - 8 tested IgG positive
Torres (2020) (34) Retrospective cohort Chile May-Jun 2020	27 cases of MIS-C in children up to age 14 are described	- Median age = 6 (range = 0-14 years) - 14/27 (52%) male - 23 (85%) parents were Chilean, 2 (7%) Venezuelan, 1 (4%) Haitian, 1 (4%) Peruvian - 4 (15%) were overweight or obese, 1 (4%) had asthma, 1 (4%) was immunocompromised

		- 16 (59%) of were admitted to ICU, 12 (44%) required mechanical ventilation - None died - 14 tested PCR positive, 10 tested serology positive
Carter (2020) (35) Prospective cohort UK Apr-May 2020	25 cases of MIS-C are described	- Median age = 12.5 years (range = 7.7-14.4 years) - 15/25 (60%) male - 10 (40%) were White, 9 (36%) Black, 5 (20%) Asian, 1 (4%) other ethnicity - 5 (20%) had comorbidities, including 2 (8%) with asthma (1 also with autism and 1 with eczema), 1 (4%) food allergy, 1 (4%) with hemoglobin C trait, and 1 (4%) with aplastic anemia and immunosuppression - 21 (84%) admitted to ICU, 2 (8%) required mechanical ventilation - None died - 18 tested serology positive and 1 tested PCR positive
Dionne (2020) (36) Retrospective cohort USA Mar-May 2020	25 cases of MIS-C are described	- Median age = 9.7 years (IQR = 2.7-15.0 years) - 15/25 (60%) male - 4 (16%) were obese, 4 (16%) had asthma, and 1 (4%) each had sickle cell anemia, mitochondrial disease, prematurity/respiratory failure - 14 (56%) admitted to ICU, 1 (4%) required mechanical ventilation - None died - 15 tested PCR positive, while 13 tested serology positive
Jain (2020) (37) Retrospective cohort India May-Jul 2020	23 cases of MIS-C are described	- Median age = 7.2 years (range = 0.8-14 years) - 11/23 (48%) male - 9 (39%) required mechanical ventilation - 1 died (4%) - 7 tested serology positive, 9 tested PCR positive - MIS-C cases peaked 2-4 weeks after local COVID-19 cases peaked
Webb (2020) (38) Retrospective cohort	23 suspected cases of MIS-C are described in	- Mean age = 6.6 years (95% CI = 4.8-8.4 years) - 17/23 (74%) male

South Africa Jun-Jul 2020	an area where COVID-19 testing is limited	- 18 (78%) were Black, 5 (22%) were South African coloured - 2 (9%) were obese, 4 (17%) prenatal exposure to HIV, but HIV-, 1 (4%) had asthma, 1 (4%) had leukemia - 12 (52%) admitted to ICU, 6 (26%) required mechanical ventilation - None died - 4 tested PCR positive - MIS-C cases occurred on average 24 days after acute COVID-19 infection (95% CI = 9-39 days)
Toubiana (2020) (39) Ambidirectional cohort France Apr-May 2020	21 cases of MIS-C are described	- 21 cases of MIS-C are described - Median age = 7.9 years (range = 3.7-16.6 years) - 24 (57%) parents of the patients were Black, 12 (29%) White, 4 (10%) Asian, 2 (5%) Middle Eastern - 24% of patients weighed above the 75th percentile - 17 (81%) admitted to ICU, 11 (53%) required mechanical ventilation - None died - 19 tested IgG positive, 8 tested PCR positive
Grimaud (2020) (40) Retrospective cohort France Apr 2020	20 cases of MIS-C admitted to ICU are described	- Median age = 10 years (range = 2.9-15 years) - 10/20 (50%) male - 20 (100%) admitted to ICU, 8 (40%) required mechanical ventilation, none required ECMO - None died - 15 tested serology positive, 10 tested PCR positive
Dhanalakshmi (2020) (41) Retrospective cohort India May-Jul 2020	19 cases of MIS-C are described	- Median age = 6 years (range = 13 months – 16 years) - 8/19 (42%) male - 1 (5%) had developmental delays - 12 (63%) admitted to ICU, none required mechanical ventilation or ECMO - None died - 8 tested serology positive, 4 tested PCR positive
Blumfield & Levin (42)	19 cases of MIS-C are described	- Median age = 8 years (range = 2 months – 18 years) - 10/19 (53%) male

Retrospective cohort USA Feb-Mar 2020		- 3 (16%) were obese, 5 (26%) had existing neurological impairment, and 1 (5%) each had congenital heart disease, cardiomyopathy, cancer, asthma, hypertension, sickle cell disease, prior thromboembolic events and Fragile X syndrome - 14 (74%) admitted to ICU, 8 (42%) required mechanical ventilation - 2 died (11%) – both had comorbidities - 18 tested PCR positive
Yonker (2020) (8) Retrospective cohort USA Aug 2020*	18 cases of MIS-C are described from a total of 192 hospitalized pediatric COVID-19 cases	- 18/192 (9%) children presenting to urgent care or hospitalized related to COVID-19 had MIS-C - Mean age = 7.7 years (SD = 7 years) - 14/18 (78%) male - 9 (50%) were White, 6 (33%) Hispanic, 2 (11%) White, and 1 (6%) Asian - 2 (11%) were obese, 1 each (6%) had inflammatory bowel disease, ADHD and autism
Cheung (2020) (43) Retrospective cohort USA Apr-May 2020	17 cases of MIS-C are described	- Median age = 8 years (range = 1.8-16 years) - 8/17 (47%) male - 3 (18%) had asthma - 1 (6%) admitted to ICU, none required mechanical ventilation or ECMO - None died - 9 tested serology positive, while 8 tested PCR positive
Pouletty (2020) (44) Retrospective cohort France Apr 2020	16 cases of MIS-C are described	- Median age = 12 years (range = 4.7-12.5 years) - 8/16 (50%) male - 4 (25%) were overweight, 2 (13%) had asthma - 7 (44%) admitted to ICU, 2 (13%) required mechanical ventilation, none required ECMO - None died - 7/8 tested IgG positive, while 11/16 tested PCR positive
Ramcharan (2020) (45) Retrospective cohort UK	15 cases of MIS-C are described	- Median age = 8.8 years (IQR = 6.4-11.2 years) - 11/15 (73%) male - 6 (40%) were Black, 6 (40%) South Asian, 3 (20%) other ethnicity

Apr-May 2020		- 4 (27%) required mechanical ventilation, none required ECMO - None died - 12 tested serology positive, 2 tested PCR positive
Riollano-Cruz (2020) (46) Retrospective cohort USA Apr-Jun 2020	15 cases of MIS-C are described	- Median age = 12 years (range = 3-20 years) - 11/15 (73%) male - 10 (67%) were Hispanic, 2 (13%) Black, 2 (13%) White, and 1 (7%) unknown ethnicity - 2 (13%) were obese, 2 (13%) were overweight, 4 (27%) had asthma, and 1 (7%) had hypothyroidism - 15 (100%) admitted to ICU, 3 (20%) required mechanical ventilation, 1 (7%) required ECMO - 1 (7%) died - 15 tested serology positive while 9 tested PCR positive - MIS-C onset began 21 days after acute COVID-19 infection (IQR= 21-24 days)
Rosat Consiglio (2020) (47) Retrospective cohort Italy, Sweden Mar-May, 2020	13 cases of MIS-C are described	- Median age = 106 months (IQR = 71-165 months) - 8/11 (73%) male (2 missing) - 3/4 (75%) tested IgG positive
Gaitonde (2020) (48) Case-control USA Mar-Jun 2020	12 cases of MIS-C are described	- Median age = 8 years (IQR = 5.5-11.5 years) - 9/12 (75%) male - 8 (80%) were Black, 3 (30%) White, 1 (10%) other ethnicity - None died
de Farias (2020) (49) Prospective cohort Brazil Apr-Jun 2020	11 cases of MIS-C are described	- Median age = 4 years (range = 7 months - 11 years) - 9/11 (82%) male - 2 (18%) were malnourished, 3 (27%) were obese, 3 (27%) were overweight - 11 admitted to ICU – required for inclusion (100%), 3 (27%) required mechanical ventilation - 2 (18%) died– both were malnourished. - 9 tested serology positive, 2 tested PCR positive

		- MIS-C onset began 15 days after acute COVID-19 infection (range = 7-60 days)
Ouldali (2020) (50) Natural experiment France Dec 2005-May 2021	10 cases of MIS-C are described after the onset of the COVID-19 pandemic, and compared to Kawasaki cases prior to April 2020	- Prior to April 2020, Kawasaki Disease hospitalization rate was 1.2 cases per month. In April 2020, this spiked to 6 cases per month (497% increase). Another peak in December 2009 reached 6 cases per month (365% increase) around the time of the influenza A H1N1 pandemic. - Median age = 11.5 years (range = 1-15 years) - 4/10 (40%) male - 6 (60%) admitted to ICU, none required mechanical ventilation or ECMO - None died - 5/10 tested IgG positive, 5/9 tested PCR positive - MIS-C cases peaked 2 weeks after local COVID-19 cases peaked
Verdoni (2020) (51) Natural experiment Italy Feb-Apr 2020	10 cases of MIS-C are described after the onset of the COVID-19 pandemic, compared to Kawasaki cases prior to Feb 2020	- This is an early study that compared Kawasaki disease rates between Jan 1, 2015, and Feb 17, 2020 (19 patients) with Feb 18, 2020 and April 20, 2020 (10 patients). The study found a 30 fold increase in Kawasaki like disease in early 2020 in Italy - Median age = 7.5 years (SD = 3.5 years) - 7/10 (70%) male - 8 tested IgG positive, 2 tested IgM positive, 2 tested PCR positive
Rostad (2020) (52) Ambidirectional cohort USA Mar-May 2020	10 cases of MIS-C are described	- Median age = 106 months (range = 71-165 months) - 6/10 (60%) male - 6 (60%) were Black, 3 (30%) White, 1 (10%) other ethnicity - 3 (30%) had underlying respiratory conditions - 10 (100%) admitted to ICU - All tested IgG and IgM positive, 2 tested PCR positive
Gruber (2020) (53) Retrospective cohort USA	9 cases of MIS-C are described	- Median age = 11.5 years - 4/9 (44%) male

Apr-Jun 2020		- 6 (67%) were Hispanic, 2 (22%) Black, 1 (11%) unknown ethnicity - 2 (22%) had asthma, 1 (11%) PTSD - None died - 9 tested serology positive, 3 tested PCR positive
Kim (2020) (9) Retrospective cohort USA Mar-Jul 2020	9 cases of MIS-C are described from a total of 83 hospitalized pediatric COVID-19 cases	- Of 83 hospitalized COVID-19 pediatric patients, 9 were diagnosed with MIS-C (11% of hospitalized children with COVID-19) - Age: 0-2 years (1), 2-4 years (5), 5-17 years (3)
Khan & Ullah (2020) (54) Case series Pakistan Aug 2020*	8 cases of MIS-C are described with data derived from news reports	- Age range = 5-15 years - All tested serology positive
Riphagen (2020) (55) Retrospective cohort UK Apr 2020	8 cases of MIS-C are described	- Median age = 8 years (range = 4-14 years) - 5/8 (63%) male - 6 (75%) were Black, 1 (13%) Asian, 1 (13%) Middle Eastern - 2 (25%) were obese, 1 (13%) overweight, 1 (13%) had autism, 1 (13%) hayfever - 8 (100%) admitted to ICU, 5 (63%) required mechanical ventilation, 1 (13%) required ECMO - 1 died (13%)
Perez-Toledo (2020) (56) *(preprint)* Retrospective cohort UK Apr-May 2020	8 cases of MIS-C are described, where patients tested PCR negative but serology positive	- Median age = 9 years (range 7-14 years) - 5/8 (63%) male - 6 (75%) admitted to the ICU - None died
Syrimi (2020) (57) *(preprint)* Retrospective cohort UK	7 cases of MIS-C are described	- Ages: <5 years (1), 5-10 years (3), 10-15 years (3) - 4/7 (57%) male - 4 (57%) were Black, 2 (29%) Asian, 1 (14%) White - 6 (86%) admitted to the ICU

Apr-May 2020		
Pereira (2020) (58) Retrospective cohort Brazil Apr-Jun 2020	6 cases of MIS-C are described, from a group of 66 hospitalized pediatric COVID-19 patients	- Of 66 hospitalized COVID-19 pediatric patients, 6 were diagnosed with MIS-C (9% of hospitalized children with COVID-19) - Median age = 7.8 years (range = 0.01-17.6 years) - 5/6 (83%) male - 5 (83%) had a pre-existing condition, 4 were immunocompromised, 3 had cancer, 1 had chronic kidney disease - 6 (100%) admitted to ICU, 5 (83%) required mechanical ventilation - 4 (67%) died
Chiara-Chilet (2020) (7) *(preprint)* Retrospective cohort Peru Mar-Jul 2020	6 cases of MIS-C are described, from a total of 91 hospitalized pediatric COVID-19 cases	- Of 91 hospitalized COVID-19 pediatric patients, 6 were diagnosed with MIS-C (7% of hospitalized children with COVID-19) - 2 (33%) admitted to ICU
Chiotos (2020) (59) Case series USA May 2020*	6 cases of MIS-C that were admitted to the ICU are described	- Median age = 7.5 years (range = 5-14 years) - 1/6 (17%) male - 2 (33%) were Black, 2 (33%) White, 2 (33%) unknown ethnicity - 6 (100%) admitted to ICU, 3 (50%) required mechanical ventilation, and none required ECMO - None died - 5 tested IgG positive, while 2 tested PCR positive
Diorio (2020) (60) Prospective cohort USA Apr-May 2020	6 cases of MIS-C are described	- Median age = 6 years (IQR = 5-7 years) - 2/6 (33%) male - 4 (66%) were White, 1 (17%) Black, 1 (17%) other ethnicity - 5 (83%) admitted to ICU, 2 (33%) required mechanical ventilation, and none required ECMO - None died

* Article publication date because case date(s) unavailable

SMALL ARTICLES

Table 3: Articles describing of one to five cases of MIS-C, by country and study size

STUDY	METHOD	KEY OUTCOMES
CASE SERIES		
Blondiaux (2020) (61) Case series France Apr 2020	Descriptive case series of 4 MIS-C patients	- 3 girls aged 6, 8 and 11; 1 boy aged 12 - All 4 admitted to ICU, 1 was intubated, none were placed on ECMO - None died - All tested PCR negative and IgG positive, 1 tested IgM positive
Labé (2020) (62) Case series France May 2020*	Descriptive case series of 2 MIS-C patients	- 2 boys aged 3 and 6 - No ICU admission, intubation or ECMO - None died - 1 tested PCR positive, no serology results
Licciardi (2020) (63) Case series Italy Arp 2020	Descriptive case series of 2 MIS-C patients	- 2 boys, aged 7 and 12, neither with comorbidities - Both admitted to ICU; neither intubated and no ECMO - None died - Both tested PCR negative, but IgG and IgM positive
Pang (2020) (64) Case series UK Mar-May 2020	Descriptive case series of 5 MIS-C patients	- 3 boys aged 8, 12 and 14; 2 girls aged 5 and 15 - 2 were Asian, 1 was Black, 1 was White and 1 was mixed-race - 2 had seizure disorders - 4 were admitted to ICU and intubated - None died - All tested PCR positive, no serology results
Ng (2020) (65) Case series UK Apr-May 2020	Descriptive case series of 3 MIS-C patients	- 2 boys aged 13 and 17; 1 girl aged 16 - 2 were Black, 1 was Asian - 1 was obese - All 3 admitted to ICU; 1 was intubated; no ECMO - None died - All 3 tested IgG positive, 1 tested PCR positive
Del Greco (2020) (66) Case series USA Oct 2020*	Descriptive case series of 4 MIS-C patients	- 3 girls aged 4, 10 and 16; 1 boy aged 13 - 1 had asthma, the rest had no comorbidities - 2 admitted to ICU; none intubated and no ECMO - None died - All 4 tested serology positive, 1 tested PCR positive

Rogo (2020) (67) Case series USA Apr-May 2020	Descriptive case series of 4 MIS-C patients	- 3 boys aged 5, 17 and 20; 1 girl aged 3 - 4 admitted to ICU, 2 intubated, 1 placed on ECMO - 1 died - All 4 tested PCR negative and IgG positive
Waltuch (2020) (68) Case series USA May 2020	Descriptive case series of 4 MIS-C patients	- 3 boys aged 5, 10, and 13; 1 girl aged 12 - 1 had hypothyroidism, another had asthma - 4 admitted to ICU; none intubated and no ECMO - None died - All 4 tested serology positive, 1 tested PCR positive
Heidemann (2020) (69) Case series USA Aug 2020*	Descriptive case series of 3 MIS-C patients	- 2 boys aged 5 and 7; 1 girl aged 6, with no comorbidities - 2 admitted to ICU and intubated; 1 was placed on ECMO - 1 died - 1 tested PCR positive, 3 tested serology positive
Schupper (2020) (70) Case series USA Jun 2020*	Descriptive case series of 2 MIS-C patients	- 2 boys aged 2 months, 5 years - 1 had tracheomalacia - Both admitted to ICU, intubated and placed on ECMO - 1 died - 1 tested serology positive, no PCR results
Spencer (2020) (71) Case series USA Sep 2020*	Descriptive case series of 2 MIS-C patients	- 1 girl aged 7; 1 boy aged 11 - 1 had seizure disorder - 1 admitted to ICU, none intubated and no ECMO - None died - Both tested PCR positive, no serology results
CASE REPORTS		
Khesrani (2020) (72) Case report Algeria Aug 2020*	Descriptive case report of 1 MIS-C patient	- 9 year-old girl with idiopathic medullar aplasia - Admitted to ICU and intubated, no ECMO - Patient died - Patient tested PCR positive, no serology results
De Paulis (2020) (73) Case report Brazil May 2020	Descriptive case report of 1 MIS-C patient	- 4 year-old girl with no comorbidities - Admitted to ICU and intubated, no ECMO - Patient survived - Patient tested PCR and IgM negative, but IgG positive
Tam (2020) (74) Case report Canada Sep 2020*	Descriptive case report of 1 MIS-C patient	- 10 years old boy with no comorbidities - Admitted to ICU, not intubated and no ECMO - Patient survived - Patient tested PCR negative, serology positive

Klocperk (2020) (75) Case report Czechia Jul 2020*	Descriptive case report of 1 MIS-C patient	- 8 year-old girl with no comorbidities - No ICU admission, intubation or ECMO - Patient survived - Patient tested PCR positive and IgG positive
Acharyya (2020) (76) *(preprint)* Case report India May 2020*	Descriptive case report of 1 MIS-C patient	- 4 month-old boy with no comorbidities - No ICU admission, intubation or ECMO - Patient survived - Patient tested PCR positive, no serology results
Balasubramanian (2020) (77) Case report India Jul 2020*	Descriptive case report of 1 MIS-C patient	- 8 year-old boy with no comorbidities - Admitted to ICU; not intubated and no ECMO - Patient survived - Patient tested PCR positive, no serology results
Gupta (2020) (78) *(preprint)* Case report India Sep 2020*	Descriptive case report of 1 MIS-C patient	- 2 year-old boy - No ICU admission, intubation or ECMO - Patient survived - Patient tested PCR negative, parents IgG positive
Rauf (2020) (79) Case report India Apr 2020	Descriptive case report of 1 MIS-C patient	- 5 year-old boy with no comorbidities - Admitted to ICU; not intubated and no ECMO - Patient survived - Patient tested PCR and serology negative
Singhi (2020) (80) Case report India Oct 2020*	Descriptive case report of 1 MIS-C patient	- 8 year-old girl - No ICU admission, intubation or ECMO - Patient survived - Patient tested PCR negative, serology positive
Tiwari (2020) (81) Case report India Oct 2020*	Descriptive case report of 1 MIS-C patient	- 9 year-old girl - Admitted to ICU and intubated, no ECMO - Patient survived - Patient tested PCR and serology positive
Bahrami (2020) (82) Case report Iran Jul 2020*	Descriptive case report of 1 MIS-C patient	- 5 year-old girl with no comorbidities - No ICU admission, intubation or ECMO - Patient survived - Patient tested PCR negative and serology positive
Parvaneh & Rahmani (2020) (83) *(preprint)* Case report	Descriptive case report of 1 MIS-C patient	- 7 year-old boy - Patient survived - Patient tested PCR positive, no serology results

Iran May 2020		
Regev (2020) (84) Case report Israel Aug 2020*	Descriptive case report of 1 MIS-C patient	- 16 year-old boy with no comorbidities - Admitted to ICU and intubated, no ECMO - Patient survived - Patient tested PCR and IgG positive
Schnapp (2020) (85) Case report Israel Jun 2020*	Descriptive case report of 1 MIS-C patient	- 16 year-old boy with no comorbidities - Admitted to ICU and intubated, no ECMO - Patient survived - Patient tested PCR negative, IgG positive
Buonsenso (2020) (86) Case report Italy Apr 2020	Descriptive case report of 1 MIS-C patient	- 11 year-old girl - Patient tested PCR positive, no serology results
Giannattasio (2020) (87) Case report Italy Jun 2020*	Descriptive case report of 1 MIS-C patient	- 9 year-old boy - No ICU admission, intubation or ECMO - Patient survived - Patient tested PCR negative, IgG and IgM positive
Yáñez (2020) (88) Case report Peru Jun 2020	Descriptive case report of 1 MIS-C patient	- 3 year-old girl - No other information provided
Tracewski (2020) (89) Case report Poland May 2020	Descriptive case report of 1 MIS-C patient	- 2 year-old boy - No ICU admission, intubation or ECMO - Patient survived - Patient tested PCR and IgM negative, IgG positive
Rodriguez-Gonzalez (2020) (90) Case report Spain Jun 2020*	Descriptive case report of 1 MIS-C patient	- 6 month-old boy with short bowel syndrome - Admitted to ICU and intubated, no ECMO - Patient survived - Patient tested PCR negative, IgG positive
Bapst (2020) (91) Case report Switzerland Apr 2020	Descriptive case report of 1 MIS-C patient	- 13 year-old boy with no comorbidities - No ICU admission, intubation or ECMO - Patient survived - Patient tested PCR negative, serology positive
Yozgat (2020) (92) *(preprint)* Case report Turkey	Descriptive case report of 1 MIS-C patient	- 3 year-old girl - Patient survived - Patient tested PCR negative, no serology results

Jul 2020*		
Domico (2020) (93) Case report UK Apr 2020	Descriptive case report of 1 MIS-C patient	- 11 year-old boy with no comorbidities - Admitted to ICU and intubated, no ECMO - Patient survived - Patient tested PCR and IgM negative, IgG positive
Chiu (2020) (94) Case report USA Jun 2020*	Descriptive case report of 1 MIS-C patient	- 10 year-old boy with no comorbidities - Admitted to ICU - Patient tested PCR positive, no serology results
Choi (2020) (95) Case report USA Aug 2020*	Descriptive case report of 1 MIS-C patient	- 19 years-old Hispanic man with sleep apnea and obesity - Admitted to ICU and intubated, no ECMO - Patient survived - Patient tested PCR positive, no serology results
Clouser (2020) (96) Case report USA May 2020	Descriptive case report of 1 MIS-C patient	- 11 year-old Black girl with obesity - Admitted to ICU and intubated, no ECMO - Patient survived - Patient tested PCR positive, no serology results
Dasgupta (2020) (97) Case report USA Jun 2020*	Descriptive case report of 1 MIS-C patient	- 8 year-old mixed race girl with no comorbidities - Admitted to ICU - Patient survived - Patient tested PCR and IgG negative
Deza Leon (2020) (98) Case report USA May 2020*	Descriptive case report of 1 MIS-C patient	- 6 year-old girl with no comorbidities - Admitted to ICU, intubated and was placed on ECMO - Patient survived - Patient tested PCR positive, no serology results
Dolhnikoff (2020) (99) Case report USA Aug 2020*	Descriptive case report of 1 MIS-C patient	- 11 year-old Black girl with no comorbidities - Admitted to ICU and intubated, no ECMO - Patient died - Patient tested PCR positive, no serology results
Dolinger (2020) (100) Case report USA May 2020*	Descriptive case report of 1 MIS-C patient	- 14 year-old boy with Crohn's disease - Patient survived - Patient tested PCR positive, no serology results
Greene (2020) (101) Case report USA Jun 2020*	Descriptive case report of 1 MIS-C patient	- 11 year-old girl with no comorbidities - Admitted to ICU; not intubated and no ECMO - Patient survived - Patient tested PCR positive, no serology results

Jones (2020) (102) Case report USA Jun 2020*	Descriptive case report of 1 MIS-C patient	- 6 month-old girl with no comorbidities - No ICU admission, intubation or ECMO - Patient survived - Patient tested PCR positive, no serology results
Kaushik, Ahluwalia, (2020) (103) Case report USA Sep 2020*	Descriptive case report of 1 MIS-C patient	- 5 year-old boy with no comorbidities - Admitted to ICU, intubated and placed on ECMO - Patient died - Patient tested PCR negative, serology positive
Nelson (2020) (104) Case report USA Oct 2020*	Descriptive case report of 1 MIS-C patient	- 15 year-old girl with no comorbidities - No ICU admission, intubation or ECMO - Patient survived - Patient tested PCR negative, no serology results
Rivera-Figueroa (2020) (105) Case report USA Jul 2020*	Descriptive case report of 1 MIS-C patient	- 5 year-old Black boy with no comorbidities - Admitted to ICU; not intubated and no ECMO - Patient survived - Patient tested PCR positive, no serology results
Stevens (2020) (106) Case report USA Apr 2020	Descriptive case report of 1 MIS-C patient	- 10 year-old Black girl with asthma - Admitted to ICU; not intubated and no ECMO - Patient survived - Patient tested PCR negative, IgG positive
Vari (2020) (107) Case report USA Apr 2020	Descriptive case report of 1 MIS-C patient	- 14 year-old boy - Admitted to ICU and intubated, no ECMO - Patient survived - Patient tested PCR negative, IgG positive
Verkuil (2020) (108) Case report USA Aug 2020*	Descriptive case report of 1 MIS-C patient	- 14 year-old girl with no comorbidities - Admitted to ICU and intubated, no ECMO - Patient survived - Patient tested PCR negative, IgG positive

Methods

A daily scan of the literature (published and pre-published) is conducted by the Emerging Science Group at the Public Health Agency of Canada (PHAC). The scan has compiled COVID-19 literature since the beginning of the outbreak and is updated daily. Searches to retrieve relevant COVID-19 literature are conducted in Pubmed, Scopus, BioRxiv, MedRxiv, ArXiv, SSRN, Research Square and cross-referenced with the literature on the WHO COVID literature list, and COVID-19 information centers run by Lancet, BMJ, Elsevier and Wiley. The

daily summary and full scan results are maintained in a Refworks database and an Excel list that can be searched.

Targeted keyword searching is conducted within these databases to identify relevant citations on COVID-19 and SARS-CoV-2. Search terms used included: "MIS-C", "PIMS", "Kawasaki", "multisystem inflam", "multi-system inflam", "inflammatory multisystem", "inflammatory multi-system".

382 papers were identified on the topic of MIS-C, after the removal of duplicates. Each potentially relevant reference was examined to confirm it had relevant data and relevant data is extracted into the review. 102 studies identified as relevant to the study question. This review contains research published up to November 10, 2020.

APPENDIX

The case definition of MIS-C published by the USA Centers for Disease Control (CDC) (3) states:

- An individual aged <21 years presenting with fever (>38.0°C for ≥24 hours, or report of subjective fever lasting ≥24 hours), laboratory evidence of inflammation, and evidence of clinically severe illness requiring hospitalization, with multisystem (>2) organ involvement (cardiac, renal, respiratory, hematologic, gastrointestinal, dermatologic or neurological);

AND

- No alternative plausible diagnoses;

AND

- Positive for current or recent SARS-CoV-2 infection by RT-PCR, serology, or antigen test; or exposure to a suspected or confirmed COVID-19 case within the 4 weeks prior to the onset of symptoms.

The definition of MIS-C published by the World Health Organization (WHO) (2) states:

- Children and adolescents 0–19 years of age with fever > 3 days

AND

- two of the following:
    - Rash or bilateral non-purulent conjunctivitis or muco-cutaneous inflammation signs (oral, hands or feet).
    - Hypotension or shock.
    - Features of myocardial dysfunction, pericarditis, valvulitis, or coronary abnormalities (including ECHO findings or elevated Troponin/NT-proBNP),
    - Evidence of coagulopathy (by PT, PTT, elevated d-Dimers).
    - Acute gastrointestinal problems (diarrhoea, vomiting, or abdominal pain).

AND

- Elevated markers of inflammation such as ESR, C-reactive protein, or procalcitonin.

AND

- No other obvious microbial cause of inflammation, including bacterial sepsis, staphylococcal or streptococcal shock syndromes.

AND

- Evidence of COVID-19 (RT-PCR, antigen test or serology positive), or likely contact with patients with COVID-19.

Finally, the definition of PIMS released by the UK Royal College of Paediatrics and Child Health (RCPCH) (4) states:

- A child presenting with persistent fever, inflammation (neutrophilia, elevated CRP and lymphopaenia) and evidence of single or multi-organ dysfunction (shock, cardiac, respiratory, renal, gastrointestinal or neurological disorder) with additional features. This may include children fulfilling full or partial criteria for Kawasaki disease.

AND

- Exclusion of any other microbial cause, including bacterial sepsis, staphylococcal or streptococcal shock syndromes, infections associated with myocarditis such as enterovirus (waiting for results of these investigations should not delay seeking expert advice).

AND

- SARS-CoV-2 PCR testing may be positive or negative.

Preuve émergente sur la COVID-19

Revue rapide sur l'utilisation du couvre-visage pour prévenir la propagation de la COVID-19 en milieu communautaire, mise à jour 1

Introduction

Quelles sont les données probantes sur l'utilisation des couvre-visages pour prévenir la propagation de la COVID-19 en milieu communautaire?

Parmi toutes les mesures de santé publique qui ont été utilisées pendant la pandémie de COVID-19, le port du couvre-visage dans la collectivité est une mesure simple sur le plan technique, qui a également eu peu d'incidence sur l'économie (1). Mais est-elle efficace? Cette revue rapide résume les preuves empiriques sur l'efficacité des couvre-visages pour prévenir la propagation de la COVID-19 en milieu communautaire. Il s'agit d'une mise à jour de la précédente *Synthèse en bref sur le port du masque pour prévenir la COVID-19 en milieu communautaire, juillet 2020* (2). Cette revue ne comporte aucune donnée expérimentale sur la filtrabilité des différents types de masques ou de couvre-visages, des matériaux ou des combinaisons de matériels non médicaux, puisque cette question fait l'objet d'une revue distincte. Elle ne comprend pas non plus de modèles prédictifs visant à estimer les effets d'atténuation associés au port d'un couvre-visage seul ou en combinaison avec d'autres interventions de santé publique. La présente revue contient la documentation disponible jusqu'au 19 novembre 2020.

Points clés

- Quarante-neuf études portant sur l'efficacité des couvre-visages pour prévenir la propagation de la COVID-19 en milieu communautaire ont été recensées, soit une étude expérimentale, 15 études d'observation, 27 études écologiques et 6 revues.
- La majorité d'entre elles démontrent que le fait de porter un couvre-visage en milieu communautaire (études d'observation) et la mise en œuvre d'une politique sur le port du couvre-visage dans la communauté (études écologiques) assurent une protection contre la COVID-19, mais que la portée de cette protection varie. Cette variabilité de la protection peut être attribuable tant au moment où l'étude a été effectuée qu'aux facteurs de confusion et aux taux d'observance sur le port du couvre-visage.
- Les études d'observation effectuées au niveau individuel (n = 15) et lors d'un essai clinique randomisé (n = 1) ont permis d'établir les principales constatations suivantes :
    - Dans sept études d'observation, le port d'un couvre-visage a été associé à une diminution de 7,0 à 79 % du taux d'infection par la COVID-19.

- Un important essai clinique randomisé (DANMASK-19) effectué au Danemark a révélé des résultats non significatifs sur le port du couvre-visage (RC 0,82, IC à 95 %, de 0,54 à 1,23, P = 0,33), bien que cet essai ait comporté un bas niveau d'adhésion dans le groupe de personnes qui devaient porter le couvre-visage probablement en raison de la faible quantité de gens qui portaient un couvre-visage dans la communauté au moment où l'étude a été effectuée (3).
- Les enquêtes sur les grappes et les éclosions ont toujours indiqué un plus petit nombre de cas secondaires lorsque les cas de référence ou leurs contacts portaient des couvre-visages.
- Aucune preuve n'a été trouvée à propos des différences dans l'efficacité des couvre-visages chez les adultes et les enfants.

- Vingt-six études écologiques ont démontré que les politiques sur les couvre-visages étaient associées à une diminution des infections par la COVID-19 et des décès dus à ce coronavirus. On trouvait cependant une certaine variabilité dans le type de politique sur les couvre-visages mise en œuvre puisque bon nombre d'entre elles exigeaient le port universel du couvre-visage dans tous les lieux publics alors que trois autres portaient spécifiquement sur le port du couvre-visage pour les employés.
  - Neuf études ont calculé l'effet des différentes politiques sur le port universel du couvre-visage, ce qui a permis de voir que la diminution des infections par la COVID-19 variait de 3,2 à 48 %. On trouvait cependant une certaine variabilité dans le type de politique sur les couvre-visages mise en œuvre puisque bon nombre d'entre elles exigeaient le port universel du couvre-visage dans tous les lieux publics alors que trois autres portaient spécifiquement sur le port du couvre-visage pour les employés.
  - Une étude canadienne a démontré que les politiques sur le port du couvre-visage mises en œuvre en juin et en juillet en Ontario avaient entraîné une diminution de 25 à 31 % des cas de COVID-19 par semaine, réduction qui fut visible deux semaines après la mise en œuvre de la politique (4).
  - Une étude sur la réduction du nombre de cas de COVID-19 pendant le premier mois ayant suivi l'entrée en vigueur d'une politique sur le port de couvre-visage universel à New York a montré des différences associées à l'âge. Ainsi, on a pu voir une réduction de 20,8 % des cas chez les 65 à 74 ans et chez les 75 ans et plus pendant le premier mois, alors que cette réduction n'a atteint que 4,5 % chez les 25 à 44 ans et 8,1 % chez les 45 à 64 ans (5).
  - Trois études sur les politiques qui exigeaient le port du couvre-visage pour tous les employés dans tous les milieux de travail d'une région (comté ou État) ont révélé une diminution des infections et des décès liés à la COVID-19 (1, 6, 7), bien que ces résultats

n'aient pas été cohérents quant à l'ampleur ou à la signification statistique dans les différents modèles (1).

- Une étude menée aux États-Unis a révélé que les politiques sur le port du couvre-visage, qu'elles aient été adoptées de façon précoce ou tardive, étaient efficaces pour réduire l'infection par la COVID-19 (8).
- Avec un résultat de -1 % (IC à 95 %, de -13 à 8 %), la seule étude qui n'a pas montré de répercussions significatives en lien avec la politique sur le port du couvre-visage a été réalisée dans des conditions de confinement (9).
- Une étude a révélé que les pays qui avaient déjà adopté une norme en vertu de laquelle toute personne malade devait porter un couvre-visage affichaient un taux de croissance quotidien des cas de COVID-19 et des décès plus faible que les pays qui n'avaient aucune norme préexistante à cet effet (10).

- La mise en œuvre d'une politique sur le port du couvre-visage dans la communauté plutôt que le fait de simplement recommander aux gens de porter un couvre-visage a eu une grande incidence sur l'adhésion au port du couvre-visage dans les établissements publics. L'étude menée en Ontario a révélé une augmentation de 30 % du port du couvre-visage après la mise en œuvre des politiques à cet égard (4). Une étude similaire menée en Australie a révélé qu'une politique sur les couvre-visages augmentait de près de 50 % le port de ceux-ci (11). En revanche, une étude américaine a montré que les recommandations sur le port du couvre-visage n'avaient eu aucune incidence sur le taux de mortalité lié à la COVID-19 (1).

Vue d'ensemble des éléments de preuve

Quarante-neuf articles portant sur l'efficacité des couvre-visages pour prévenir la transmission de la COVID-19 dans les milieux communautaires ont été déterminés et inclus dans la présente revue. De ce nombre, 23 sont des préimpressions ou des rapports pour lesquels le processus d'examen par les pairs n'est pas terminé. Les publications qui indiquent l'efficacité des couvre-visages comprennent un essai clinique randomisé (n = 1), des études longitudinales (n = 2), des études de cohorte (n = 2), une expérience naturelle (n = 1), une étude cas/témoin (n = 1), des études transversales (n = 5), des enquêtes sur les grappes et les éclosions (n = 4), des études écologiques (n = 27), ainsi que des examens systématiques ou des revues rapides (n = 6).

Les études qui permettent de tirer des déductions à propos des individus incluent des essais cliniques randomisés qui constituent la norme de référence pour mesurer les répercussions d'une intervention, sachant que dans un tel essai, le processus de randomisation contrôle les variables confusionnelles et permet de présumer que l'échantillon est représentatif de la population. Les essais cliniques randomisés devraient donc,

de par leur conception, isoler l'effet de l'intervention. L'essai clinique randomisé inclus dans cette revue a été réalisé dans une communauté dans laquelle aucune politique sur le port universel du couvre-visage n'avait été adoptée. Il y a donc eu un manque en ce qui concerne l'adhésion au port du couvre-visage dans le groupe visé, les données et l'aveuglement des auteurs de l'essai. Cet essai clinique randomisé présente donc un certain risque de biais qui ébranle la confiance selon laquelle les recherches futures ne modifieront pas les conclusions obtenues.

Les quinze études d'observation ont évalué les données au niveau de l'individu. Les études de cohorte, les expériences naturelles, les études longitudinales et les études cas/témoin peuvent présenter un risque de biais modéré à élevé selon que la stratégie d'échantillonnage utilisée a permis ou non d'obtenir un échantillon représentatif de la population cible. Les études transversales donnent une image ponctuelle d'un problème, mais ne peuvent établir de lien de cause à effet, ce qui fait qu'elles fournissent des données probantes de basse qualité. Les enquêtes rétrospectives sur les grappes et les éclosions présentent également un risque élevé de biais. Puisque les résultats et facteurs de risque de nombreuses études étaient autodéclarés, ces études pourraient donc comporter un biais de rappel et de désirabilité sociale. De façon générale, les études d'observation ne peuvent pas établir le lien de causalité, mais elles peuvent cependant être utiles pour formuler des hypothèses ou comprendre les facteurs de transmission observés.

Les 27 études écologiques ont évalué les données au niveau de la population. Ces études sont peu coûteuses et peuvent être réalisées rapidement, puisqu'elles tirent largement parti des données accessibles au public. Elles présentent cependant un risque élevé de biais en raison de données disparates au niveau de la population, en plus d'être assujetties à des erreurs écologiques (puisque ce qui est vrai au niveau de la population pourrait ne pas s'appliquer au niveau individuel).

Les six revues ont été évaluées à l'aide de l'outil AMSTAR conçu pour les revues systématiques et visant à déterminer si l'exécution d'un examen pourrait minimiser les biais. Les revues rapides et systématiques étaient de qualité variable (de faible à élevée) en fonction du nombre de rapports et de questions inclus dans chacune. Malgré cela, les résultats étaient généralement les mêmes dans l'ensemble des documents examinés.

La documentation sur la COVID-19 évolue rapidement et, avec le temps, les études présentant un faible risque de biais peuvent être utilisées pour combler les lacunes existantes dans les connaissances. Une lacune importante en ce qui concerne les connaissances est le manque d'études qui permettent de tirer des conclusions sur l'adhésion au port du masque au niveau individuel (tant l'adhésion au port du couvre-visage que la façon appropriée de le porter) et ses effets sur l'infection par SRAS-CoV-2 en milieu communautaire. Il existe également peu de preuves de l'efficacité des couvre-visages ou des politiques sur les masques pour les employés, ainsi que dans les milieux scolaires.

TABLE DES MATIÈRES

ÉTUDES EXPÉRIMENTALES ET D'OBSERVATION ÉVALUANT LA PRÉVENTION

Seize études, soit une étude expérimentale et 15 études d'observation, ont utilisé des données individuelles (tableau 1) pour évaluer l'efficacité des couvre-visages pour prévenir la propagation de la COVID-19 en milieu communautaire.

- L'étude expérimentale était un essai clinique randomisé de grande envergure (DANMASK-19) effectué au Danemark. Il a montré que lorsqu'il n'y avait pas de politique sur les couvre-visages déjà en place dans la communauté, le fait de recommander le port du masque n'était pas efficace. Même si les personnes qui portaient un couvre-visage étaient 18 % moins susceptibles d'être infectées par le SRAS-CoV-2 que celles qui n'en portaient pas, ces résultats n'étaient cependant pas significatifs (RC 0,82, IC à 95 %, de 0,54 à 1,23, P = 0,33). Le niveau variable d'adhésion au port du couvre-visage, les données manquantes et le manque d'aveuglement des auteurs de l'essai sont les principales limites de cette étude (3).
- Les 15 études d'observation comprenaient, quant à elles, deux études longitudinales, deux études de cohorte, une étude cas/témoin, cinq études transversales, quatre enquêtes sur les grappes et éclosions, et une expérience naturelle. La majorité de ces études ont démontré que le port d'un couvre-visage protégeait contre la COVID-19, mais l'ampleur variait cependant d'une étude à l'autre.
    - Une étude longitudinale effectuée dans 24 pays montre que le port généralisé du couvre-visage par 100 % des personnes dans un pays est associé à une réduction de 7 % (IC à 95 %, de 3,94 à 9,99 %) des cas quotidiens actifs de COVID-19. En 30 jours, ce taux cumulatif a permis d'obtenir une réduction des cas actifs de 88,5 % (IC à 95 %, de 68,7 à 89,2 %) (12).
    - Une diminution de 7,0 à 7,9 % des cas de COVID-19 associée à l'utilisation de couvre-visage a également été observée dans trois études transversales, deux études de cohorte, une étude longitudinale et une étude cas/témoin (12 à 18).
    - Une étude cas/témoin menée en Thaïlande a montré que le fait de porter un couvre-visage en tout temps, comparativement au fait de ne jamais en porter, était associé à une diminution du risque d'infection par le SRAS-CoV-2 (RCA 0,23, IC à 95 %, de 0,09 à 0,60), alors que le port

irrégulier du couvre-visage n'était associé à aucune diminution du risque (RCA 0,87, IC à 95 %, de 0,41 à 1,84) (18).

- Quatre enquêtes sur les grappes et les éclosions ont continuellement indiqué moins de cas secondaires lorsque les cas de référence ou leurs contacts portaient des couvre-visages (19 à 22).

Tableau 1. Études expérimentales et d'observation sur l'efficacité des couvre-visages pour se protéger contre la COVID-19 en milieu communautaire (n = 16)

RÉFÉRENCE	DESCRIPTION DE L'ÉTUDE	RÉSULTATS PERTINENTS
Essais cliniques randomisés (n = 1)		
Bundgaard (2020) (3) Essai clinique randomisé Danemark Avril et mai 2020	Cet essai clinique randomisé visait à déterminer si le port d'un masque chirurgical à l'extérieur du domicile réduisait le risque d'infection par le SRAS-CoV-2. L'étude a été menée dans une collectivité où le port du couvre-visage ne faisait pas partie des habitudes, mais était recommandé par la santé publique. 4 862 participants ont pris part à l'essai (3 030 personnes choisies au hasard devaient porter un couvre-visage alors que 2 994 ne devaient pas en porter). Limites de l'essai clinique : données manquantes, adhésion variable au port du couvre-visage, résultats déclarés par les patients lors des vérifications à domicile, absence d'aveuglement et aucune évaluation de la possibilité à savoir si les couvre-visages pouvaient réduire la transmission de la maladie entre les personnes qui portent un couvre-visage et les autres.	• Parmi les participants à qui l'on avait recommandé de porter un couvre-visage, 42 (1,8 %) ont attrapé l'infection associée au SRAS-CoV-2 tout comme et 53 participants témoins (2,1 %). • La différence entre les groupes était de 0,3 point de pourcentage (IC à 95 %, de 1,2 à 0,4 point de pourcentage, p = 0,38) (RC 0,82, IC à 95 %, de 0,54 à 1,23, p = 0,33). • L'adhésion au port du couvre-visage était autodéclarée. Selon le plus faible niveau d'adhésion indiqué pendant la période de suivi, 46 % des participants auraient porté le couvre-visage de la façon recommandée, 47 % l'auraient porté majoritairement de la façon recommandée et 7 % l'auraient porté d'une façon autre que celle qui avait été recommandée.
Études longitudinales (n = 2)		

Aravindakshan (2020) *préimpression* (12) Étude longitudinale À l'échelle mondiale Février à juillet 2020	Une analyse économétrique avec modèle de forme réduite a été utilisée pour mesurer les liens entre le port déclaré d'un couvre-visage et la propagation du SRAS-CoV-2 dans 24 pays. Une enquête longitudinale a été effectuée tous les 7 jours pour recueillir des informations sur les interventions non pharmaceutiques (INP) et l'adhésion au port du couvre-visage dans 24 pays.	• Le port généralisé d'un couvre-visage par 100 % des personnes dans un pays a été associé à une réduction de 7 % (IC à 95 %, de 3,94 à 9,99 %) des cas quotidiens actifs de COVID-19. En 30 jours, ce taux cumulatif a permis d'obtenir une réduction des cas actifs de 88,5 % (IC à 95 %, de 68,7 à 89,2 %).
Rader (2020) *préimpression* (23) Étude longitudinale États-Unis Juin et juillet 2020	Des enquêtes en série ont été effectuées du 3 juin au 27 juillet aux États-Unis (n = 378 207) afin de recueillir des données sur le port du couvre-visage dans la communauté et sur les comportements de distanciation sociale dans différentes collectivités. Ces données ont été combinées au Rt local, aux données sur la mobilité et aux informations sur les politiques mises en œuvre avant d'être analysées avec des analyses de régression multivariées afin de déterminer les facteurs associés au contrôle de la transmission communautaire du SRAS-CoV-2 aux États-Unis.	• Un lien important a été établi entre la proportion de personnes qui ont déclaré porter un couvre-visage et le contrôle de la transmission dans la collectivité (Rt < 1) : RC = 1,14 (IC à 95 %, de 1,07 à 1,20). • Le rapport de contrôle de transmission (Rt < 1) a augmenté (RC 3,53, IC à 95 %, de 2,03 à 6,43) pour chaque hausse de 10 % dans le port du couvre-visage en collectivité signalée dans l'enquête. • Dans toutes les analyses, le port d'un couvre-visage s'est révélé être un facteur de protection robuste dans le contrôle de la transmission dans la collectivité. • L'on avait prédit que le contrôle de la transmission dans la communauté serait plus élevé lorsque les gens porteraient le couvre-visage et respecteraient les mesures de distanciation sociale. Lorsque la distanciation sociale était basse malgré la forte utilisation du couvre-visage, le contrôle de transmission communautaire est descendu jusqu'à atteindre 35 %.

		• L'analyse n'a pas révélé d'augmentation importante dans l'utilisation des couvre-visages à la suite de la mise en œuvre de la politique sur le port du couvre-visage ni abordé les raisons pour ce faire. • L'adhésion au port du couvre-visage était plus élevée chez les femmes, les personnes âgées, les groupes ethniques non blancs ou hispaniques et les personnes à faible revenu. • Le couvre-visage était plus fréquemment porté dans les régions le long de la côte, à la frontière sud et dans les zones urbaines des États-Unis.
Études de cohorte (n = 2)		
Kwon (2020) *préimpression* (15) Étude de cohorte prospective États-Unis Mars à juillet 2020	Cette cohorte prospective d'étude des symptômes de la COVID-19 a été effectuée du 29 mars au 16 juillet et comprenait des participants des États-Unis ayant utilisé une application. Ces participants ont fourni des informations de base et sur la santé, avant d'être invités à enregistrer quotidiennement leurs informations relatives à la santé et à la COVID-19. 139 690 participants ont fourni des informations afin d'établir un lien entre l'utilisation autodéclarée d'un couvre-visage et le risque prévisible d'avoir la COVID-19. En raison du petit nombre d'utilisateurs de l'application ayant reçu un résultat positif à la COVID-19 pendant la période de l'étude, cette dernière a utilisé le risque	• Les personnes qui ont dit avoir porté un couvre-visage dans la communauté (parfois, la plupart du temps ou toujours) ont obtenu un RR ajusté de 0,35 (IC à 95 %, de 0,30 à 0,42) pour le risque prévisible d'être atteintes de la COVID-19 comparativement à celles qui ont déclaré n'avoir jamais porté de couvre-visage. • Le port autodéclaré du couvre-visage a été associé à une réduction de 69 %, de 71 % et de 63 %, respectivement, du risque prévisible d'être atteint de la COVID-19 pour les personnes qui vivent dans des collectivités où le respect de la distanciation sociale a été jugé excellent, passable et faible, respectivement. • Les résultats confirment l'efficacité du port du couvre-visage pour réduire la transmission de la COVID-19, même dans les milieux où le respect de la distanciation sociale est faible.

	prévisible d'être atteint de la COVID-19 comme approximation pour le nombre de tests positifs. L'analyse de survie a été ajustée pour l'âge, le sexe, l'origine ethnique, la condition, le tabagisme, les travailleurs de première ligne et les comorbidités.	
Wang (2020) (17) Étude de cohorte rétrospective Chine Février et mars 2020	Cette étude de cohorte rétrospective comprenait 335 personnes de 124 familles ayant eu au moins un cas de COVID-19 confirmé par un laboratoire à Beijing, en Chine, entre le 28 février et le 27 mars 2020.	• Le taux d'attaques secondaires dans les familles était de 23,0 % (77/335). • L'utilisation d'un couvre-visage par le cas primaire et les contacts de la famille avant l'apparition des symptômes chez le cas primaire a permis de réduire de 79 % la transmission (RC = 0,21, IC à 95 %, de 0,06 à 0,79). • Toutefois, le port du couvre-visage après l'apparition de la maladie chez le cas primaire ne s'est pas révélé très protecteur.
Études cas/témoin (n = 1)		
Doung-ngern (2020) (18) Étude cas/témoin Thaïlande Mars 2020	Cette étude cas/témoin rétrospective a utilisé les registres de recherche de contacts en Thaïlande pour établir son échantillon. 1 050 contacts de patients atteints de la COVID-19 entre le 1er et le 31 mars 2020 ont pris part à des entrevues rétrospectives. Les cas (n = 211) ont été définis comme des contacts asymptomatiques de patients atteints de la COVID-19 qui ont ensuite obtenu un résultat positif au test de dépistage de l'infection à SRAS-CoV-2, alors que les témoins (n = 839) étaient des contacts	• Le port d'un couvre-visage en tout temps (RCA de 0,23; IC à 95 %, de 0,09 à 0,60) était associé de façon indépendante à un risque plus faible d'infection par la COVID-19 que le fait de ne pas en porter. Toutefois, le port du couvre-visage à l'occasion (RCA de 0,87, IC à 95 %, de 0,41 à 1,84) n'a pas eu le même effet. • Les personnes qui portaient un couvre-visage en tout temps étaient plus susceptibles de se laver les mains et de mettre en œuvre les pratiques de distanciation sociale.

	asymptomatiques qui n'ont jamais obtenu de résultat positif.	
Études transversales (n = 5)		
Lopez (2020) *préimpression* (14) Étude transversale États-Unis Juillet 2020	Dans cette étude, on a déterminé la séroprévalence du SRAS-CoV-2 chez 753 membres du personnel des écoles publiques et analysé les corrélations entre la séropositivité, les antécédents autodéclarés (p. ex., port d'un couvre-visage) et les données démographiques.	• La séroprévalence a été estimée à 1,7 % (IC à 90 %, de 0,27 à 3,3). • Après avoir contrôlé six facteurs de confusion, les résultats de l'analyse multivariée ont révélé que les antécédents autodéclarés de port de couvre-visage réduisaient le risque de séropositivité (RR de 0,83, IC à 95 %, de 0,18 à 3,8).
Rodríguez-Barranco (2020) (24) Étude transversale Espagne Avril et mai 2020	Cette étude a examiné les voies possibles d'exposition au SRAS-CoV-2, les facteurs de risque et l'efficacité des mesures d'hygiène recommandées. Des renseignements autodéclarés ont été recueillis auprès de 2 086 personnes dans un sondage en ligne.	• 73,4 % des personnes ont dit avoir porté un couvre-visage, une fois le confinement terminé (34,9 % ont porté des masques FFP2/FFP3, 64,4 % des masques chirurgicaux et 0,7 % des couvre-visages maison). • La prévalence estimée de COVID-19 était de 4,7 % (49 cas confirmés et 50 cas soupçonnés). • Lorsqu'on ne tient compte d'aucune autre variable, on ne peut établir de lien entre le fait d'être ou non atteint de la COVID-19 et le port du couvre-visage (p = 0,205) puisque 3,9 % (masque FFP2/FFP3), 5,7 % (masque chirurgical), 0 % (couvre-visage maison), 3,1 % (aucun couvre-visage) et 5,8 % (ne pas être sorti de chez elles) respectivement, des personnes ont dit avoir été infectées de manière présumée ou confirmée par la COVID-19.
Payne (2020) (13) Étude transversale États-Unis	Une enquête a été menée auprès de membres de la Marine américaine (échantillon de commodité, n =382) associés à une éclosion de COVID-19 dans un porte-avions afin de recueillir des	• Les participants qui ont déclaré porter un couvre-visage (55,8 %) présentaient une plus faible probabilité d'être atteint de la COVID-19 (RC de 0,3, IC à 95 %, de 0,2 à 0,5) comparativement à ceux qui ont déclaré ne pas en porter (80,8 %).

Mars et avril 2020	renseignements sur l'utilisation autodéclarée du couvre-visage et d'autres mesures de protection (p. ex., éviter les aires communes, distanciation sociale). Les résultats ont été analysés afin de déterminer les liens avec le risque d'infection. Dans l'échantillon, 284 personnes avaient obtenu un résultat positif pour le SRAS-CoV-2 au moment de l'analyse du sérum ou avant celle-ci.	
Clipman (2020) (16) Étude transversale États-Unis Juin 2020	Les associations avec la positivité autodéclarée au SRAS-CoV-2 et l'adoption des INP ont été analysées par un sondage en ligne effectué auprès de 1 030 résidents du Maryland. La régression logistique a été utilisée pour déterminer les variables associées à des tests positifs pour le SRAS-CoV-2.	• Parmi l'échantillon de l'étude, 5 % (n = 55) ont déclaré avoir déjà obtenu un résultat positif au test de dépistage du SRAS-CoV-2. • 53 % des participants ont déclaré toujours porter un couvre-visage à l'intérieur et à l'extérieur. • Un petit lien a été établi entre le fait de porter un masque (toujours) et un résultat positif au test de dépistage du SRAS-CoV-2, soit un RCA de 0,63 (IC à 95 %, de 0,36 à 1,09).
van den Broek (2020) *préimpression* (25) Étude transversale États-Unis Avril à juin 2020	Cette étude a sondé des résidents (n = 454) de la collectivité, avant de leur offrir de passer des tests RT-PCR et sérologiques pour le SARS-CoV-2. Une analyse multivariée a ensuite été effectuée avec des probits pour établir de possibles liens.	• Ainsi, 2,2 % (IC à 95 %, de 0,8 à 3,6 %) des répondants qui faisaient partie de l'échantillon de l'étude ont obtenu un résultat positif au test sérologique du SRAS-CoV-2. • Le fait de porter un couvre-visage à l'extérieur du lieu de travail n'a pas créé de différence statistique importante entre les résidents qui ont obtenu un résultat positif (0,5 %, ET 0,189) ou un résultat négatif (0,7 %, ET 0,230) au test de dépistage de la COVID-19.

Enquêtes sur les grappes et les éclosions (n = 4)		
Hendrix (2020) (19) Enquête sur les grappes États-Unis Mai 2020	Cette enquête épidémiologique rétrospective a permis d'analyser les résultats de 139 clients qui ont été exposés à deux coiffeurs infectés par le SRAS-CoV-2 au Missouri, aux États-Unis. Les clients comme les coiffeurs portaient tous un couvre-visage.	• Des 139 clients ayant été exposés, 67 ont été testés. • Aucun cas secondaire symptomatique n'a été signalé, probablement en raison de l'utilisation des couvre-visages.
Cheng (2020) (20) Enquête sur les grappes Hong Kong Janvier à avril 2020	Cette enquête décrit les résultats des recherches effectuées à Hong Kong au cours des 100 premiers jours de la pandémie. On y a comparé le nombre de grappes de COVID-19 et le fait de porter ou non un couvre-visage. Hong Kong avait mis en place une politique sur le port obligatoire des couvre-visages, ce qui a permis d'obtenir un taux de respect estimé à 96,6 % (IC à 95 %, de 95,7 à 97,2 %).	• Au 100e jour de l'épidémie, 961 cas confirmés de COVID-19 avaient été déclarés à Hong Kong. De ces cas, 11 groupes de 113 personnes participaient de façon active à des activités sans couvre-visage, comme manger et boire dans un restaurant ou un bar, faire du karaoké et faire de l'exercice dans des centres d'entraînement, comparativement à 3 groupes de 11 personnes qui prenaient part à des activités avec couvre-visage dans leur lieu de travail (chi carré p = 0,036).
Hong (2020) (22) Enquête sur les grappes Chine Janvier à mars 2020	Les données cliniques et épidémiologiques ont été extraites rétrospectivement du 23 janvier au 1er mars 2020 des dossiers médicaux électroniques et des questionnaires individuels valides de 127 patients atteints de la COVID-19 à Zhejiang, en Chine.	• Avant leur diagnostic, 41 patients présymptomatiques avaient eu des contacts étroits avec les résidents locaux. • De ces personnes, 28 ont porté un couvre-visage et été en contact étroit avec 123 résidents, ce qui a entraîné 10 infections secondaires au SRAS-CoV-2. • Les 13 autres personnes, qui ne portaient pas de couvre-visage, ont été en contact étroit avec 74 résidents, ce qui a entraîné 14 infections secondaires au SRAS-CoV-2. • Le pourcentage de résidents locaux infectés par le SRAS-CoV-2 était beaucoup plus faible dans le groupe qui

		est entré en contact avec des personnes infectées portant un masque que dans celui des personnes qui sont entrées en contact avec des personnes infectées ne portant pas de masque (8,1 % contre 19,0 %; p < 0,001).
Liu (2020) (21) Enquête sur l'épidémie Chine 2020	Il s'agit d'une enquête épidémiologique rétrospective sur l'exposition au SRAS-CoV-2 dans les transports en commun. Elle décrit deux trajets d'autobus successifs effectués par une personne infectée et symptomatique au départ de Chongqing, le premier sans couvre-visage et le second avec un couvre-visage.	• Pendant le trajet en autobus où la personne infectée portait un masque, aucune personne n'a été infectée (14 passagers). • Au cours du trajet en autobus où la personne infectée ne portait pas de masque, 5 personnes sur 39 ont été infectées.
Expérience naturelle (n = 1)		
Pletz (2020) *préimpression* (26) Expérience naturelle Allemagne Avril 2020	Les effets du port universel d'un couvre-visage dans les lieux publics ont été comparés dans deux villes proches dont la taille et la structure communautaires étaient semblables. En ce qui concerne les INP, la ville de Jena a adopté une politique sur le port des couvre-visages au début d'une période de confinement de quatre semaines alors que la ville d'Erfurt n'a adopté sa politique sur le port du masque qu'à la fin de la période de confinement. Remarque : les couvre-visages en tissu et les foulards étaient acceptables tant qu'ils couvraient la bouche et le nez.	• Aucun nouveau cas de SRAS-CoV-2 n'a été observé à Jena 5 jours après la mise en œuvre de la politique obligeant le port du couvre-visage. • À Erfurt cependant, l'infection a continué de se propager au sein de la communauté pendant le confinement, jusqu'à ce que la politique sur le port obligatoire du couvre-visage dans la collectivité soit mise en œuvre, une fois le confinement levé. • Puisque ces observations peuvent être liées à d'autres facteurs, les conclusions tirées de cette étude sont limitées, mais cette étude offrait une occasion unique d'examiner les répercussions d'une politique sur le port du couvre-visage dans deux collectivités semblables.

IC = intervalle de confiance, RR = rapport de risque, INP = intervention non pharmaceutique, RC = rapport de cotes, Rt = nombre de reproduction effectif

ÉTUDES ÉCOLOGIQUES ÉVALUANT LES RÉPERCUSSIONS DES POLITIQUES ET DES NORMES SOCIÉTALES

Vingt-sept études écologiques sur l'incidence des recommandations et des politiques sur le port du couvre-visage afin de prévenir la propagation de la COVID-19 en milieu communautaire ont été recensées (tableau 2). Elles ont toutes analysé des données agrégées au niveau de la population afin d'estimer l'incidence des politiques sur le port du couvre-visage sur la réduction de la propagation de la COVID-19. Diverses approches et analyses de sensibilité ont été utilisées dans toutes les études et ne sont pas détaillées ici. Les lecteurs sont encouragés à consulter les études individuelles pour en savoir plus sur la méthodologie utilisée.

- La majorité (n = 26) de ces études écologiques ont démontré que les politiques sur le port du couvre-visage protégeaient contre la COVID-19, mais que l'ampleur de la protection variait d'une étude à l'autre.
    - Neuf études associées à la mise en œuvre de politiques communautaires sur le port du couvre-visage ont montré une diminution de 3,2 à 48 % de l'infection par la COVID-19 (4 à 7, 9, 27 à 30).
    - Cinq études ont montré une réduction de 17 à 23 % du Rt après la mise en œuvre des politiques sur le port du couvre-visage (11, 29, 31 à 33).
    - Dans une étude ontarienne, les politiques sur le port du couvre-visage ont entraîné une réduction hebdomadaire de 25 à 31 % des cas de COVID-19 deux semaines après leur mise en œuvre (4).
    - Comme l'a démontré une étude menée aux États-Unis, que les politiques sur le port du couvre-visage aient été mises en œuvre de façon précoce ou tardive, elles ont toutes été efficaces pour réduire la propagation de la COVID-19 (8).
    - Une étude qui a comparé l'efficacité des couvre-visages dans les pays ayant des normes préexistantes et dans ceux qui n'en avaient pas a révélé que dans les pays où toutes les personnes malades portaient généralement un couvre-visage, le taux quotidien d'augmentation des cas et des décès liés à la COVID-19 était inférieur (10).
- La seule étude qui n'a pas démontré que la politique sur le port du couvre-visage avait eu des répercussions importantes a été effectuée pendant le confinement et donné un résultat de -1 % (IC à 95 %, de -13 à 8 %) (9).
- Une étude a évalué l'efficacité d'une politique sur le port universel du couvre-visage selon l'âge. La réduction du nombre de cas de COVID-19 liés à l'âge, combinée à une politique universelle sur le port du couvre-visage à New York, a permis de réduire de 20,8 % le nombre de cas chez les 65 à 74 ans et les

75 ans et plus au cours du premier mois, alors que cette réduction a atteint 4,5 % chez les 25 à 44 ans et 8,1 % chez les 45 à 64 ans (5).

- Les politiques sur le port du couvre-visage par les employés ont également été associées à une diminution des infections et des décès liés à la COVID-19 dans trois études (1, 6, 7). Cette association n'est cependant pas aussi forte ni aussi cohérente d'une analyse à l'autre que les politiques universelles sur le port du couvre-visage (7).
- Les recommandations relatives au port du couvre-visage dans la collectivité ne sont pas aussi efficaces que les politiques sur le port du couvre-visage (1). Il a été démontré dans deux études que la mise en œuvre de politiques sur le port du couvre-visage augmentait l'utilisation de ces deniers de 30 à 54 % (4, 11).
- Le respect de l'une ou de l'autre de ces INP est essentiel à la réussite. Une étude a notamment indiqué qu'un taux de respect de 75 % était nécessaire pour que le couvre-visage soit efficace en milieu communautaire et que si plus de 85 % des gens le portaient, les politiques de distanciation sociale n'avaient aucun effet supplémentaire sur l'atténuation du nombre de cas de COVID-19 (34).

Tableau 2. Études écologiques sur l'efficacité des politiques sur le port du couvre-visage ou des normes sociétales pour se protéger contre la COVID-19 en milieu communautaire (n = 27)

RÉFÉRENCE	DESCRIPTION DE L'ÉTUDE	RÉSULTATS PERTINENTS
À l'échelle mondiale (n = 8)		
Haug (2020) (32) Étude écologique À l'échelle mondiale Mars à août 2020	Cette étude visait à évaluer l'efficacité des INP pour atténuer la propagation du SRAS-CoV-2. Elle a utilisé quatre approches statistiques différentes et un ensemble de données codées portant sur 6 068 INP mises en œuvre entre mars et avril 2020 dans 79 territoires pour évaluer l'incidence des interventions gouvernementales sur le Rt. Les résultats ont ensuite été validés à l'aide de deux ensembles de données externes contenant 42 151 INP supplémentaires provenant de 226 pays.	• Trois méthodes différentes (ΔRt entre -0,018 et -0,12) ont établi un lien important entre le port du couvre-visage et une incidence importante sur le Rt. • Les résultats indiquent notamment qu'une combinaison appropriée d'INP est nécessaire pour freiner la propagation du virus.
Miyazawa (2020) *préimpression* (35)	L'étude visait à identifier le lien entre le taux de port du couvre-visage et le nombre cumulatif de	• En mars, le taux de gens qui ne portaient pas le couvre-visage a été associé positivement au nombre cumulatif de

Étude écologique 22 pays Mars à mai 2020	décès causés par la COVID-19 dans les pays. Les taux de port du couvre-visage ont été calculés à partir des réponses au sondage effectué entre le 9 et le 18 mars et entre le 26 avril et le 1er mai 2020, respectivement.	décès (β 0,0048, ET 0,011, R2 ajusté 0,680), mais pas en avril et en mai (β 0,0020, ET 0,011, R2 ajusté 0,466) • Les modèles de régression expliquaient 69 % de la variation du nombre cumulatif de décès par million dans 22 pays et ont déterminé que le taux de port du couvre-visage en mars était un prédicteur important.
Brauner (2020) *préimpression* (9) Étude écologique À l'échelle mondiale Janvier à mai 2020	Dans cette étude, un modèle hiérarchique bayésien a été utilisé pour estimer l'efficacité de huit INP dans 41 pays en établissant un lien entre les dates de mise en œuvre des INP et le nombre total de cas et de décès. Ces modèles ont examiné les politiques sur le port obligatoire du couvre-visage, le fait de limiter les rassemblements à moins de 1 000, à moins de 100 ou à moins de 10 personnes, le fait de fermer des entreprises à risque élevé de propagation, des entreprises non essentielles, des écoles et des universités et le fait de diffuser des ordres de confinement.	• Pendant les périodes où les gens étaient confinés, l'obligation de porter un couvre-visage en public n'a pas vraiment eu d'incidence. La réduction de la moyenne proportion associée au port obligatoire du couvre-visage dans (certains) lieux publics a atteint -1 % (IC à 95 %, de -13 à 8 %). • L'étude a donc voulu examiner les répercussions de l'adoption des politiques sur le port obligatoire du couvre-visage, même si celles-ci ont été mises en œuvre après les mesures de distanciation sociale et la fermeture de toutes les écoles et entreprises, mais elle a pris fin avant la levée de ces différentes restrictions.
Esra (2020) *préimpression* (29) Étude écologique À l'échelle mondiale Janvier à mai 2020	En utilisant les cas de SRAS-CoV-2 déclarés à l'échelle mondiale pour les inscrire dans un cadre de modèle bayésien, cette étude visait à estimer la transmission associée aux INP dans 26 pays et 34 États américains. Les INP examinées comprenaient l'obligation de rester à la maison, les limites imposées aux	• La réduction moyenne du Rt en ce qui concerne l'infection par le SRAS-CoV-2 a atteint 17 % (IC à 95 %, de 6 à 28 %) avec les politiques sur le port du couvre-visage.

	rassemblements, les fermetures d'école et les politiques sur le port du couvre-visage.	
Zhang (2020) (36) Étude écologique Chine, Italie, États-Unis Janvier à mai 2020	Cette analyse des tendances quotidiennes sur l'infection par le SRAS-CoV-2, effectuée du 23 janvier au 9 mai, porte spécifiquement sur la trajectoire linéaire des cas de COVID-19 et les changements qui se sont produits après la mise en œuvre des politiques sur le port du couvre-visage en Italie et à New York.	• On estime que le port du couvre-visage a permis d'éviter plus de 75 000 infections en Italie (entre le 6 avril et le 9 mai) et plus de 66 000 à New York (entre le 17 avril et le 9 mai). • Alors que d'autres régions du monde affichaient une augmentation linéaire, cette étude montre que la mise en œuvre des politiques sur le port du couvre-visage en Italie et à New York a réduit la propagation de la COVID-19.
Leffler (2020) (37) Étude écologique 196 pays Janvier à mai 2020	Cette étude utilise les données sur la mortalité dans 196 pays pour évaluer l'incidence du port du couvre-visage sur la mortalité par COVID-19 par habitant (des données jusqu'au 9 mai 2020 ont été fournies).	• La durée du port du couvre-visage par le public avait un lien négatif indépendant avec la mortalité ($p < 0,001$). • Dans les pays où les normes culturelles ou les politiques publiques favorisaient le port du couvre-visage, la mortalité par habitant due au coronavirus n'a augmenté en moyenne que de 16,2 % chaque semaine, contre 61,9 % chaque semaine dans les autres pays.
Abaluck (2020) *préimpression* (10) Étude écologique À l'échelle mondiale Février et mars 2020	Cette étude analyse donc l'incidence du port du couvre-visage en tenant compte du lien entre les normes d'utilisation des couvre-visages et la propagation de la COVID-19 au niveau national. Les pays qui ont des normes préexistantes en vertu desquelles toutes les personnes malades doivent porter un couvre-visage ont été comparés aux pays qui n'avaient pas adopté de telle	• Les pays qui ont des normes préexistantes en vertu desquelles les personnes malades doivent porter un couvre-visage (Corée du Sud, Japon, Hong Kong et Taïwan) ont été parmi les pays les plus efficaces pour contenir la propagation de l'épidémie. • Le taux de croissance quotidien moyen de cas confirmés est de 18 % dans les pays qui n'avaient aucune norme préexistante sur le port du couvre-visage et de

	obligation, mais ont ensuite décidé d'obliger les personnes infectées à porter un couvre-visage, ainsi qu'aux pays qui n'ont ni norme ni recommandation officielle en ce qui concerne le port du couvre-visage. Les pays qui comptent au moins 5 millions d'habitants et ont au moins 8 jours de données disponibles après le premier jour où 100 cas ont été signalés ont été inclus dans l'étude.	10 % dans les pays ayant déjà adopté de telles normes. • Le taux de croissance quotidien moyen de décès est de 21 % dans les pays qui n'avaient aucune norme préexistante sur le port du couvre-visage et de 11 % dans les pays ayant déjà adopté de telles normes. • Après correction pour les interventions simultanées, l'incidence des normes sur le port du couvre-visage (β [ET]) était de 0,076 [0,030], p < 0,05 pour les cas et de 0,107 [0,024], p < 0,01 pour les décès.
Kenyon (2020) *préimpression* (38) Étude écologique 49 pays Janvier à mars 2020	Le lien entre les cas de COVID-19 et la promotion nationale du port des couvre-visages en public a été analysé, en tenant notamment compte de l'âge de l'épidémie et de l'intensité des tests effectués. Seuls les pays ayant au moins 500 cas cumulatifs et dont le premier cas a été signalé avant le 7 mars 2020 ont été inclus. Ainsi, 8 pays sur 49 préconisaient le port de couvre-visage en public (Chine, Tchéquie, Hong Kong, Japon, Singapour, Corée du Sud, Thaïlande et Malaisie).	• Les résultats de l'analyse multivariée montrent que le port du couvre-visage en public avait un lien négatif avec le nombre de cas de COVID-19 par habitant (β -326, IC à 95 %, de -601 à -51, P = 0,021).
Amérique du Nord (n = 13)		
Karaivanov (2020) *préimpression* (4) Étude écologique Canada	L'incidence des INP a été évaluée à l'aide de données accessibles au public portant notamment sur les politiques sur le port des couvre-visages en Ontario, sur d'autres INP mises en œuvre au Canada et sur le nombre de cas de COVID-19.	• Après un délai de deux semaines, les politiques sur le port des couvre-visages ont entraîné une réduction hebdomadaire de 25 à 31 % des cas de COVID-19. • Les politiques sur le port du couvre-visage ont également augmenté de 30 % l'utilisation de ces derniers.

Juillet et août 2020		
Spiegel (2020) *préimpression* (1) Étude écologique États-Unis Mars à octobre 2020	Cette analyse de régression a porté sur l'augmentation du nombre de décès attribuables à la COVID-19 et sur l'incidence des politiques sur le port obligatoire du couvre-visage dans chacun des comtés américains entre mars et octobre.	• Les politiques sur le port obligatoire du couvre-visage ont entraîné pendant 4 et 6 semaines un taux d'augmentation des décès inférieur de 1 % au taux obtenu lorsqu'aucune politique sur le port du couvre-visage n'était en vigueur, $p < 0,01$. • Les politiques sur le port du couvre-visage se sont révélées efficaces dans chacune des spécifications du modèle, en plus de s'accompagner de coûts économiques et sociaux relativement faibles. Ce résultat était à la fois significatif sur le plan statistique et important sur le plan de la portée. • Les politiques sur le port du couvre-visage présentées dans les analyses n'offraient pas toutes la même protection aux employés. • Les recommandations relatives aux couvre-visages n'ont pas eu d'effet protecteur constant comparativement au taux de mortalité.
Shacham (2020) *préimpression* (28) Étude écologique États-Unis Juin à septembre 2020	Cette étude a analysé l'incidence sur les cas de COVID-19, pendant une période de trois mois, d'une politique sur le port des couvre-visages mise en œuvre dans deux comtés d'une région métropolitaine qui en comptait cinq.	• Les politiques des comtés sur le port du couvre-visage ont été associées à une croissance beaucoup plus faible avec le temps du nombre de cas de COVID-19 comparativement aux comtés voisins qui n'avaient pas mis de telles politiques en œuvre. • La modélisation brute avec un indicateur de différence dans la différence a montré que trois semaines après la mise en œuvre de la politique sur le port du couvre-visage, les comtés qui avaient adopté une telle politique avaient un taux de croissance quotidien de COVID-19 de

		1,32 fois inférieur (diminution de 32 %) à celui des comtés n'ayant pas adopté ce type de politique. • Douze semaines après la mise en œuvre de la politique, la croissance quotidienne moyenne des cas de COVID-19 dans les pays n'ayant pas adopté ce type de politique était de 2,42 % (± 1,92), ce qui veut dire qu'elle était beaucoup plus élevée que la croissance quotidienne moyenne des cas de COVID-19 dans les pays ayant une politique sur le port du couvre-visage (1,36 % [± 0,96 %]) (p < 0,001).
Yilmazuday (2020) *préimpression* (34) Étude écologique États-Unis Février à août 2020	Les données au niveau du comté sur les changements dans le nombre de cas ou de décès liés à la COVID-19 ont été analysées en utilisant un plan de différence dans la différence et les interactions sociales mesurées par les données de Google sur la mobilité. Les comtés ont été répartis en deux catégories, soit ceux dans lesquels les gens portaient un couvre-visage et ceux dans lesquels les gens n'en portaient pas, en fonction des données fournies par Mask-Wearing Survey Data. L'incidence du port du masque sur la relation causale entre les cas de COVID-19 et les interactions sociales a ensuite été analysée.	• Il faut que plus de 75 % des gens d'un comté portent un couvre-visage pour que cela réduise le nombre de cas et de décès liés à la COVID-19. Les effets de l'interaction sociale sur la COVID-19 ont été éliminés de façon statistique lorsque plus de 85 % des habitants d'un comté portaient « toujours » un masque dans les établissements publics.
Matzinger (2020) *préimpression* (8) Étude écologique	Une analyse de régression a été effectuée pour évaluer l'incidence des INP sur les cas de COVID-19, ainsi que sur les hospitalisations et	• L'analyse de régression a montré que la fermeture des écoles et des bars et le port du couvre-visage ont eu des effets très importants sur le niveau d'infection, les

États-Unis Mars à juillet 2020	les décès liés à ce virus. Les politiques sur le port du couvre-visage ont ensuite été mises en œuvre entre mars et juillet, ce qui a permis d'évaluer l'effet tant des politiques précoces que des politiques tardives.	hospitalisations et les taux de mortalité aux États-Unis pendant la pandémie de COVID-19. • On a observé dans quatre États (IL, NJ, MA, MD) une baisse des taux d'infection après la mise en œuvre d'une politique sur le port du couvre-visage, baisse qui a été suivie d'une diminution des hospitalisations et des décès deux fois supérieure. • Les données présentées dans l'étude sont liées à des politiques sur le port du couvre-visage mises en œuvre à différents moments et les auteurs montrent de façon prévisible les réductions de taux qui ont suivi. Les politiques mises en œuvre plus tard sont liées à des points d'inflexion ultérieurs. Cela appuie la preuve que ces réductions de taux étaient attribuables au port de couvre-visage plutôt qu'à d'autres changements potentiels dans la mobilité ou le comportement. • Les politiques sur le port du couvre-visage, qu'elles aient été mises en œuvre de façon précoce ou tardive, ont toutes deux été efficaces pour réduire la propagation de la COVID-19. • Le délai entre la mise en œuvre des politiques sur le port du couvre-visage et la réduction des infections par la COVID-19 variait de 16 à 23 jours. • Une exception en ce qui concerne l'effet des politiques précoces sur le port du couvre-visage est apparue dans les données de l'État de New York, qui a rendu les couvre-visages obligatoires

		après avoir déjà transformé en nombre décroissant un nom de cas d'infections auparavant en croissance rapide. La politique sur le port du couvre-visage n'a pas eu d'autre effet suppresseur sur le taux d'infection. Cependant, lorsque l'économie de l'État de New York a repris et que le nombre d'infections a recommencé à augmenter, le niveau de l'augmentation a été très inférieur à celui que l'on trouvait dans les États qui ont rouvert les entreprises et écoles sans avoir mis en œuvre de politiques sur le port du couvre-visage et montre donc que les effets de cette politique se sont poursuivis lorsque les autres INP ont été levées.
Kaufman (2020) (39) Étude écologique États-Unis Janvier à juillet 2020	Cette étude a estimé le fardeau excessif associé à la COVID-19 pour deux types d'États américains, soit ceux qui avaient adopté une stratégie de réouverture fondée sur des preuves, incluant la réouverture des salles à manger intérieures après la mise en œuvre d'une politique sur le port du couvre-visage dans l'ensemble de l'État, et ceux qui n'avaient pas établi de stratégie de réouverture fondée sur des preuves et avaient donc décidé de rouvrir les salles à manger intérieures sans mettre en œuvre de politique sur le port du couvre-visage dans tout l'État.	• On estime que plus de 50 000 décès supplémentaires ont été évités en six semaines dans les 13 États qui ont mis en œuvre des politiques sur le port du couvre-visage avant la réouverture. • Huit semaines après la réouverture, on peut voir que dans les États qui ont rouvert sans avoir adopté de politique sur le port du couvre-visage, le nombre de cas excédentaires par 100 000 résidents est dix fois plus élevé que dans les États qui ont adopté de telles politiques (643,1 cas; IC à 95 %, de 406,9 à 879,2 comparativement à 62,9 cas; IC à 95 %, de 12,6 à 113,1). • Après six semaines, les cas excédentaires auraient pu diminuer de 90 %, passant de 576 371 à 63 062, et les décès excédentaires auraient aussi pu être réduits de 80 %, passant de 22 851 à 4858, si les États avaient mis en œuvre

		des politiques sur le port du couvre-visage avant la réouverture.
Yang (2020) *préimpression* (31) Étude écologique États-Unis Janvier à juillet 2020	Cette étude a analysé les valeurs de Rt au niveau du comté au fil du temps grâce à un modèle de métapopulation mécaniste avant de les associer à des caractéristiques au niveau du comté et à des INP comme la fermeture des écoles et des garderies, l'interdiction des visites dans les maisons de soins infirmiers, les ordres de confinement et le port d'un couvre-visage. À l'exception de la politique sur le port du couvre-visage qui était claire, les fermetures ont engendré une certaine confusion puisque les gens continuaient à se rendre sur leur lieu de travail. Le nombre d'employés sur les lieux de travail a cependant diminué au fur et à mesure que le nombre de fermetures augmentait.	• Alors que les répercussions des interventions individuelles ont pu être mesurées par des stratégies d'intervention à plusieurs niveaux, il n'est pas possible d'estimer les répercussions potentielles lorsque seules ces interventions sont effectuées. • Les politiques sur le port du couvre-visage ont cependant été associées à une réduction de 18 % du Rt (IC à 95 %, de 16 à 20 %).
Tchernozhukov (2020) (6) Étude écologique États-Unis Mars à juin 2020	Cette étude utilise des données sur les cas et des renseignements sur les modifications apportées aux INP pour évaluer l'incidence de ces INP sur le taux de croissance des cas confirmés de COVID-19 et des décès associés. La politique sur le port du couvre-visage évaluée dans cette étude obligeait les employés à porter un masque. Les INP examinées incluaient les ordres de confinement, ainsi que	• Les résultats obtenus attribuent une réduction de 9 % du taux hebdomadaire de cas et de 15 % du taux de décès à la période de 14 jours qui s'est écoulée avant que le port du couvre-visage soit imposé aux employés, $p < 0,01$. Plusieurs types d'analyse ont donné des chiffres semblables.

	des fermetures d'entreprises et d'écoles.	
Maloney (2020) *préimpression* (40) Étude écologique États-Unis Mars à juin 2020	Cette étude a utilisé un algorithme d'apprentissage machine non paramétrique pour vérifier l'hypothèse selon laquelle les politiques sur le port du couvre-visage étaient associées à des réductions du nombre de nouveaux cas de COVID-19. Les données sur les nouveaux cas COVID-19 dans 38 États américains ont été analysées dans le mois qui précédait et suivait la date de mise en œuvre de la politique.	• Analyse de tous les États : le nombre total moyen de nouveaux cas de COVID-19 avant et après l'entrée en vigueur de la politique sur le port du couvre-visage était de 654 (N = 1 138, ET = 1 357) comparativement à 639 (N = 1 177, ET = 975), respectivement. Dans 13 États, le nombre moyen de cas était plus élevé avant qu'après l'adoption de cette politique. • Analyse à l'échelle de l'État : à l'exception de la Géorgie et du Wyoming, les États dont la moyenne était plus élevée avant la mise en œuvre de la politique sur le port du couvre-visage se sont révélés statistiquement significatifs puisque la mise en œuvre de la politique dans onze États a permis de réduire de fortement à modérément le nombre de cas de COVID-19. • Il a été démontré que la cohésion sociale et les liens sociaux étroits étaient les meilleurs facteurs de prédiction pour savoir dans quels États les politiques sur le port du couvre-visage donnaient de bons résultats, sans oublier qu'ils indiquent également le niveau de conformité entre les différents États.
Li (2020) (30) Étude écologique États-Unis	L'analyse du nombre total d'infections et du nombre d'infections quotidiennes dans les 15 États les plus infectés des États-Unis a été menée afin d'étudier les répercussions des INP, comme la distanciation sociale, les ordres de	• L'analyse révèle que, malgré les ordres de confinement, la plupart des États ont vu une tendance à la hausse dans le nombre de nouvelles infections quotidiennes. Huit États ont vu une tendance à la baisse ou un ralentissement du nombre d'infections

Mars à mai 2020	confinement et les politiques sur le port du couvre-visage (six États n'avaient pas d'ordonnance en ce qui concerne le port du couvre-visage, neuf États avaient des politiques sur le port du couvre-visage) entre le 1er mars et le 18 mai 2020. Les variations dans les pentes de régression après la mise en œuvre des INP ont été mesurées et comparées entre les États.	après l'adoption de politiques sur le port du couvre-visage. • En revanche, dans les États où ces couvre-visage n'étaient pas obligatoires, la tendance à la hausse dans le nombre de cas s'est prolongée jusqu'à deux mois de plus. • L'analyse estime qu'environ 252 000 infections ont été évitées dans les sept États qui ont adopté des politiques sur le port obligatoire du couvre-visage avec une proportion prévue de cas évités variant entre 3,2 % et 48 % jusqu'au 18 mai.
Lyu (2020) (7) Étude écologique États-Unis Mars à mai 2020	Cette étude a mesuré les effets des politiques gouvernementales des États sur le port du couvre-visage par le public, en fonction des données publiées par 15 États (et DC) du 8 avril au 15 mai 2020. Les données utilisées sur les cas au niveau du comté portaient sur la période entre le 31 mars (sept jours avant que le premier État n'adopte de politique port du couvre-visage) et le 22 mai. Entre le 17 avril et le 9 mai 2020, l'étude a également évalué l'incidence dans les 20 États qui exigeaient que certains employés portent un couvre-visage.	• Il y a eu une baisse importante du taux de croissance quotidien du nombre de cas de COVID-19 après l'imposition du port du couvre-visage, un effet qui a augmenté avec le temps. • Le taux de croissance quotidien du nombre de cas de COVID-19 a diminué de 0,9 (1 à 5 jours), de 1,1 (6 à 10 jours), de 1,4 (11 à 15 jours), de 1,7 (16 à 20 jours) et de 2,0 % (21 jours et plus) après la mise en œuvre des politiques obligatoires sur le port du couvre-visage. • On a estimé que l'imposition de ces politiques avait pu permettre d'éviter entre 230 000 et 450 000 cas d'ici au 22 mai. • L'incidence de l'utilisation obligatoire d'un couvre-visage par les employés était cependant faible et non statistiquement significative.

Yang (2020) *préimpression* (5) Étude écologique États-Unis Avril 2020	Cette étude a utilisé une régression linéaire qui tenait compte des données sur la mobilité à New York pour estimer l'efficacité des INP, tant pour l'ensemble de la population que par groupe d'âge.	• Les politiques sur le port du couvre-visage ont entraîné une réduction de 6,6 % (IC à 95 %, de 0,8 à 12,4 %) des cas au cours du premier mois et une réduction de 3,4 % (IC à 95 %, de -1,9 à 8,6 %) pour l'ensemble des huit semaines de confinement. • Cet effet variait selon l'âge. Il a atteint 20,8 % (IC à 95 %, de -0,1 à 41,6 %) pour les 65 à 74 ans et 20,8 % (IC à 95 %, de -0,9 à 42,5 %) pour les 75 ans et plus pendant le premier mois, avant de se maintenir à des niveaux semblables par la suite. Chez les 25 à 44 ans et les 45 à 64 ans, l'efficacité s'est chiffrée à 4,5 % (IC à 95 %, de -0,6 à 9,7 %) et à 8,1 % (IC à 95 %, de -0,1 à 16,1 %) au cours du premier mois, respectivement. Elle a toutefois considérablement diminué par la suite, probablement en raison du comportement inversé face au risque.
Xu (2020) (41) Étude écologique États-Unis Mars et avril 2020	Cette étude a analysé les liens entre les ordres de confinement et la recommandation de porter un couvre-visage en lien avec la pandémie de COVID-19. Les tendances temporelles pour les nouveaux cas et les décès quotidiens de COVID-19 et de Rt ont été modélisées. Le CDC a recommandé aux gens de porter un couvre-visage le 3 avril 2020.	• Les changements globaux dans la pente des nouveaux décès quotidiens masqués ont atteint 0,13 (IC à 95 %, de 0,25 à 0,07). • Quant aux changements globaux dans la pente des nouveaux cas quotidiens attribuables au port du couvre-visage, ils se chiffraient à 0,10 (IC à 95 %, de 0,18 à 0,08).
Australie (n = 1)		
Scott (2020) *préimpression* (11) Étude écologique	En raison d'une résurgence de la COVID-19 à Melbourne, une politique sur le port obligatoire du couvre-visage a été mise en œuvre le 22 juillet, ce qui a donné lieu à	• L'introduction d'une politique sur le port obligatoire du couvre-visage a été associée à une réduction du nombre de

Australie Juillet et août 2020	une expérience naturelle qui a permis d'évaluer l'indice de la politique sur le taux de croissance de l'épidémie, puisque l'introduction de la politique s'est faite sans que d'autres changements aux restrictions ne soient apportés.	cas estimée à 23 % du Rt, qui est ainsi passé de 1,18 à 0,91. • Le changement dans la croissance de l'épidémie a été observé huit jours après la mise en œuvre de la politique, ce qui est conforme au temps d'incubation de la COVID-19 auquel s'ajoute le temps nécessaire pour tester et signaler de nouveaux cas. • L'analyse des images des personnes qui circulent dans les espaces publics a révélé que le port du couvre-visage est passé d'environ 43 % à 97 %. Les données du sondage ont quant à elles révélé qu'avant l'adoption de la politique, 44 % des participants avaient déclaré porter « souvent » ou « toujours » un masque alors qu'après la mise en œuvre de la politique, 100 % d'entre eux ont déclaré « toujours » le faire.
Europe (n = 4)		
Sruthi (2020) *préimpression* (33) Étude écologique Suisse Mars à septembre 2020	Cette étude visait à développer une relation systématique entre les niveaux d'INP mis en œuvre dans les 26 cantons en Suisse et leurs contributions respectives au Rt. La politique sur le port du couvre-visage ne s'appliquait que dans les transports en commun et les écoles secondaires.	• La politique sur le port du couvre-visage dans les transports en commun et les écoles secondaires a contribué à réduire le Rt de 0,025 (IC : 0,018 à 0,03) comparativement au niveau de référence obtenu alors qu'aucune politique n'était en vigueur. • Lorsque ces données ont été analysées séparément, l'on a pu estimer une réduction de 0,011 (IC : 0,008 à 0,0127) et de 0,0139 (IC : 0,0132 à 0,0144) respectivement grâce au port du couvre-visage dans les écoles secondaires et les transports en commun. • Certains endroits ont également obligé les employés dans les ateliers à porter le

		couvre-visage, mais cela n'a donné lieu à aucune autre réduction du Rt.
Mergel (2020) *préimpression* (42) Étude écologique Allemagne Avril à juillet 2020	Cette étude a étudié l'impact du port du couvre-visage sur le Rt quotidien pour la COVID-19 et sur le taux de mortalité en raison de la COVID-19. L'étude s'est également penchée sur la mise en œuvre et la levée des INP (rassemblements en groupe interdits, restriction en ce qui concerne la fréquentation des lieux publics et les contacts privés, obligation de porter le couvre-visage dans les espaces publics et levée partielle du confinement).	• Dans le cadre de cette étude, le port du couvre-visage est devenu obligatoire à compter du 27 avril, après toutes les autres restrictions. • Il n'a cependant pas été possible de faire de distinction entre l'effet positif potentiel du printemps et de l'été sur la trajectoire de la pandémie et l'effet positif associé à la mise en œuvre de la politique sur le port du couvre-visage. • Les auteurs de l'étude n'ont détecté aucun impact sur le Rt attribuable à la politique sur le port du couvre-visage. • Pendant la période pendant laquelle la politique sur le port du couvre-visage a été mise en œuvre, le niveau de fatalité des cas a diminué, passant de 7 % le 27 avril à 1 % en juillet.
Pedersen (2020) *préimpression* (43) Étude écologique Italie Février à juillet 2020	Pour déterminer quelles mesures de la santé publique ont modifié la dynamique des maladies, des données régionales et nationales ont été utilisées pour estimer certains points de changement associés à la dynamique de la COVID-19. Un point de virage se définit comme le point temporel déterminé à partir duquel un changement se produit dans le nombre quotidien de cas confirmés en raison d'une intervention publique effectuée entre 7 et 11 jours auparavant.	• En Vénétie, un point de virage a été défini le 21 avril (IC à 95 %, de 14 à 28), ce qui correspond au délai comparativement à la date à laquelle la politique sur le port obligatoire du couvre-visage est entrée en vigueur le 14 avril. • En Toscane, un point de virage a été défini le 16 avril (IC à 95 %, de 8 à 24), ce qui correspond au délai comparativement à la date à laquelle la distribution de couvre-visage a débuté, soit le 7 avril. • Les points de virage dans les nombres régionaux de cas de COVID-19 correspondent bien aux dates d'entrée en vigueur des politiques sur le port des couvre-visages.

Mitze (2020) *non publié* (27) Étude écologique Allemagne Janvier à mai 2020	Une méthode de contrôle synthétique a utilisé des données sur l'épidémie provenant de l'Allemagne pour évaluer l'effet des couvre-visages sur la propagation de la COVID-19. La ville de Jena a mis en œuvre une politique sur le port couvre-visage du couvre-visage le 6 avril 2020. Jena a ensuite été comparée à un emplacement témoin synthétique qui suivait de près la tendance pour la COVID-19 avant la mise en place des couvre-visages obligatoires à Jena.	• Dix jours après que les masques soient devenus obligatoires en Allemagne, le nombre cumulatif de cas enregistrés de COVID-19 a diminué de 2,3 à 13 %. • Une fois la politique sur le port des couvre-visages mise en œuvre, le taux de croissance quotidien des infections signalées a baissé de 18,94 %. Après avoir tenu compte de l'effet du traitement dans les grandes villes, les auteurs ont conclu à une réduction d'environ 40 % du taux de croissance des infections.
Moyen-Orient (n = 1)		
Saki (2020) *préimpression* (44) Étude écologique Iran Juin et juillet 2020	Cette étude a examiné les effets de la mise en œuvre d'une politique sur la distanciation sociale et de sa levée, ainsi que les effets des politiques sur le port du couvre-visage sur la tendance temporelle des nouveaux cas de COVID-19. Les données ont été recueillies pendant deux semaines avant et après la mise en œuvre de chacune des politiques.	• Avant la mise en œuvre de la politique sur le port du couvre-visage dans la collectivité, environ 2 491,97 nouveaux cas confirmés s'ajoutaient chaque jour et on pouvait voir la pente ascendante des cas ($p < 0,001$). • Après la mise en œuvre de la politique sur le port du couvre-visage, une tendance à la baisse est apparue dans le nombre de cas confirmés au quotidien, ce qui a entraîné un changement de -25,84 ($p < 0,001$) de la pente de la courbe de l'épidémie.

IC = intervalle de confiance, RR = rapport de risque, INP = intervention non pharmaceutique, NYC = New York, RR = rapport de cotes, Rt = nombre de reproduction effectif, ET = erreur type

RECHERCHE DE SYNTHÈSE VISANT À ÉVALUER L'EFFICACITÉ

Six études de synthèse sur l'effet protecteur associé au port des couvre-visages en milieu communautaire ont été recensées, dont quatre revues systématiques et deux revues rapides (tableau 3). La première revue a été effectuée en avril 2020. Deux des examens ultérieurs incluaient des études publiées jusqu'au début d'octobre. Ces revues permettent de discerner une progression dans la preuve entre avril et octobre. Bon nombre des

études incluses dans ces revues sont jugées pertinentes dans le cadre de la présente revue rapide et figurent donc dans les tableaux de données présentés ci-dessus.

Tableau 3. Recherche de synthèse sur le port des couvre-visages pour prévenir la propagation de la COVID-19 en milieu communautaire (n = 6)

RÉFÉRENCE	DESCRIPTION DE L'ÉTUDE	RÉSULTATS PERTINENTS
Examens systématiques (n = 4)		
Li (2020) *préimpression* (45) Examen systématique et méta-analyse Chine, Inde, Thaïlande, États-Unis Octobre 2020	Cet examen visait à évaluer l'efficacité du port des couvre-visages comme mesure de protection contre l'infection par le SRAS-CoV-2. Six études cas/témoins ont été incluses. Cinq portaient sur les travailleurs de la santé et une sur la population en général. L'examen contient les documents disponibles jusqu'en octobre 2020. Cote AMSTAR : haute qualité Remarque : une méta-analyse (MA) a été effectuée. Dans cette étude, un modèle d'effets aléatoires a été utilisé lorsque I^2, la mesure de l'hétérogénéité de l'étude, était supérieure à 50 % alors qu'un modèle à effet fixe a plutôt été utilisé lorsqu'elle était inférieure à ce niveau.	• Dans l'ensemble, le port d'un masque a réduit considérablement le risque d'infection par le SRAS-CoV-2 (RC de la méta-analyse : 0,38, IC à 95 %, de 0,21 à 0,69, I^2 = 54,1 %). • Dans une analyse de sous-groupe, les travailleurs de la santé qui portaient un couvre-visage avaient environ 70 % moins de risques d'attraper la COVID-19 (RC de la méta-analyse : 0,29, IC à 95 %, de 0,18 à 0,44, I^2 = 11 %). • En ce qui concerne la seule étude effectuée sur la population en général, le port d'un couvre-visage a réduit le risque d'infection par le SRAS-CoV-2 d'environ 28 % (RC 0,72, IC à 95 %, de 0,46 à 1,12) et donné les résultats suivants, après ajustement pour tenir compte des facteurs de confusion (RCA 0,23, IC à 95 %, de 0,09 à 0,59) (18). • Des études menées en Chine ont montré un effet protecteur plus élevé que dans d'autres pays : Chine (RC de la méta-analyse : 0,21, IC à 95 %, de 0,09 à 0,53, I^2 = 26,1 %) comparativement aux autres pays (RC de la méta-analyse : 0,55, IC à 95 %, de 0,32 à 0,95, I^2 = 39,3 %).
Coclite (2020) (46)	Cet examen visait à résumer les données probantes sur l'efficacité du port du couvre-visage dans la collectivité pour réduire la	• Aucune étude d'observation sur le port du couvre-visage dans la collectivité pour réduire la propagation de la COVID-19 n'a été relevée.

Examen systématique et méta-analyse Chine, Hong Kong, Iran, Israël, Italie, Japon, Malaisie, Pays-Bas, Arabie saoudite, Corée du Sud, Taiwan, Royaume-Uni, États-Unis Avril 2020	propagation de la maladie. Trente-cinq études ont été incluses (3 ECR, 13 modèles prédictifs, 10 études d'observation et 9 expériences en laboratoire). Sept modèles prédictifs et une étude de laboratoire étaient propres au SRAS-CoV-2. L'examen contient la documentation disponible jusqu'au 22 avril 2020. Cote AMSTAR : haute qualité	• Les modèles mathématiques indiquent une diminution de la mortalité lorsque le port du couvre-visage dans la population est presque universel, peu importe l'efficacité du couvre-visage. • Tous les types de masques peuvent réduire l'exposition aux aérosols. Cependant, les respirateurs personnels sont plus efficaces que les masques chirurgicaux, qui sont plus efficaces que les couvre-visages maison. • Les ECR ont montré une tendance vers l'effet protecteur du port du couvre-visage comparativement à l'absence de couvre-visage (RCA 0,90, IC à 95 %, de 0,78 à 1,05), mais ces résultats n'étaient pas significatifs. Des conclusions semblables ont été indiquées dans des études d'observation.
Chou (2020) (47) Chou (2020) (mise à jour 1) (48) Chou (2020) (mise à jour 2) (49) Chou (2020) (mise à jour 3) (50) Revue rapide en direct Chine, Thaïlande, États-Unis Octobre 2020	L'efficacité des masques N95, des masques chirurgicaux et des masques en tissu dans la communauté et les établissements de soins de santé pour prévenir les infections respiratoires virales a été évaluée dans cet examen systématique en direct. Dates des recherches : Recherche originale : 2002 - 2 juin 2020 Mise à jour 1 : 2 juin au 2 juillet 2020 Mise à jour 2 : 3 juillet au 2 août 2020 Mise à jour 3 : 3 août au 2 octobre 2020	• Dans la première version et la deuxième mise à jour de cette revue, aucune étude visant à évaluer l'efficacité des couvre-visages pour prévenir les infections par le SRAS-CoV-2 dans les milieux communautaires n'a été indiquée. • La première mise à jour a présenté une étude de cohorte comprenant 124 ménages avec un cas de référence de SRAS-CoV-2 et 355 contacts familiaux non infectés. Les ménages dans lesquels les couvre-visages ont été portés par au moins un membre de la famille (y compris le cas de référence) avant l'apparition des symptômes ont été associés à une diminution du risque d'infections accidentelles (RCA 0,21, IC à 95 %, de 0,06 à 0,79). Il n'y a pas eu d'association

	Cote AMSTAR : qualité modérée à élevée (aucun protocole *a priori*, l'évaluation de la qualité n'a pas été effectuée avec un instrument officiel, rapport sous-optimal, par exemple, incertitude quant à la présence de responsables du double examen pour l'évaluation de la qualité).	entre le port du couvre-visage après l'apparition de la maladie dans le cas de référence et le risque d'infection par le CoV-2 du SRAS chez les membres de la famille (17). • La troisième mise à jour comprenait une étude cas/témoins en Thaïlande. Le fait de porter un couvre-visage en tout temps a été associé à une diminution du risque d'infection par le SRAS-CoV-2 (RCA 0,23, IC à 95 %, de 0,09 à 0,60), alors que le port non uniforme d'un couvre-visage n'a pas été associé à une diminution du risque (RCA 0,87, IC à 95 %, de 0,41 à 1,84). Le type de masque (masque médical seulement, masque non médical seulement, ou les deux) n'était pas lié de manière indépendante au risque d'infection par le SRAS-CoV-2 (p = 0,54) (18).
Chaabna (2020) (51) Examen systématique et méta-analyse Australie, Chine, France, Allemagne, Hong Kong, Thaïlande, États-Unis Mai 2020	Les données probantes sur l'efficacité des masques en tissu et des masques médicaux pour prévenir la transmission des infections respiratoires dans les milieux communautaires ont été évaluées dans le cadre de cet examen. Douze études ont été incluses, dont une seule portait sur le SRAS-CoV-2. L'examen contient les documents disponibles jusqu'au 12 mai 2020. Cote AMSTAR : qualité médiocre (absence de protocole *a priori* et de responsables du double examen, examen effectué seulement dans	• Aucune étude primaire sur l'efficacité du couvre-visage en tissu pour prévenir la transmission des infections respiratoires n'a été relevée. • La méta-analyse a révélé que le port d'un masque médical réduisait considérablement le risque de transmission d'infections respiratoires (RC combiné = 0,66, IC à 95 %, de 0,54 à 0,81). • Une étude portant spécifiquement sur le SRAS-CoV-2 a été sélectionnée. Cette étude de cohorte rétrospective a démontré que les masques médicaux sont efficaces pour réduire la transmission du SRAS-CoV-2 lorsqu'ils sont utilisés avant que les personnes infectées ne développent des symptômes (17).

	deux bases de données, aucune évaluation officielle de la qualité).	
Revues rapides (n = 2)		
Warkentin (2020) *non publiée* (52) Revue rapide Canada, Chine, Allemagne, Israël, Japon, Afrique du Sud, Thaïlande, Ouganda, Royaume-Uni, États-Unis Août 2020	Cette revue rapide visait à évaluer les données probantes sur l'incidence du port du couvre-visage en milieu communautaire en ce qui concerne la susceptibilité à la COVID-19 et la transmission de ce virus, ainsi que les répercussions sur l'efficacité du couvre-visage selon la façon de porter le couvre-visage, qu'elle soit uniforme ou non. Trente et une études ont été incluses (21 modèles principaux, 10 modèles sur l'efficacité des masques et 5 sur la conformité dans le port du couvre-visage). Les 17 études primaires sur l'efficacité des couvre-visages comprenaient 9 études écologiques, 1 étude de cohorte, 1 étude cas/témoin et 6 études de rapport de cas/épizootie. La recherche documentaire portait sur la période entre décembre 2019 et août 2020. Cote AMSTAR : qualité médiocre (absence de protocole *a priori*, de responsables du double examen et d'évaluation officielle de la qualité).	• Il n'y avait pas suffisamment de preuves pour quantifier l'efficacité de l'utilisation du couvre-visage. • Dans l'ensemble, le port du couvre-visage dans la collectivité a réduit le nombre de cas de COVID-19 au sein d'une population. • Les rapports de cas ont toujours indiqué moins de cas secondaires lorsque les cas de référence ou leurs contacts portaient des couvre-visages. • Des études de modélisation ont révélé que le port d'un couvre-visage, combiné à d'autres stratégies d'atténuation, pouvait réduire la mortalité causée par la COVID-19 et éviter une résurgence des cas dans les endroits où les mesures de confinement avaient déjà réduit le nombre de cas. • Aucune étude n'a été menée sur l'incidence du port du couvre-visage dans les écoles.
The Royal Society (2020)) *non publiée* (53) Revue rapide Chine	Cette revue rapide visait à évaluer l'efficacité des masques en tissu et des couvre-visages dans le grand public et dans les établissements de soins de santé. Elle comprenait notamment une comparaison internationale du moment où la politique sur les couvre-visages a	• Les résultats ont révélé qu'aucun examen systématique et aucune méta-analyse n'avaient encore été effectués sur l'efficacité des types de masques en tissu autres que les masques chirurgicaux et les masques N95.

Juin 2020	été introduite. Une seule étude sur le SRAS-CoV-2 était incluse. La revue contient la documentation disponible jusqu'au 26 juin 2020. Cote AMSTAR : qualité médiocre (peu de détails sur la façon d'effectuer l'étude : recherche, sélection, évaluation ou extraction des données ou de l'analyse).	• Les données empiriques et expérimentales sur le port du couvre-visage dans la collectivité ou sur le port du couvre-visage en tissu sont limitées. • Une étude portant spécifiquement sur le SRAS-CoV-2 a été sélectionnée. Cette étude de cohorte rétrospective a démontré que les masques médicaux sont efficaces pour réduire la transmission du SRAS-CoV-2 lorsqu'ils sont utilisés avant que les personnes infectées ne développent des symptômes (17). • La méta-analyse fondée sur la littérature non liée au SRAS-CoV-2 dans le milieu des soins de santé a indiqué que les masques en gaze ou en tissu (RR = 0,46; IC à 95 %, de 0,22 à 0,97; N = 746) et les masques en papier (RR = 0,61; IC à 95 %, de 0,41 à 0,90; N = 166) assuraient une certaine protection comparativement au fait de ne pas porter de masque.

RCC = rapport de cotes corrigé, IC = intervalle de confiance, ECR = essai clinique randomisé

Méthodologie

Une analyse documentaire quotidienne (ouvrages publiés et en prépublication) est effectuée par le Groupe des sciences émergentes de l'Agence de la santé publique du Canada. L'analyse a compilé les ouvrages sur la COVID-19 depuis le début de l'éclosion et est mise à jour quotidiennement. Les recherches visant à extraire les ouvrages pertinents sur la COVID-19 sont menées dans Pubmed, Scopus, BioRxiv, MedRxiv, ArXiv, SSRN, Research Square et dans les centres d'information de la COVID-19 gérés par Lancet, BMJ, Elsevier et Wiley. Les résultats cumulatifs de l'analyse sont conservés dans une base de données Refworks et une liste Excel consultable. Des détails sur cette stratégie de recherche sont disponibles sur demande. Une recherche ciblée par mot-clé dans les titres et les résumés des articles a été effectuée dans ces bases de données et dans la liste en Excel. Les termes de recherche utilisés comprenaient : mask* OU (face ET cover*). Chaque référence potentiellement pertinente a été examinée pour confirmer qu'elle comportait des données pertinentes, qui ont été extraites dans la revue. La présente revue contient des recherches publiées jusqu'au 19 novembre 2020.

Nouveaux éléments de preuve sur la COVID-19

Note d'information sur le risque lié à la COVID-19 et les sports non professionnels

Introduction

Quelles sont les données probantes accessibles sur le risque de transmission du SRAS-CoV-2 par la pratique de sports non professionnels et des recherches ont-elles été menées sur les modifications apportées au jeu pour atténuer le risque de transmission?

Les gouvernements et les autorités sanitaires du monde entier ont mis en œuvre des pratiques de confinement et de distanciation sociale afin d'atténuer la propagation du SRAS-CoV-2 au sein des populations. Il s'agissait notamment de la fermeture de lieux de travail, d'écoles et d'autres lieux publics, ainsi que de l'annulation d'événements sportifs et de jeux. Alors que les mesures de santé publique visant à endiguer la pandémie sont prudemment assouplies, beaucoup envisagent de reprendre l'activité physique et le sport. Cette note d'information donne un aperçu de la littérature publiée sur les risques de transmission du SRAS-CoV-2 associés à la pratique de sports non professionnels en date du 18 août 2020.

Points clés

- Deux enquêtes publiées sur les épidémies de SRAS-CoV-2 associées à l'activité physique récréative apparaissent dans la littérature (tableau 1). Ces événements de transmission ont été liés à des installations sportives intérieures et à des activités aérobiques (l'une étant un cours de Zumba, l'autre un match de squash) et se sont produits en mars 2020.
- Dix autres cas de transmission liés au sport ou à l'exercice ont été relevés dans une base de données de cas de superpropagation de la COVID-19(Swinkles, 2020).
    - Plusieurs cas de transmission ont été signalés dans des gymnases associés à des cours en salle, des tournois de curling, des danses carrées et du football. Bon nombre de ces activités sont considérées comme des activités à contact élevé dans les articles de presse.
    - Les sources réelles d'infection et de transmission au sein de ces groupes s'adonnant à des sports d'équipe n'ont pas été identifiées. Par exemple, dans le cas de deux tournois de curling et d'un match de hockey sur la route, des activités sociales avaient également eu lieu avant et/ou après le match. Dans le même ordre d'idées, la source d'une éclosion dans une équipe de football au Japon n'a pas été identifiée.
    - Par ailleurs, des activités telles que la course à pied ne semblent pas présenter un risque élevé de transmission; un seul groupe de partenaires de course à pied a été identifié.

- Des simulations informatiques des caractéristiques aérodynamiques du SRAS-CoV-2 ont conclu que les gouttelettes respiratoires suivront le sillage d'un coureur et qu'il faut donc éviter de courir ou de marcher directement derrière une autre personne (Blocken, Malizia, van Druenen, & Marchal, 2020).
- Wong et coll., rapportent les conclusions de deux enquêtes indépendantes applicables à la participation aux sports et à la transmission du SRAS-CoV-2 (Wong et al., 2020).
    - Selon une analyse de séquences vidéo de matchs de football professionnel, on estime qu'un joueur de football semi-professionnel passe en moyenne 20 % du match en contact étroit avec un autre joueur.
    - Des simulations expérimentales de l'activité physique chez les athlètes ont révélé que les personnes qui portaient un masque enregistraient des fréquences cardiaques et des efforts perçus plus élevés que celles qui ne portaient pas de masque.
- Les documents d'orientation de l'Organisation mondiale de la santé (OMS), les outils d'évaluation des risques et les commentaires publiés comprennent des stratégies utiles pour réduire le risque de transmission du SRAS-CoV-2 lors de la pratique d'un sport (tableau 2).
    - Les orientations de l'OMS décrivent les principales considérations, les risques et les mesures d'atténuation en fonction du type de sport (c'est-à-dire le niveau de contact entre les joueurs), de la taille de l'événement, des lieux intérieurs et extérieurs, des installations du site, des données démographiques des concurrents et des spectateurs, et de la communication des risques, et fournissent des conseils sur la gestion des cas de SRAS-CoV-2 qui peuvent être détectés lors d'un événement sportif (WHO, 2020a). Le document doit être utilisé de pair avec les Key Planning Recommendations for Mass Gatherings in the Context of the Current COVID-19 Outbreak [recommandations clés pour la planification des rassemblements de masse dans le contexte de l'épidémie actuelle de COVID-19](WHO, 2020b) (en anglais seulement) et le Mass Gathering COVID-19 Risk Assessment Tool – Sports Events [outil d'évaluation des risques liés à la COVID-19 lors de rassemblements de masse – événements sportifs] (en anglais seulement) (WHO, 2020c).
    - Carmody et coll. proposent une matrice d'évaluation des risques pour aider les décideurs à redémarrer les événements sportifs, basée sur les orientations de l'OMS et tenant compte de la transmission du SRAS-CoV-2 dans les communautés locales (Carmody, Murray, Borodina, Gouttebarge, & Massey, 2020).
    - Dans une note technique, Blocken et coll. examinent le processus de réouverture des installations sportives intérieures tout en réduisant au minimum la transmission du SRAS-CoV-2. S'appuyant sur l'application de preuves circonstancielles limitées, les auteurs concluent que l'inspiration et l'expiration profondes résultant de l'exercice physique peuvent augmenter l'émission et l'inhalation d'aérosols respiratoires. À ce titre, ils préconisent l'utilisation de systèmes de ventilation par déplacement d'air (plutôt que par mélange d'air), de filtres HEPA et

d'une occupation limitée dans les installations intérieures où l'exercice physique est fréquent (B. Blocken et al., 2020).

- Les directives destinées aux éducateurs physiques des écoles chinoises qui rouvrent après le confinement imposé par la COVID-19 proposent diverses stratégies, telles que des exercices et l'échelonnement des périodes d'activité physique, qui peuvent être adoptées par des équipes sportives non professionnelles pour atténuer les risques de transmission.

Vue d'ensemble des éléments de preuve

Les publications qui traitent directement du SRAS-CoV-2 et des sports non professionnels sont rares. Nous avons donc appliqué les données disponibles sur les installations sportives intérieures (p. ex. les gymnases) et les sports professionnels pour déduire les risques de transmission. Quinze publications et documents d'orientation pertinents sur l'activité physique et le sport ont été utilisés pour étayer cette revue.

Parmi les publications incluses figurent deux enquêtes détaillées sur des foyers d'éclosion et dix rapports sur des foyers d'éclosion de SRAS-CoV-2 associés à des sports ou à des exercices physiques, tirés de la base de données de cas de superpropagation de la COVID-19 (tableau 1). Bien que les enquêtes sur les épidémies puissent être sensibles à un risque élevé de biais, les deux enquêtes publiées semblent avoir été menées avec soin, avec de solides activités de recherche de cas et de recherche de contacts afin de réduire au minimum les biais d'échantillonnage. La base de données de cas de superpropagation comprend des groupes de cas de COVID-19 (n>5 cas) identifiés à partir des tableaux de bord sur la COVID-19 du Canada et d'articles de presse, dont aucun ne fournit de renseignements détaillés sur l'événement de transmission. Les renseignements contenus dans cette base de données sont donc incomplets et imparfaits, et très sensibles aux multiples biais et facteurs confusionnels.

Les analyses de données d'observation portaient sur des séquences vidéo d'un match de football. Elles présentent un risque modéré de biais de la part des chercheurs, mais les mesures physiologiques rapportées étaient moins sensibles à ce biais; il s'agissait simplement de comparer la fréquence cardiaque et la mesure de la perception de l'effort chez ceux qui portaient un masque et chez ceux qui n'en portaient pas. L'étude par simulation informatique pour observer la dynamique des flux d'air chez les coureurs est largement théorique et aurait un faible risque de biais.

La littérature sur les stratégies visant à atténuer le risque de transmission des infections dans les sports non professionnels se limite en grande partie à des commentaires et à des conseils d'experts (tableau 3). Cette littérature se fonde sur les données de santé publique disponibles et adopte des stratégies couramment utilisées pour réduire au minimum la transmission du SRAS-CoV-2 dans les lieux publics.

Dans l'ensemble, les connaissances contenues dans cette littérature présentent toujours d'importantes lacunes, car les orientations actuelles dépendent largement des principes généraux d'évaluation et d'atténuation des risques ainsi que des orientations de la santé publique en matière de COVID-19.

TABLE DES MATIÈRES

ÉCLOSIONS ASSOCIÉES À LA PARTICIPATION À DES ACTIVITÉS SPORTIVES/PHYSIQUES

Il y a peu de cas de transmission associés au sport dans la littérature actuelle sur la COVID-19. Cela pourrait être dû en grande partie aux mesures de santé publique qui ont mis fin à la plupart des activités sportives depuis le début de la pandémie. À l'exception de l'éclosion liée à la pratique de la Zumba décrite par Jang et coll., d'autres éclosions n'ont pas fait l'objet d'une enquête détaillée ou ont été associées à des activités sociales s'étant déroulées avant ou après l'activité sportive, ce qui rend difficile d'attribuer la transmission à la participation au sport lui-même.

La flambée de cas observée actuellement au sein d'une équipe de soccer japonaise montre comment les infections par le SRAS-CoV-2 peuvent se propager au sein d'une équipe, et les directives et précautions de lutte contre l'infection devraient faire partie des plans de reprise des sports (Swinkles, 2020).

Tableau 1. Douze éclosions de COVID-19 liées au sport et à l'exercice

Référence	Titre de la publication	Résultats pertinents
(Jang, Han, & Rhee, 2020)	Cluster of Coronavirus Disease Associated with Fitness Dance Classes, South Korea	Résume l'enquête portant sur 112 cas de COVID-19 associés aux classes de Zumba dans 12 installations sportives différentes en Corée du Sud. Le taux d'attaque primaire a été estimé à 26,3 % (IC 95 % 20,9 % à 32,5 %) et le taux d'attaque secondaire à 4,10 % (IC 95 % 2,95 % à 5,67 %). On suppose que la transmission initiale a eu lieu chez les instructeurs de conditionnement physique lors d'un atelier, où huit des vingt-sept participants ont reçu un diagnostic positif pour le SRAS-CoV-2. Au cours des semaines suivantes, l'infection a été transmise aux participants aux cours de danse, aux contacts familiaux, aux collègues et aux connaissances des instructeurs et des participants. Selon l'étude, 50,9 % (n=63) des cas provenaient d'une transmission par les instructeurs et 52 cas ont été identifiés parmi les participants aux cours de danse. Les instructeurs et les participants se rencontraient uniquement pendant les cours, qui duraient 50 minutes, à raison de 2 fois par semaine, et n'avaient pas de contact en dehors des cours.

		Aucun cas n'a été observé chez les participants aux cours de Pilates et de yoga, également dispensés par un instructeur infecté dans le même établissement de sport ou de conditionnement physique. Ces observations suggèrent que la plus faible intensité du Pilates et du yoga n'a pas entraîné les mêmes effets de transmission que dans le cas des cours de danse, bien qu'il n'ait pas été déterminé que cela puisse être dû à une moins grande quantité de gouttelettes respiratoires ou à une circulation d'air moins importante.
(Brlek, Vidovič, Vuzem, Turk, & Simonović, 2020)	Possible Indirect Transmission of COVID-19 at a Squash Court, Slovenia, March 2020: Case Report	Cette publication décrit un groupe de cas de SRAS-CoV-2 (n=6) liés à la pratique du squash dans un centre sportif à Maribor, en Slovénie. Le cas index (personne A), supposé avoir contracté l'infection lors d'un voyage en Italie, a développé des symptômes (c'est-à-dire fatigue et épuisement) pendant une partie de squash. Les enquêtes épidémiologiques relient des cas supplémentaires (quatre cas confirmés et un suspect) à la même salle de squash et aux mêmes vestiaires. Le cas B a eu un contact direct avec le cas index, car ils ont passé du temps dans les vestiaires et ont joué un match de squash ensemble. Les cas C et D ne signalent pas de contact direct avec le cas index (ou le cas B), et sont épidémiologiquement liés par l'utilisation de vestiaires et le fait de jouer sur le même court de squash dans les 20 minutes après que les cas A et B y aient joué. Les deux autres cas, le cas E et le cas F, sont arrivés au centre sportif environ 1,5 heure après le départ du cas index. Ces deux cas ont discuté avec les cas C et D à l'extérieur du court de squash, et ils ont utilisé le même vestiaire et le même court de squash. Aucun des cas n'a partagé d'équipements sportifs ou n'a eu de contact avec le personnel de l'installation. Aucun autre cas n'a été identifié.
(Swinkles, 2020)	SARS-CoV-2 Super Spreading Events Around the World	Dix autres événements sportifs liés à la transmission ont été signalés dans des articles de presse, tels qu'ils figurent dans la base de données de cas de superpropagation de la COVID-19 du monde entier. Dans cette source d'information, les renseignements sur l'éclosion ou les activités qui ont probablement entraîné la transmission ne sont souvent pas mentionnés : - 2 tournois de curling (tournoi de plusieurs jours et activités sociales) à Edmonton, au Canada, les 14 et 15 mars. 24/72 participants ont développé la COVID-19 et dans le Maryland aux É.-U. le 27 mars, il y a eu environ 20 cas, - Hockey-balle en plein air « sur une même patinoire » Racine, Québec, Canada, 29 février. 15/21 ont été infectés par la COVID-19

		- En février, en Italie, un marathonien infecté a transmis le virus à son partenaire de course - Équipe de soccer, Sagan Tosu J1, éclosion, Japon, août. 11 joueurs et entraîneurs infectés à ce jour - Danse carrée, Lynnwood, Washington, É.-U., février, il y a eu peu de tests et aucune enquête. Seules des informations anecdotiques indiquent que certaines personnes testées étaient bel et bien atteintes de la COVID-19 (>15 personnes), - Des foyers d'éclosion dans deux écoles de gymnastique et une école de tennis de table sont enregistrés au Japon sans autre précision et un foyer dans une école de gymnastique est enregistré à Singapour.

RISQUE DE TRANSMISSION LORS DE LA PRATIQUE D'UN SPORT

Deux études fournissent des preuves applicables au risque de transmission de la COVID-19 pendant la pratique d'un sport. L'une des études consistait en une analyse vidéo d'un match de soccer professionnel. Elle a révélé qu'il avait eu contact étroit entre les joueurs pendant environ 19 minutes sur 90 minutes de jeu et environ 52 épisodes d'interactions à risque élevé (Wong et al., 2020). Le port d'un masque pendant l'exercice a été étudié en laboratoire et cette petite étude a conclu que la fréquence cardiaque et la perception de l'effort étaient significativement plus élevées après six minutes d'exercice modéré avec un masque que sans masque (Wong et al., 2020).

L'autre étude a examiné la dispersion aérodynamique des gouttelettes lorsqu'une personne court afin d'évaluer le risque de transmission lorsqu'une personne suit un coureur infecté (Bert Blocken et al., 2020). Si les personnes courent ou marchent rapidement, même à 1,5 mètre l'une de l'autre, il existe un risque d'exposition aux particules infectieuses si la personne qui suit est directement derrière la personne qui précède (placée dans son sillage). Cette exposition peut être évitée si deux coureurs sont côte à côte (1,5 mètre de distance) ou sont décalés.

Tableau 2. Risque de transmission de la COVID-19 lors de la pratique d'un sport

Référence	Titre de la publication	Principaux résultats
(Wong et al., 2020)	Impact of the COVID-19 Pandemic on sports and exercise	Des séquences vidéo de joueurs de soccer professionnels à Hong Kong ont été analysées pour suivre le temps passé par les joueurs en contact physique étroit et la fréquence des comportements qui augmentent le risque de transmission de l'infection. L'analyse révèle que la durée moyenne des contacts étroits entre les joueurs est de 19 minutes (plage de 5,9 à 35,5) par partie de 90 minutes, et que chaque joueur s'est commis en moyenne 52 fois des gestes à risque accru de transmission d'infection (toucher des yeux, de la bouche ou du nez) au cours d'une partie de 90 minutes.

		Les effets physiologiques du port d'un masque pendant le jeu ont également été examinés en laboratoire. La fréquence cardiaque et la perception de l'effort (RPE) des participants portant un masque étaient significativement élevées par rapport à celles des participants sans masque après 6 minutes d'exercice modéré (fréquence cardiaque de 128 battements par minute et RPE à 12,7 pour les participants portant le masque, et fréquence cardiaque de 124 battements par minute et RPE à 10,8 pour les participants sans masque). Les valeurs étaient statistiquement significatives, mais elles ne sont pas nécessairement significatives sur le plan biologique. L'enquête conclut que le risque de transmission de l'infection est élevé entre les joueurs pendant un match, même sans spectateurs. Le port du masque pendant l'exercice physique augmente la charge physiologique du corps, avec des répercussions pour ceux qui présentent de multiples comorbidités sous-jacentes.
(Bert Blocken et al., 2020)	Towards aerodynamically equivalent COVID-19 1.5 m social distancing for walking and running	L'étude de la dynamique des fluides par ordinateur, éclairée par des données antérieures sur la dispersion des gouttelettes autour d'un coureur, prend en compte les effets aérodynamiques potentiels introduits par les mouvements individuels (par exemple, marcher rapidement, courir et faire du vélo) sur la distance de déplacement des gouttelettes. L'étude vise à déterminer si une personne infectieuse principale qui se tient immobile et se déplace à proximité d'une deuxième personne sensible à une distance de 1,5 mètre ou plus peut présenter un risque de transmission de l'infection. Bien que l'exposition aux particules soit négligeable lorsque deux personnes se tiennent à 1,5 mètre l'une de l'autre, si les personnes courent ou marchent rapidement même à 1,5 mètre de distance, il existe un certain risque d'exposition aux particules infectieuses. Les résultats de l'étude suggèrent que la plus grande exposition de la personne qui suit se produit si elle se trouve directement derrière la personne qui précède (positionnée dans son sillage). Une réduction substantielle du risque d'exposition aux gouttelettes peut être obtenue en 1) évitant de marcher ou de courir dans le sillage de la personne en tête, 2) gardant la distance de 1,5 mètre en se décalant ou en se tenant côte à côte, ou 3) gardant des distances sociales supérieures à 1,5 mètre lorsqu'on se déplace rapidement ou qu'on court.

STRATÉGIES ET ORIENTATIONS

La littérature sur les stratégies visant à atténuer le risque de transmission des infections dans les sports non professionnels comprend deux documents d'orientation provisoires de l'OMS, deux outils d'évaluation des risques et plusieurs commentaires d'experts (tableau 2). La prise en compte des taux locaux de transmission et de cas de SRAS-CoV-2, l'évaluation des risques pour déterminer les niveaux potentiels de contact entre les joueurs, la limitation du nombre de joueurs, la priorité donnée au jeu en plein air et à la distanciation sociale, l'interdiction de l'utilisation partagée des équipements sportifs, l'amélioration des pratiques de nettoyage et de désinfection, et le dépistage des participants pour identifier et isoler efficacement les cas de SRAS-CoV-2 sont des stratégies globales. L'OMS recommande de s'abstenir de pratiquer des sports de contact direct, car ils augmentent le risque d'exposition directe à l'infection.

Deux outils d'évaluation du risque de contracter la COVID-19 chez les spectateurs et les participants à un événement sportif ont été relevés. Le WHO Mass Gathering COVID-19 Risk Assessment Tool [outil d'évaluation des risques liés à la COVID-19 lors de rassemblements de masse – événements sportifs] (en anglais seulement), fournit un arbre décisionnel et des outils pour l'évaluation des risques, l'atténuation des risques, ainsi qu'une matrice de décision et un outil pour la communication des risques que les organisateurs d'événements sportifs de masse et les pays hôtes peuvent appliquer pour déterminer la propagation des infections associées à un événement. Une autre matrice de risque est présentée par Carmody et coll. Cet outil d'évaluation des risques est fondé sur les orientations provisoires de l'OMS, applique les taux locaux de transmission communautaire et les mesures d'atténuation afin de calculer le risque résiduel associé à divers sports professionnels. Le commentaire de Timpka souligne l'importance de la confiance, en ce sens que si les joueurs pensent que les autres joueurs ne respecteront pas les restrictions pour se protéger contre la COVID-19, il est également peu probable qu'ils y adhèrent, d'où l'importance d'un excellent plan de communication.

Certaines preuves circonstancielles antérieures à la pandémie de SRAS-CoV-2, telles que présentées dans la note technique de Blocken, suggèrent que l'activité physique peut augmenter l'émission et l'inhalation d'aérosols respiratoires susceptibles de provoquer une infection (B. Blocken et al., 2020). Bien qu'une bonne partie des données sur la transmission du SRAS-CoV-2 par aérosol continuent d'évoluer, les données probantes et l'information sur les éclosions qui sont accessibles révèlent des risques élevés de transmission de l'infection lors d'une activité physique intense dans un environnement intérieur bondé. Ces données probantes doivent être pondérées de manière appropriée lorsque l'on envisage le retour à des sports non professionnels en salle.

Tableau 3. Stratégies pour réduire la transmission de la COVID-19 pendant la pratique d'un sport

Référence	Titre de la publication	Déclarations clés
(WHO, 2020a)	Considerations for sports federations/sports event organizers when planning mass gatherings in the context of COVID-19	Fournit des considérations clés et des techniques d'atténuation des facteurs de risque. Les recommandations sont fondées sur la prise en compte du risque de contact et de transmission dans le cadre de la pratique d'un sport, la taille de l'événement (c'est-à-dire le nombre de participants), l'emplacement de l'événement, les installations du site, les données démographiques des joueurs participants et l'adoption de directives de santé publique pertinentes. Les recommandations comprennent un examen de santé quotidien pour les concurrents; la distance (au moins 1 mètre) entre les concurrents, les officiels, les spectateurs et le personnel de soutien; une désinfection et un nettoyage approfondis; l'interdiction de partager l'équipement; l'utilisation de sites extérieurs lorsque cela est possible; l'utilisation de sièges désignés et physiquement séparés ainsi que de zones d'isolement au soutien des éventuelles activités de gestion des cas et de recherche des contacts; une communication efficace des risques; et la communication d'information aux personnes présentant un risque accru de mortalité et de morbidité liées au SRAS-CoV-2 leur conseillant de ne pas assister à l'événement sportif. Orientations provisoires, 14 avril 2020
(WHO, 2020c)	WHO mass gathering COVID-19 risk assessment tool – sports events	Un outil formel d'évaluation et de communication des risques à utiliser de pair avec le document intitulé « Considerations for Sports Federations/Sports Event Organizers when Planning Mass Gatherings in the Context of COVID- » (ci-dessus). Mis à jour le 10 juillet 2020
(WHO, 2020b)	Key planning recommendations for mass gatherings in the context of COVID-19	Fournit des conseils aux gouvernements hôtes, aux autorités sanitaires et aux organisateurs nationaux ou internationaux de rassemblements de masse sur la manière de contenir les risques de transmission de la COVID-19 associés aux rassemblements de masse. Orientations provisoires, 29 mai 2020
(Carmody et al., 2020)	When can professional sport	Présente une matrice d'évaluation des risques pour aider les décideurs à redémarrer les activités de sport professionnel

	recommence safely during the COVID-19 Pandemic? Risk assessment and factors to consider	lorsque les mesures de santé publique relatives à la COVID-19 commenceront à s'assouplir. En plus de s'appuyer sur les considérations exposées dans les lignes directrices de l'OMS (c'est-à-dire celles concernant les rassemblements de masse, les considérations relatives aux événements sportifs et l'évaluation des risques liés aux activités sportives), l'évaluation des risques tient compte de la transmission communautaire de la COVID-19 à l'échelle locale. L'approche de base consiste à évaluer le risque, puis à envisager des mesures d'atténuation, et enfin à calculer le risque résiduel. Sur la base de l'application de cette évaluation des risques, le soccer professionnel est considéré comme présentant un risque résiduel élevé, tandis que le golf professionnel est considéré comme présentant un risque résiduel faible, si des mesures appropriées d'atténuation des risques d'infection sont appliquées. Sur la base de l'application de cette matrice des risques, les auteurs suggèrent que le risque global de reprise des événements sportifs peut être faible, si la transmission au sein de la communauté locale est faible et si des procédures adéquates d'atténuation des risques sont en place. Selon les évaluations faites, le soccer professionnel est considéré comme présentant un risque résiduel élevé, tandis que le golf professionnel est considéré comme présentant un risque résiduel faible.
(Timpka, 2020)	Sports health during the SARS-Cov-2 pandemic	Rédigé avant la publication des lignes directrices de l'OMS, ce commentaire indique que les organisations sportives doivent répondre aux besoins des athlètes et des entraîneurs, tout en se conformant aux mesures de distanciation sociale et aux orientations régionales de santé publique sur la COVID-19, lorsqu'elles élaborent une stratégie de réponse à une pandémie. Souligne l'importance de la confiance : « Si les sportifs ne croient pas que la plupart des autres respecteront les restrictions temporaires, il est également peu probable qu'ils y adhèrent. Les auteurs suggèrent que les activités sportives doivent être pratiquées en plein air, en petits groupes, et le contact physique entre les joueurs doit être évité autant que possible. Les compétitions virtuelles sont encouragées entre les athlètes des sports individuels.
(B. Blocken et al., 2020)	Can indoor sports centers be allowed	Ce document présente les preuves (antérieures à l'émergence de la COVID-19) qui montrent que l'expiration profonde

	to re-open during the COVID-19 Pandemic based on a certificate of equivalence?	(comme lors d'un exercice physique) produit des concentrations plus élevées d'aérosols et que l'inhalation profonde augmente l'exposition aux aérosols. À la lumière de cette constatation, les auteurs indiquent qu'il est nécessaire d'assurer une bonne ventilation (le déplacement de l'air du sol au plafond est préférable au mélange d'air), d'utiliser des filtres HEPA, d'appliquer des mesures de santé publique pour les visiteurs et le personnel, de nettoyer les surfaces afin d'éliminer les vecteurs passifs et de s'assurer que les activités se font sans contact. Les auteurs ont également proposé l'idée de délivrer un certificat aux centres sportifs intérieurs avant leur réouverture.
(Chen et al., 2020)	Returning Chinese school-aged children and adolescents to physical activity in the wake of COVID-19: Actions and precautions	Résume les précautions qui peuvent être prises par les directeurs d'écoles, les éducateurs physiques et les parents concernant l'activité physique, alors que les écoles en Chine commencent à rouvrir après le confinement imposé par la COVID-19. Ces précautions comprennent : - Encourager une bonne distanciation sociale (au moins 1 mètre), - Décaler les horaires pour éviter que trop de personnes se retrouvent en même temps au même endroit, - Rendre les stations de lavage ou de désinfection des mains facilement accessibles, - Désinfecter régulièrement toutes les surfaces et tous les équipements, - Limiter les activités physiques qui impliquent un contact physique et le partage d'équipements sportifs et de bouteilles d'eau.
(Peter, 2020)	Return to play after COVID-19: a sport cardiologist's view	L'article souligne la nécessité de subir un examen cardiaque avant un retour au sport pour les cas de COVID-19 chez les adultes, soulignant que des lésions cardiaques subcliniques peuvent survenir à la suite d'une infectionpar le SRAS-CoV-2.

(Dores & Cardim, 2020)	Returning to play after coronavirus infection: a perspective from pediatric cardiologists	L'article souligne la nécessité de procéder à un examen cardiaque avant un retour au sport pour les cas de COVID-19 chez les enfants à la suite d'une infectionpar le SRAS-CoV-2, car une lésion cardiaque subclinique peut être présente après l'infection.

Méthodologies

Toute la littérature sur la COVID-19 a été compilée et classée par le Groupe des sciences émergentes de l'Agence de la santé publique du Canada depuis le début de l'épidémie. Cela suppose une recension quotidienne de la littérature pour tous les articles publiés et prépubliés. Les recherches pour trouver de la littérature pertinente sur la COVID-19 sont menées dans PubMed, Scopus, BioRxiv, MedRxiv, ArXiv, SSRN et Research Square. Elles sont mises en correspondance avec les publications figurant sur la liste de littérature de l'Organisation mondiale de la santé au sujet de la COVID et les centres d'information COVID-19 gérés par Lancet, BMJ, Elsevier et Wiley. Le résumé quotidien et les résultats complets de la recension sont conservés dans une base de données Refworks et un fichier Excel qui peut être consulté. Chaque article est étiqueté en fonction de divers critères permettant de déterminer le thème central de l'article (p. ex. épidémiologie, données cliniques, thérapeutique, etc.) Une recherche ciblée par mot-clé est effectuée dans ces bases de données pour y relever des citations pertinentes sur la COVID-19 et le SRAS-CoV-2. Les termes de recherche inclus dans cet examen étaient « sports », « exercise » et « physical fitness/activity ». Chaque référence potentiellement pertinente a été analysée pour confirmer sa pertinence, et des données ont été extraites et incluses dans la recension de la littérature. Cette revue contient des recherches publiées jusqu'au 18 août 2020.

Preuve émergente sur la COVID-19

Synthèse en bref sur le risque d'infection à la suite du contact oculaire pour orienter les précautions à prendre en cas de contact et d'exposition aux gouttelettes

Introduction

Quelles sont les données disponibles en ce qui concerne la protection des yeux (en plus des masques médicaux et des respirateurs standard) pour prévenir la transmission de l'infection à la COVID-19 chez les travailleurs de la santé?

La COVID-19 est une infection respiratoire qui se transmet principalement par des gouttelettes, et peut-être par des aérosols, lors d'interactions non protégées (Vuorinen et al., 2020). La parole, la toux et les éternuements des patients symptomatiques sont tous des vecteurs de transmission de l'infection puisqu'ils génèrent des gouttelettes chargées de virus (et peut-être d'aérosols) qui se retrouveront ensuite dans l'air, dans le milieu des soins de santé (Liu et al., 2020; Loh et al., 2020; Ong et al., 2020; Vuorinen et al., 2020). L'équipement de protection individuelle efficace et approprié fournit cependant une barrière qui empêche la transmission de l'infection des patients aux travailleurs de la santé.

Cette synthèse en bref met donc en évidence les données probantes disponibles à l'appui de l'utilisation d'une protection oculaire chez les travailleurs de la santé pour ainsi réduire l'infection par la COVID-19 publiées jusqu'au 18 juin 2020.

Points clés

- À ce jour, aucune étude n'a porté spécifiquement sur l'infection par le SRAS-CoV-2 à la suite de l'exposition des surfaces oculaires. Le tableau 1 présente les données probantes à l'appui de l'utilisation d'une protection oculaire par les travailleurs de la santé pour réduire au minimum la transmission des coronavirus par l'infection.
    - Le récepteur ACE-2, un récepteur cellulaire pour la fixation du virus SRAS-CoV-2, se trouve dans les tissus oculaires humains. De nombreuses études, y compris une revue systématique, fournissent des preuves biologiques moléculaires que le SRAS-CoV-2 peut utiliser les tissus oculaires (c.-à-d. l'œil) comme portail d'entrée pour infecter les

hôtes humains (Aiello et al., 2020; Lange et al., 2020; Ma et al., 2020; Zhang, Jin, & Lei, 2020; Zhou et al., 2020).

  - Les données sur l'exposition provenant de plusieurs hôpitaux pendant l'éclosion de SRAS en Ontario, au Canada, fournissent des données d'observation indiquant que la protection des yeux a réduit l'incidence des infections par le SRAS chez les travailleurs de la santé qui l'ont utilisée (Raboud et al., 2010).

- Dans sa dernière mise à jour le 19 mai 2020, le document Prévention et contrôle de la maladie COVID-19 : Lignes directrices provisoires pour les établissements de soins actifs de l'Agence de la santé publique du Canada sur la prévention et le contrôle des infections à l'intention des travailleurs de la santé recommande : (PHAC & Canada, 2020)
  - Les précautions à prendre en cas de contact ET d'exposition aux gouttelettes (c.-à-d. gants, masques, écrans faciaux et lunettes de protection) lorsque les travailleurs de la santé interagissent avec des patients soupçonnés d'être infectés par la COVID-19 ou dont l'infection a été confirmée;
  - Les précautions à prendre en cas de contact ET d'exposition aux gouttelettes qui doivent être utilisées par les travailleurs de la santé 1) en ce qui concerne les patients qui présentent une fièvre ou une toux nouvelle ou qui s'aggrave ou une maladie respiratoire aiguë, 2) qui entrent dans les chambres des patients, ou 3) qui se trouvent à proximité de toute procédure générant des aérosols, indépendamment de l'apparition de symptômes d'infection respiratoire aiguë chez le patient.
  - Des dépistages actifs doivent être mis en œuvre dans les endroits où les travailleurs de la santé et les patients accèdent aux milieux de soins de santé. Les responsables de l'examen doivent être protégés par des barrières transparentes ou porter l'EPI approprié (p. ex., gants, blouse, masque et protection du visage ou des yeux) lorsqu'une barrière transparente ne peut être mise en place.
  - À l'heure actuelle, des évaluations des risques au point d'intervention doivent également être effectuées (en fonction du patient, de l'interaction et de la tâche) afin de déterminer toute précaution supplémentaire nécessaire pour TOUS les patients et visiteurs (PHAC & Canada, 2020).
- De nouvelles données probantes sur les tests sérologiques effectués sur des travailleurs d'hôpitaux révèlent que la positivité de l'IgG est liée à la prévalence géographique de l'infection dans une région (Sandri et al., 2020). Il peut donc être avantageux pour les travailleurs de la santé de tenir compte de la prévalence de la COVID-19 dans les circonscriptions hospitalières des patients lorsqu'ils évaluent le risque de transmission et l'utilisation de la protection oculaire.

Vue d'ensemble des éléments de preuve

Les données d'études d'observation sur les effets protecteurs de la protection oculaire propre à la transmission de la COVID-19 dans les soins de santé sont insuffisantes, et ce, même si les données de biologie moléculaire appuient la plausibilité de l'infection par le SRAS-CoV-2 en utilisant l'œil de l'hôte comme portail d'entrée. Il y a donc des lacunes dans les connaissances de la recherche qui permettent d'estimer les risques de transmission des infections aux travailleurs de la santé associés à la protection des yeux.

Littérature primaire		
Enquêtes améliorées sur les contacts pour neuf cas précoces de SRAS-CoV-2 à la suite de déplacements aux États-Unis.	L'étude fait état de l'utilisation de différents types d'équipement de protection individuelle (EPI) chez les travailleurs de la santé qui s'occupent de la grappe de cas précoces de COVID-19 à la suite de déplacements aux États-Unis. Il s'agit de la seule étude (à ce jour) à examiner et à fournir des données sur l'utilisation de l'équipement de protection individuelle sélectif chez les travailleurs de la santé pendant l'épidémie de COVID-19. Le risque relatif d'infection par la COVID-19 fondé sur la protection des yeux par rapport à l'absence de protection des yeux ne peut cependant PAS être estimé, car aucun cas secondaire chez les travailleurs de la santé n'a été relevé.	(Burke et al., 2020)

Expression du récepteur ACE2 du SRAS-CoV-2et TMPRSS2 dans la conjonctive primaire humaine et les lignées cellulaires du ptérygium, ainsi que dans la cornée des souris Expression de la COVID-19 récepteur ACE2 dans la conjonctive humaine Répartition et importance clinique de l'ACE2, un récepteur clé du 2019-nCoV dans les tissus oculaires ACE2 et TMPRSS2 sont exprimés sur la surface oculaire de l'être humain, ce qui suggère une susceptibilité à l'infection par le SRAS-CoV-2	Les tissus oculaires humains expriment donc les récepteurs ACE-2, les récepteurs cellulaires du SRAS-CoV-2, ce qui confirme la capacité du virus à infecter un hôte par son œil.	(Ma et al., 2020), (Lange et al., 2020), (Zhang et al., 2020), (Zhou et al., 2020)
Facteurs de risque de transmission du SRAS par des patients qui doivent être intubés : une enquête multicentrique effectuée à Toronto, au Canada	Selon une enquête multicentrique effectuée sur une éclosion antérieure de SRAS à Toronto, le manque d'uniformité des lunettes de protection portées par les travailleurs de la santé lorsqu'ils entraient dans la chambre des patients augmentait le risque d'infection chez ces travailleurs (n=624). Un lien statistiquement significatif entre la protection des yeux et l'infection a été identifié, ce qui suggère que la conjonctive aurait pu être un portail d'entrée pour les agents pathogènes.	(Raboud et al., 2010)

Titre de la publication	Principaux résultats	Référence
Commentaires clés et revues		
Interventions physiques visant à interrompre ou à réduire la propagation des virus respiratoires. Partie 1 - Masques faciaux, protection des yeux et distanciation des personnes : revue systématique et méta-analyse	La revue systématique n'a pas permis de relever de rapports associés à l'épidémie de SRAS en 2003 ayant évalué l'utilisation de la protection oculaire et la prévention des infections.	(Jefferson et al., 2020)
Distanciation physique, masques faciaux et protection des yeux pour prévenir la transmission de la COVID-19 d'une personne à l'autre : revue systématique et méta-analyse	Une revue systématique et une méta-analyse effectuées par Chu et coll. examinent les preuves disponibles, tirées des études d'observation sur le risque de transmission des coronavirus (SRAS-CoV-2, MERS-CoV, SRAS), en fonction de la protection des yeux. La revue conclut que la protection des yeux et l'utilisation d'un masque ou d'un respirateur sont associées à une réduction de la transmission du coronavirus (différence de risque de -10,6 % (-12,5 à -7,7, IC à 95 %) et probabilité ajustée de 0,22, -12 à 0,39, IC à 95 % respectivement avec une fiabilité jugée faible). Toutefois, le SRAS-CoV-2 n'a cependant pas été pris en compte dans les estimations des risques liés à la protection des yeux, car cette preuve n'existe pas à l'heure actuelle.	(Chu et al., 2020)
Maladie à coronavirus 2019 (SRAS-CoV-2) et colonisation des tissus oculaires et des sécrétions : une revue systématique	Une revue systématique par Aiello résume l'information disponible sur la présence du SRAS-CoV-2 dans la cornée, la conjonctive, le larmoiement, le sac lacrymal et les larmes. Elle confirme que le SRAS-CoV-2 peut être présent et infecter les tissus oculaires, ce qui veut dire qu'il peut donc utiliser les structures oculaires comme voie de transmission supplémentaire.	(Aiello et al., 2020)
La transmission de 2019-nCoV par l'entremise de la surface oculaire ne doit donc pas être ignorée.	Commentaire dans lequel les auteurs font référence à un reportage médiatique (en chinois) portant sur la transmission d'une infection à un travailleur portant un masque N95, mais aucune protection oculaire.	(Lu, Liu, & Jia, 2020)

Méthodes :

Une analyse quotidienne de la littérature (publiée et prépubliée) est effectuée par le groupe de science émergente de l'ASPC. L'analyse a permis de compiler la littérature sur la COVID-19 depuis le début de l'épidémie et est mise à jour quotidiennement. Les recherches pour trouver la littérature pertinente sur la COVID-19 sont menées par Pubmed, Scopus, BioRxiv, MedRxiv, ArXiv, SSRN, Research Square et sont recoupées avec la littérature de la liste de littérature COVID de l'OMS, et les centres d'information de la COVID-19 gérés par Lancet, BMJ, Elsevier et Wiley. Le résumé quotidien et les résultats complets de l'analyse sont conservés dans une base de données Refworks et une liste Excel consultable. Une recherche ciblée par mot-clé était effectuée dans ces bases de données pour identifier les citations pertinentes sur la COVID-19 et le SRAS-COV-2. Une recherche supplémentaire par mot-clé ciblé a été effectuée sur Pubmed pour identifier les citations pertinentes non spécifiques à COVID-19 et à SRAS-CoV-2. Termes de recherche utilisés comprennent : Goggle, ocular, eye, ACE2 Chaque référence potentiellement pertinente a été examinée pour confirmer qu'elle comportait des données pertinentes et les données pertinentes sont extraites dans l'examen.

Cet examen contient des recherches publiées jusqu'au 20 juin 2020.

Preuve émergente sur la COVID-19

Synthèse en bref sur l'infectiosité et l'apparition des symptômes

Introduction

Existe-t-il une différence de risque de transmission entre les personnes présymptomatiques et asymptomatiques infectées et les cas symptomatiques?

Des études de cas, des séries de cas, des enquêtes sur les contacts et les grappes, ainsi que des études sur de grandes populations, ont démontré que la transmission se produit fréquemment chez des personnes présymptomatiques et asymptomatiques. Cette revue visait à résumer la littérature publiée jusqu'au 29 mai 2020.

Points clés

- La littérature provenant des milieux de soins de santé souligne que la transmission de la COVID-19 est complexe et liée à la situation, à la durée de l'exposition et aux facteurs individuels.
    - La transmission asymptomatique potentielle a été documentée dans les milieux de soins de santé chez les résidents de l'établissement, les travailleurs de la santé et les visiteurs (Arons et coll., 2020; McMichael et coll., 2020). Une épidémie, dans un établissement de soins infirmiers spécialisé de l'État de Washington, a permis de constater que plus de la moitié des résidents qui avaient des résultats positifs étaient asymptomatiques au moment des tests et que des virus viables pouvaient se développer chez des personnes présymptomatiques jusqu'à six jours avant l'apparition des symptômes (Arons et coll., 2020).
    - Une autre étude n'a cependant pas pu démontrer que la transmission asymptomatique se produisait en raison des contacts étroits et dans les établissements de soins (Canova et coll., 2020). Cette étude n'était cependant pas assez puissante et n'aurait donc pas été suffisante pour estimer un risque de transmission.
- Il a été démontré que la transmission asymptomatique se produit et qu'elle peut être liée au temps passé en contact étroit avec une personne infectée, ainsi qu'à d'autres attributs du scénario dans lequel la transmission s'est produite.
    - Dans une méta-analyse de cas bénins (n=8) et asymptomatiques (n=36), on a pu observer des taux élevés de transmission dans des situations de proximité comme lors des repas et dans des événements familiaux, des conversations en voiture, des réunions privées et lors des cérémonies de prière (Prakash, 2020a). Il est probable que dans de telles situations, la

propagation asymptomatique soit facilitée par le contact (contamination des mains et des fomites) ainsi que par la génération de gouttelettes par la parole et le chant.

- La charge virale estimée dans les aérosols émis par les patients qui respirent normalement était en moyenne de 0,34 à 11,5 copies/cm^3, tandis que les chiffres correspondants pour les patients qui présentaient des symptômes respiratoires étaient beaucoup plus élevés, atteignant de 10 900 à 366 000 copies/cm^3 par quinte de toux (Riediker et Tsai, 2020). Une personne qui passait du temps dans une pièce avec une personne respirant normalement (c.-à-d. sans symptômes respiratoires) était tout de même susceptible d'inhaler des dizaines ou des centaines de copies du virus.
- Dans les enquêtes épidémiologiques, la proportion d'événements de transmission chez les personnes présymptomatiques et asymptomatiques est très variable (plage <10 à 73 %) (tableau 1). Les modèles prédictifs estiment que 40 à 80 % des événements de transmission se produisent chez des personnes présymptomatiques et asymptomatiques (Ferretti et coll., 2020; Javid et Balaban, 2020; Li et coll., 2020).
- Les probabilités de transmission pour les cas symptomatiques et asymptomatiques peuvent cependant être très semblables :
    - Une analyse n'a révélé aucune différence significative dans les taux de transmission entre les patients symptomatiques et asymptomatiques (6,3/100 et 4,1/100, respectivement) (Yin et Jin, 2020).
    - Des charges virales dans les voies respiratoires supérieures semblables pour le SRAS-CoV-2 ont été signalées chez les patients asymptomatiques et symptomatiques (Zou et al., 2020).

Vue d'ensemble des éléments de preuve

Peu d'études comparent directement le potentiel de transmission et l'infectiosité entre les personnes qui présentent des symptômes respiratoires et celles qui ne présenteront pas de symptômes respiratoires. Aux fins de cette revue, la majorité des données probantes sur ce sujet ont été extrapolées à partir d'études comparant les cas symptomatiques et présymptomatiques ou asymptomatiques en général, ainsi que dans le contexte des soins de santé.

Les données probantes à ce sujet sont principalement décrites dans des exposés de cas et études de recherche des contacts, qui présentent un risque élevé de biais et sont donc jugés être de basse qualité. De nombreuses études sont des prépublications qui n'ont donc pas fait l'objet d'un examen par les pairs. Dans l'ensemble, il faut donc interpréter les résultats avec prudence.

Aucune évaluation des risques ou étude n'a permis d'estimer le risque d'infection pour les travailleurs de la santé qui s'occupent de patients présymptomatiques ou asymptomatiques par rapport aux patients symptomatiques.

Les estimations changent à mesure que de nouvelles recherches deviennent disponibles puisqu'il y a de nombreuses lacunes dans les connaissances actuelles. De nouvelles recherches visant à combler ces lacunes

pourraient modifier considérablement notre compréhension de l'infectiosité du SRAS-CoV-2 chez les personnes symptomatiques et asymptomatiques. Il faut davantage de données probantes démontrant l'existence d'un virus cultivable provenant d'infections asymptomatiques, présymptomatiques et symptomatiques pour déterminer avec plus de certitude l'infectiosité à différents stades.

CONTENU

SIGNES DE POTENTIEL DE TRANSMISSION PRÉSYMPTOMATIQUE ET ASYMPTOMATIQUE

Il est important de garder à l'esprit que la transmission entre les personnes dépend du contexte et de multiples facteurs. Les personnes qui présentent des symptômes respiratoires sont beaucoup plus susceptibles de s'isoler que les personnes asymptomatiques, ce qui explique les taux élevés de transmission présymptomatique et asymptomatique indiqués dans cette littérature. Des études sur la transmission des cas présymptomatiques et asymptomatiques ont montré que la transmission présymptomatique et asymptomatique atteint des proportions élevées dans cette pandémie, et ce, tant dans la population générale que dans les milieux de soins de santé. Par conséquent, les cas qui ne présentent pas de signes évidents d'infection, y compris des événements générateurs de gouttelettes comme la toux et les éternuements, peuvent quand même se révéler très infectieux.

Tableau 1 : Études fournissant des preuves liées à l'infectiosité et au potentiel de transmission des infections présymptomatiques et asymptomatiques. Un indicateur de la qualité des données probantes est fourni (faible, modéré, élevé) en fonction du risque de biais dans le plan de l'étude et la production de rapports.

Référence	Principaux résultats	Qualité
Estimations de la transmission présymptomatique		
(Arons et coll., 2020)	Enquête sur l'éclosion chez des résidents dans un établissement de soins infirmiers spécialisés à Washington, aux États-Unis Date de fin : 3 avril 2020 - Quarante-huit (63 %) des résidents qui ont participé aux enquêtes sur la prévalence ponctuelle ont obtenu un résultat positif. - Vingt-quatre étaient présymptomatiques et deux étaient asymptomatiques. - Un virus viable a pu être isolé dans les spécimens prélevés 6 jours avant l'apparition des symptômes et 9 jours après.	Faible

	- Cela indique que l'infection présymptomatique et asymptomatique a été un facteur important dans la transmission du SRAS-CoV-2 dans cet établissement.	
(Du et coll., 2020) *Prépublication*	Étude de cas de données accessibles au public en Chine Étude de 468 paires d'infecteur/infecté identifiées par la recherche des contacts 21 janvier au 8 février 2020 - 59 paires d'infecteur/infecté (12,6 %) ont indiqué que l'infecté avait eu des symptômes plus tôt que l'infecteur. - Ces intervalles de série négatifs suggèrent que la transmission présymptomatique s'est probablement produite.	Faible
(Chun, Baek et Kim, 2020) *Prépublication*	Étude de cas de données accessibles au public en Corée du Sud Étude de 72 paires de transmissions entre infecteur et infecté 23 janvier au 31 mars 2020 - La proportion de transmission présymptomatique était de 37 % (16 à 52 %, IC à 95 %).	Faible

(Pham et coll., 2020) *Prépublication*	Étude de cas de données accessibles au public au Vietnam Étude de 33 paires de transmissions entre infecteur et infecté 15 avril au 1er mai 2020 - Les intervalles des séries ont été calculés à partir de paires infecteur/infecté et utilisés pour estimer la proportion d'événements de transmission présymptomatique. - 27,5 % (15,7 % à 40,0 %, IC à 95 %) des transmissions se sont produites de manière présymptomatique.	Faible
(Wei et coll., 2020)	Étude de recherche des contacts pour 243 cas et sept grappes de cas à Singapour 23 janvier au 16 mars 2020 - Sept grappes de cas avec une transmission présymptomatique probable ont été identifiées. - La proportion globale de transmission à partir de cas présymptomatiques représentait 6,3 % de la transmission globale.	Faible
(Xia et coll., 2020) *Prépublication*	Enquête sur 50 grappes de cas en Chine Apparition des symptômes avant le 25 janvier 2020 - Enquête portant sur 124 cas dans lesquels le contact secondaire avec le cas de première génération s'est produit avant l'apparition des symptômes. La courbe infectieuse a montré que chez 73,0 % des personnes infectées, la date d'infection était antérieure à l'apparition	Modérée

	des symptômes de leurs infecteurs, en particulier dans les trois derniers jours de la période d'incubation.	
(Casey et coll., 2020) *Prépublication*	Analyse secondaire des données publiées indiquant l'intervalle de série ou le temps de génération en provenance de Hong Kong, de Tianjin, de Singapour, de la Chine continentale, à l'exception d'Hubei, de sources mixtes, de Shenzhen, du nord de l'Italie et de Wuhan 1 décembre 2019 au 15 avril 2020 - Période d'incubation soustraite de l'intervalle de série ou du temps de génération pour déduire la période d'infection présymptomatique et estimer la proportion de transmission présymptomatique. - La transmission présymptomatique a été estimée à 56,1 % d'après les estimations des intervalles en série et à 65,5 % d'après les estimations du temps de génération.	Faible
(Prakash, 2020b) *Prépublication*	Analyse secondaire des données publiées Comprend 1 251 personnes mentionnées dans la littérature - On estime que 68,4 % (67,0-69,7 %, IC à 95 %) des infections sont causées par des infecteurs présymptomatiques.	Faible
(Nishiura, Linton et Akhmetzhanov, 2020)	Modèle bayésien log-normal basé sur l'examen de cas des rapports de recherche et d'enquête publiés Étude de 28 paires infecteur/infecté Date de fin : 12 février 2020 - En tenant compte de la troncature à droite et en analysant toutes les paires, les auteurs ont estimé un intervalle de série de 4,0 jours (3,1 à 4,9, IC à 95 %). - Cet intervalle est plus court que les estimations préliminaires de la période d'incubation d'environ 5 jours. - Cela suggère que la transmission présymptomatique peut représenter une proportion importante de la transmission secondaire.	Faible
Estimations de la transmission asymptomatique		
(McMichael et coll., 2020)	Enquête sur l'éclosion d'une épidémie dans un établissement de soins de longue durée à Washington, aux États-Unis qui a touché les résidents, les travailleurs de la santé et les visiteurs Date de fin : 18 mars 2020 - Au total, 167 cas confirmés de COVID-19, dont 101 résidents, 50 professionnels de la santé et 16 visiteurs, ont été associés épidémiologiquement à l'établissement. - Aucun symptôme n'a été documenté chez 7 résidents (6,9 %).	Faible
(Yin et Jin, 2020)	Nouvelle analyse des données sur le cas et les contacts à Ningbo, en Chine Analyse de 157 cas symptomatiques et de 30 cas asymptomatiques 21 janvier au 6 mars 2020 -Les taux de transmission pour les patients symptomatiques et asymptomatiques étaient de 0,063 et de 0,041 respectivement (aucune différence significative).	Faible

	- La probabilité de transmission à une personne en bonne santé par un patient symptomatique est de 1,2 fois celle d'un patient asymptomatique (non statistiquement significative).	
(Danis et coll., 2020)	Étude des grappes dans les Alpes françaises avec exportation et diffusion du virus dans plusieurs pays d'Europe. Cas index présymptomatique et 15 contacts dans le chalet; 172 contacts ont été identifiés dans l'ensemble des cas. À compter du 25 janvier 2020 - Taux d'attaque du cas index asymptomatique 12/15 (75 %) pour 4 jours de contact; 1/15 asymptomatique. Seul 1 des 172 contacts subséquents était positif. - Charge virale d'un cas symptomatique similaire à un cas asymptomatique.	Faible
(Wang et coll., 2020)	Étude rétrospective en Chine Étude de 125 patients confirmés par RT-PCR en temps réel. 20 janvier au 18 février 2020. - 22,4 % des cas n'ont pas fait état d'une exposition connue à des personnes malades.	Faible
(Wong et coll., 2020)	Examen du cas des voyageurs et des résidents de retour à Brunei Examen de 53 paires infecteur/infecté symptomatiques. 5 mars au 24 avril 2020 -Vingt et un cas (39,6 %) avaient un SI de 3,0 jours et six (11,3 %) avaient des valeurs SI nulles ou négatives, ce qui suggère une infectiosité potentielle lorsque les personnes sont asymptomatiques.	Faible
(Zou et coll., 2020)	Étude sur la charge virale de 17 patients symptomatiques et d'un patient asymptomatique en Chine 7 au 26 janvier 2020 - Analyse de la charge virale dans les écouvillons dans le nez et dans la gorge. - La charge virale détectée chez le patient asymptomatique était similaire à celle détectée chez les patients symptomatiques. Cela suggère le potentiel de transmission des patients asymptomatiques ou paucisymptomatiques.	Faible
(Li et coll., 2020) *Prépublication*	Modèle mathématique qui simule la dynamique spatiotemporelle des infections en Chine 10 janvier au 8 février 2020 - On estime que 86 % de toutes les infections n'étaient pas documentées avant l'arrêt des voyages à Wuhan, et que par personne, ces infections non documentées (dont bon nombre n'étaient probablement pas gravement symptomatiques) étaient 55 % aussi contagieuses que les infections documentées et la source de l'infection dans 79 % des cas documentés.	Faible
(Riediker et Tsai, 2020) *Prépublication*	Un modèle à un compartiment a été utilisé pour estimer la concentration de charge du virus dans une salle parfaitement mélangée d'un volume de 50 m^3 avec un patient comme source	Faible

	- L'émission totale cumulative par respiration des patients ayant une respiration normale était de 0,34 copie/cm^3 (air) pour un patient moyen, et de 11,5 copies/cm^3 pour les patients dont le niveau d'émission était élevé. - Les émissions virales des patients qui toussaient étaient beaucoup plus élevées, avec une émission totale cumulative par toux de 19 400 copies/cm^3 pour un patient moyen et de 651 315 copies/cm^3 pour les patients dont le niveau d'émission était élevé. Une personne qui passe du temps dans une pièce avec un patient ayant une respiration moyenne a normalement une forte probabilité d'inhaler des dizaines ou des centaines de copies du virus même lorsqu'elle pratique la distanciation. La probabilité est plus grande en présence d'un patient dont le niveau d'émission est élevé ou si le patient a un niveau d'émission élevé et qu'il tousse. - Conclure que les concentrations de virus prédites élevées peuvent expliquer la fréquence de la transmission communautaire des cas asymptomatiques et les taux élevés d'infection chez le personnel médical. - Les auteurs recommandent une protection respiratoire stricte lorsque vous êtes dans une chambre avec un patient, que le patient soit symptomatique ou non.	
(Aguirre-Duarte, 2020) *Prépublication*	Examen systématique et rapport narratif sur les enquêtes dans les grappes/contact. Études primaires sur la capacité des porteurs asymptomatiques d'infecter d'autres personnes. Neuf articles ont porté sur 83 personnes asymptomatiques ou présymptomatiques. Publié dans des revues indexées du 1er janvier au 31 mars 2020. - Bien qu'aucune estimation précise n'ait été indiquée, il existe des preuves que les personnes asymptomatiques et présymptomatiques peuvent infecter d'autres personnes avec la COVID-19.	Modérée
(Prakash, 2020a) *Prépublication*	Cette synthèse n'est pas effectuée à l'aide de la méthode d'examen systématique standard, bien qu'une recherche approfondie ait été effectuée. Vingt situations ont entraîné 418 infections dans 32 instances chez 44 personnes (huit présentaient des symptômes légers, 36 étaient asymptomatiques). Situation (taux de transmission) : • Repas/événements familiaux (15,7 % à 66,7 %) • Réunions (réunion privée d'une heure, 72,7 % (IC de 43,6 à 98,0 %) • Espace de travail ouvert avec circulation des personnes (78,7 % (70,3 à 85,3 %)) • Chant (par exemple, pratique de deux heures 86,7 % (76,2 à 93,2 %)	Modérée

	• Cérémonie de prière (a entraîné une à sept infections secondaires par personne infectée) • Déplacement en voiture (environnement fermé) et discussions présentait un risque élevé (100 % (20 à 100 %)) • Transports publics, port d'un masque sans parler (~0 %) • Hôtels (53,3 % (30,1 à 75,2 %))/bateaux de croisière (28,1 % (27,3 à 29,0 %)) où l'espace est partagé pendant des jours • Interaction directe avec un représentant infecté (25,0 % (10,2 à 49,5 %)) • Boîte de nuit, taux d'attaque pour les contacts directs >50 %, parmi les clients de la boîte de nuit (6,27 % (5,15 à 7,61 %)) • Taux d'attaque global pour le restaurant (9,9 % (5,3 à 17,7 %) contre ceux dans le flux d'air du climatiseur (45,0 % (25,8 à 65,8 %))	

Méthodes :

Une analyse quotidienne de la littérature (publiée et prépubliée) est effectuée par le groupe de science émergente de l'ASPC. L'analyse a permis de compiler la littérature sur la COVID-19 depuis le début de l'épidémie et est mise à jour quotidiennement. Les recherches pour trouver la littérature pertinente sur la COVID-19 sont menées par Pubmed, Scopus, BioRxiv, MedRxiv, ArXiv, SSRN, Research Square et sont recoupées avec la littérature de la liste de littérature COVID de l'OMS, et les centres d'information de la COVID-19 gérés par Lancet, BMJ, Elsevier et Wiley. Le résumé quotidien et les résultats complets de l'analyse sont conservés dans une base de données Refworks et une liste Excel consultable. Des recherches ciblées par mot-clé ont été effectuées en utilisant une combinaison des termes « outbreak », « hospital », « long-term care » et « nursing ». Des résumés et des notes d'information sur l'infection asymptomatique, les événements de super-diffusion et la période infectieuse ont été utilisés pour rassembler des preuves liées aux symptômes respiratoires et à l'infectiosité. Cet examen contient des recherches publiées jusqu'au 29 mai 2020. Chaque référence potentiellement pertinente a été examinée pour confirmer qu'elle comportait des données pertinentes et les données pertinentes sont extraites dans l'examen.

Preuve émergente sur la COVID-19

Synthèse en bref sur la distance de dispersion du virus SRAS-CoV-2

Introduction

Quel est l'impact d'une distance physique de 1 mètre, de 1,5 mètre et de 2 mètres sur le risque de transmission du virus SRAS-CoV-2?

La physique complexe et la dynamique des particules entourant la dispersion des gouttelettes et des aérosols, ainsi que les preuves limitées sur la dose infectieuse et la viabilité des virus dans les particules expulsées, font qu'il est difficile de quantifier avec certitude le risque d'exposition au SRAS-CoV-2 en fonction de la distance. Cette synthèse en bref met en évidence des documents précis sur la distance de dispersion des gouttelettes expulsées et des particules d'aérosol publiés jusqu'au 22 juin 2020.

Points clés

- L'ensemble des preuves suggère que la vitesse des particules, l'évaporation, la circulation de l'air, l'humidité, la température jouent toutes un rôle dans les distances que les particules respiratoires chargées de virus peuvent parcourir après avoir été libérées par une personne infectieuse. Par conséquent, les effets protecteurs de la distance physique à différentes distances dépendent également des conditions dans lesquelles ils sont pratiqués.
- Les données empiriques et modélisées disponibles indiquent que, dans certaines circonstances, les gouttelettes respiratoires et les aérosols expulsés d'individus infectieux peuvent parcourir des distances supérieures à 2 mètres (tableau 1), mais les masques faciaux sont efficaces pour limiter les distances de dispersion à moins de 0,5 mètre (tableau 2).
- Selon les modèles mathématiques et l'analyse dynamique des fluides, la taille des gouttelettes, l'humidité, la température, le flux d'air et les turbulences de l'air ont tous un impact sur le mouvement et la décomposition des particules en suspension dans l'air contenant le virus (tableau 1).
    - Certains modèles prédisent que les gouttelettes et les aérosols peuvent parcourir des distances allant jusqu'à dix mètres lorsqu'ils sont générés par la toux ou les éternuements et concluent fréquemment qu'une distance sociale de deux mètres n'est pas toujours suffisante pour annuler la transmission du SRAS-CoV-2 par voie

aérienne (Feng, Marchal, Sperry, & Yi, 2020; Guerrero, Brito, & Cornejo, 2020; Zhao, Qi, Luzzatto-Fegiz, Cui, & Zhu, 2020).

- La basse température et l'humidité élevée facilitent la transmission et la dispersion des gouttelettes respiratoires. La température élevée et le faible taux d'humidité favorisent la perte rapide de la masse des gouttelettes respiratoires (due à l'évaporation) réduisant ainsi la distance de déplacement des gouttelettes (Feng et al., 2020; Zhao et al., 2020).
- Un consortium de recherche multidisciplinaire a appliqué des modèles Monte-Carlo fondés sur des données probantes et des simulations en 3D pour étudier la physique de la dispersion des aérosols du SRAS-CoV-2 (Vuorinen et al., 2020). Les chercheurs utilisent des simulations informatiques pour démontrer que les aérosols SRAS-CoV-2 peuvent parcourir des distances allant jusqu'à dix mètres, et que l'inhalation de concentrations suffisantes d'aérosols (on a supposé que 100 particules chargées de virus étaient infectieuses) est possible en une seconde à une heure selon les conditions ambiantes.
- Les résultats d'un modèle basé sur des agents ont révélé une diminution du risque d'un événement de transmission à l'intérieur (p. ex., supermarché) lorsque la distance entre les individus passe de 30 cm à 2 mètres (Hernandez Mejia & Hernandez-Vargas, 2020).
- La vitesse de déplacement a également une incidence sur la distance parcourue par les gouttelettes. Les simulations informatiques de la dynamique des fluides montrent que, bien qu'une distance de 1,5 mètre puisse être suffisante à l'arrêt, des distances supérieures à 1,5 mètre sont nécessaires lorsque deux personnes courent ou se déplacent rapidement, car l'inertie des gouttelettes expulsées a également un impact sur la propagation des gouttelettes (Blocken, Malizia, van Druenen, & Marchal, 2020).

- Des études de simulation en laboratoire indiquent que les gouttelettes de toux produites par les humains et les mannequins peuvent parcourir de un à deux mètres et un maximum de quatre mètres dans certaines simulations (Loh et al., 2020; Rodriguez-Palacios, Cominelli, Basson, Pizarro, & Ilic, 2020; Viola et al., 2020).
- Deux études de simulation ont examiné les effets de la couverture faciale sur la distance de dispersion des particules expulsées. Les deux études révèlent que l'inclusion de masques faciaux, comme des écrans faciaux, des respirateurs filtrants pour masque facial, des masques faciaux chirurgicaux et des masques maison, a réduit la dispersion des gouttelettes expulsées à moins de 0,5 mètre, même lorsqu'elles toussent.
- Une revue systématique récente de Chu et coll. quantifie le risque relatif d'infection par le virus bêta-Corona en fonction de la distance (Chu et al., 2020). Les auteurs signalent que la

transmission des virus est plus faible avec une distance physique de 1 m ou plus, comparativement à une distance de moins de 1 m (n=10 736, probabilités ajustées [aOR] combinées 0 à 18, 0,09 à 0,38, IC à 95 %; différence de risque [DR] de 10 2 %, 11,5 à 7,5, IC à 95 %; fiabilité modérée); la protection augmentait à mesure que la distance s'allongeait (changement du risque relatif [RR] 2,02 par m; *p* interaction=0,041; fiabilité modérée). Il semble y avoir une certaine ambiguïté dans la mesure de la distance physique pour certaines des données probantes incluses dans le présent examen et, à ce titre, elles sont de piètre qualité. Par conséquent, il pourrait être prématuré de quantifier le risque relatif d'infection par le SRAS-CoV-2 en fonction des différences progressives de distance physique, en raison du manque de preuves suffisantes.

- À l'heure actuelle, aucune étude d'observation n'évalue le risque de transmission de l'infection par le SRAS-CoV-2 en fonction d'une distance variable d'une source infectieuse.

Vue d'ensemble des éléments de preuve

Les publications parues dans la littérature émergente jusqu'au 22 juin 2020 ont alimenté cette synthèse en bref. Le corpus de données disponibles est limité et repose en grande partie sur des simulations dans des conditions contrôlées. Ces études sont de bonne qualité, mais la généralisation de ces résultats à des situations réelles est inconnue. Pour cette raison, des recherches supplémentaires sur la transmission du SRAS-CoV-2 dans des situations et des distances variables pourraient modifier les conclusions de cette revue.

CONTENU

DISTANCE DE DISPERSION DU SRAS-COV-2

Tableau 1 : Littérature primaire sur la distance de dispersion des aérosols et gouttelettes

Titre de la publication	Principaux résultats	Référence
Études expérimentales et de simulation		
Impact de la canule nasale à débit élevé (HFNC) sur la distance de toux : répercussions de l'utilisation pendant la nouvelle éclosion de coronavirus	Une étude simulée menée auprès de volontaires en bonne santé (n=5) a révélé que les gouttelettes générées par la toux se propageaient sur une distance moyenne de 2,48 mètres (écart-type de 1,03) au niveau de référence, jusqu'à un maximum de 3,90 mètres. Lorsqu'on portait une canule nasale à débit élevé bien ajustée, la propagation moyenne des gouttelettes générées par la toux était de 2,91 mètres (1,09) avec une distance maximale de 4,50 mètres.	(Loh et al., 2020)
Masques faciaux, dispersion des aérosols et atténuation du risque de transmission du virus	Les chercheurs utilisent une technique Schlieren orientée vers l'arrière-plan pour visualiser le flux d'air et étudier l'efficacité de différents masques faciaux pour atténuer la dispersion des aérosols pendant la respiration et la toux. L'étude rapporte qu'un panache thermique contenant des particules respiratoires était visible à des distances inférieures à 0,5 mètre lors d'une respiration normale simulée par des sujets humains et des mannequins. Des panaches thermiques étaient visibles à environ 1,1 mètre de la bouche source pendant la toux simulée par le mannequin.	(Viola et al., 2020)
Masques textiles et revêtements de surface – Une méthode de simulation de pulvérisation et un « modèle universel de réduction des gouttelettes » contre les pandémies respiratoires	Les distances de dispersion des gouttelettes respiratoires lorsque l'on porte un masque fait de matériaux ménagers courants ont été mesurées à l'aide d'une simulation de pulvérisation en suspension bactérienne (imitant un éternuement). La plupart des gouttelettes porteuses de bactéries ont atterri à moins de 1,2 mètre de la source avec un masque en textile, alors que les gouttelettes ont parcouru des distances supérieures à 1,8 mètre lorsqu'aucune barrière (censée imiter l'absence de protection du visage) n'était en place.	(Rodriguez-Palacios et al., 2020)
Modèles mathématiques et simulations		
Titre de la publication	**Principaux résultats**	**Référence**
Vers une distance sociale de 1,5 m de	L'étude de la dynamique des fluides par ordinateur, éclairée par des données antérieures sur la dispersion des gouttelettes autour d'un	(Blocken et al., 2020)

la COVID19 aérodynamiquement équivalente pour la marche et la course	coureur, prend en compte les effets aérodynamiques potentiels introduits par les mouvements d'une personne (par exemple, marcher rapidement, courir et faire du vélo) sur la distance de déplacement des gouttelettes. L'étude vise à déterminer si une personne infectieuse principale qui se tient immobile et se déplace à proximité d'une deuxième personne sensible à une distance de 1,5 mètre ou plus peut présenter un risque de transmission de l'infection. Bien que l'exposition aux particules soit négligeable lorsque deux personnes se tiennent à 1,5 mètre l'une de l'autre, si les personnes courent ou marchent rapidement même à 1,5 mètre de distance, il existe un certain risque d'exposition aux particules infectieuses. Les résultats de l'étude suggèrent que la plus grande exposition de la personne qui suit se produit si elle se trouve directement derrière la personne qui précède (positionnée dans son sillage). Une réduction substantielle du risque d'exposition aux gouttelettes peut être obtenue en 1) évitant de marcher ou de courir dans le sillage de la personne en tête, 2) gardant la distance de 1,5 m en se décalant ou en se tenant côte à côte, ou 3) gardant des distances sociales supérieures à 1,5 m lorsqu'on se déplace rapidement ou qu'on court.	
À quel moment le SRAS-CoV-2 s'ajoute-t-il à votre liste d'épicerie?	La propagation de la COVID-19 dans un supermarché commercial et le potentiel de contagion sont estimés à l'aide d'une modélisation basée sur les agents. Cette méthode permet de cartographier toutes les caractéristiques souhaitées des clients et du personnel (p. ex., nombre de personnes infectées ou vulnérables, utilisateurs simultanés) et de l'agent infectieux, ainsi que les interactions/trajectoires possibles dans une disposition hypothétique. L'analyse du modèle révèle une augmentation de la distance entre les individus dans un supermarché (les distances testées étaient de 30 cm, de 50 cm, de 1 mètre, de 1,5 mètre et de 2 mètres), ainsi que la limitation du nombre d'individus dans le supermarché ont amélioré le pourcentage d'événements de transmission potentiels évités dans les simulations.	(Hernandez Mejia & Hernandez-Vargas, 2020)
COVID-19 : Effets des conditions météorologiques sur la propagation des gouttelettes respiratoires	Un modèle mathématique complet a été créé pour explorer l'évaporation des gouttelettes générées par la parole, le transfert de chaleur et la cinématique dans différentes conditions (par exemple, la température, l'humidité et la ventilation). La basse température et la forte humidité facilitent la transmission et la dispersion des gouttelettes, mais qu'elles empêchent la formation d'aérosols. D'autre part, une température élevée et une faible humidité favorisent une perte rapide de la masse des gouttelettes respiratoires (par	(Zhao et al., 2020)

	évaporation) et réduisent la distance de parcours des gouttelettes, mais ces conditions augmentent le risque de transmission des particules d'aérosol. L'étude conclut que les recommandations actuelles en matière de distanciation sociale pourraient ne pas être suffisantes pour diminuer tous les risques de transmission par voie aérienne, car les gouttelettes peuvent parcourir des distances allant jusqu'à 6 mètres.	
COVID-19. Transport de gouttelettes respiratoires dans un scénario urbain microclimatologique	Examen de la propagation des gouttelettes respiratoires dans les environnements extérieurs en appliquant un modèle de calcul d'une personne qui éternue dans un scénario urbain sous un vent climatologique d'intensité moyenne. La propagation des gouttelettes respiratoires est caractérisée par la dynamique de la taille des gouttelettes : les gouttelettes les plus grosses (de 400 à 900 µm) se propagent entre 2 et 5 mètres pendant 2,3 secondes tandis que les gouttelettes plus petites (de 100 à 200 µm) sont transportées entre huit et onze mètres en 14,1 secondes lorsqu'elles sont portées par un vent turbulent.	(Guerrero et al., 2020)
Influence du vent et de l'humidité relative sur l'efficacité de la distanciation sociale pour prévenir la transmission aérienne de la COVID-19 : Une étude numérique	La transmission aérienne des gouttelettes de toux avec des effets de condensation et d'évaporation est modélisée entre deux humains virtuels dans des environnements et des vitesses de vent différents. Les microgouttelettes suivent les courants d'air et peuvent être déposées sur des corps humains virtuels (y compris les régions de la tête) à des distances supérieures à 3,05 mètres. Une humidité relative élevée (99,5 %) entraîne également des gouttelettes plus grosses et un dépôt plus important de gouttelettes de toux sur les surfaces (en raison des effets de croissance hygroscopique). Des microgouttelettes en suspension pourraient être transmises entre les deux humains virtuels en moins de 5 secondes. L'étude conclut qu'en raison du vent ambiant, des effets de convection et de l'humidité relative sur les particules respiratoires émises par l'homme, les 1,83 mètre de distance sociale fréquemment recommandés pourraient ne pas être suffisants pour prévenir la transmission d'aérosols entre les personnes.	(Feng et al., 2020)
Modélisation du transport des aérosols et de l'exposition aux virus par des simulations numériques en relation avec la transmission du	Les preuves disponibles sur le transport des aérosols dans l'air sont combinées à des simulations 0D-3D dans des modèles basés sur la physique et des calculs théoriques. Les simulations de Monte-Carlo indiquent que les gouttelettes produites par la parole et la toux (diamètre < 20 µm) peuvent se propager dans l'air et y rester de 20 minutes à 1 heure, et être inhalées par d'autres personnes. La durée d'exposition pour inhaler 100 aérosols (supposée être une dose	(Vuorinen et al., 2020)

SRAS-CoV-2 par inhalation à l'intérieur	infectieuse adéquate) est variable en fonction de la situation et peut aller d'une seconde, à une minute, à une heure. Les simulations 3D de la dynamique des fluides suggèrent que les aérosols (dp <20 µm) peuvent être transportés sur des distances de 10 mètres dans des environnements génériques, en fonction de l'humidité relative et du débit d'air. Enfin, le séchage rapide des gouttelettes de mucus expulsées produirait des noyaux de gouttelettes et des aérosols qui pourraient potentiellement transporter des particules de virus en suspension dans l'air. Ces gouttelettes (diamètre initial des particules de 50 µm à 100 µm) pourraient rester en suspension dans l'air pendant environ 20 secondes à 3 minutes.	
Domaine d'études		
Titre de la publication	**Principaux résultats**	**Référence**
Potentiel de transmission du SRAS-CoV-2 par les aérosols et les surfaces	Des échantillons d'air et de surface provenant d'espaces isolés abritant des cas de COVID-19 aux États-Unis ont été recueillis et testés pour détecter la présence de l'ARN viral du SRAS-CoV-2. Des échantillons d'air de grands espaces et des échantillons d'air d'espaces personnels ont été testés par PCR en temps réel pour détecter la présence du SRAS-CoV-2. 63,2 % des échantillons d'air provenant des zones d'isolement des patients étaient positifs à l'ARN viral, et 58,3 % des échantillons d'air provenant des couloirs en dehors des zones d'isolement des patients ont également été testés positifs au virus. Les conclusions suggèrent que les particules d'aérosol viral peuvent être produites par les personnes infectées même en l'absence de toux, et qu'elles peuvent parcourir des distances supérieures à 1,8 mètre.	(Santarpia et al., 2020)

DISPERSION DU SRAS-COV-2 DISTANCE ET COUVRE-VISAGE

Tableau 2 : Littérature primaire sur l'efficacité du couvre-visage et de la distance

Titre de la publication	Principaux résultats	Référence
Masques textiles et revêtements de surface – Une méthode de simulation de pulvérisation et un « modèle	Les distances de dispersion des gouttelettes respiratoires lorsque l'on porte un masque fait de matériaux ménagers courants ont été mesurées à l'aide d'une simulation de pulvérisation en suspension bactérienne (imitant un éternuement). La plupart des gouttelettes porteuses de bactéries ont atterri à moins de 1,2 mètre de la source, alors que certaines gouttelettes	(Rodriguez-Palacios et al., 2020)

universel de réduction des gouttelettes » contre les pandémies respiratoires	ont parcouru des distances supérieures à 1,8 mètre lorsqu'aucune barrière (censée imiter l'absence de protection du visage) n'était en place. Tous les textiles testés ont réduit le nombre de gouttelettes atteignant les surfaces, limitant leur dispersion à moins de 30 cm, lorsqu'ils sont utilisés comme couches individuelles. Lorsqu'ils étaient utilisés en double couche, les textiles étaient aussi efficaces que les masques médicaux/tissus chirurgicaux, réduisant la dispersion des gouttelettes à moins de 10 cm, et la zone de contamination circonférentielle à environ 0,3 %.	
Masques faciaux, dispersion des aérosols et atténuation du risque de transmission du virus	Les chercheurs utilisent une technique Schlieren orientée vers l'arrière-plan pour visualiser le flux d'air et étudier l'efficacité de différents masques faciaux pour atténuer la dispersion des aérosols pendant la respiration et la toux. L'étude rapporte qu'un panache thermique contenant des particules respiratoires était visible à des distances inférieures à 0,5 mètre lors d'une respiration normale générée par des sujets humains et des mannequins. Des panaches thermiques étaient visibles à environ 1,1 mètre de la bouche source pendant la toux simulée par le mannequin. On a constaté que tous les masques faciaux testés (y compris les masques chirurgicaux, les masques maison, les appareils respiratoires filtrants et les écrans faciaux) réduisaient de plus de 90 % le débit des jets respiratoires à l'avant, et que les panaches thermiques étaient visibles à moins de 0,5 mètre pour la toux. Plusieurs jets de fuite vers l'arrière et vers le bas ont également été détectés à des distances inférieures à 0,2 de la source de la toux.	(Viola et al., 2020)

Méthodes :

Une analyse quotidienne de la littérature (publiée et prépubliée) est effectuée par le groupe de science émergente de l'ASPC. L'analyse a permis de compiler la littérature sur la COVID-19 depuis le début de l'épidémie et est mise à jour quotidiennement. Les recherches pour trouver la littérature pertinente sur la COVID-19 sont menées par Pubmed, Scopus, BioRxiv, MedRxiv, ArXiv, SSRN, Research Square et sont recoupées avec la littérature de la liste de littérature COVID de l'OMS, et les centres d'information de la COVID-19 gérés par Lancet, BMJ, Elsevier et Wiley. Le résumé quotidien et

les résultats complets de l'analyse sont conservés dans une base de données Refworks et une liste Excel consultable. Une recherche ciblée par mot-clé est effectuée dans ces bases de données pour identifier les citations pertinentes sur la COVID-19 et le SRAS-CoV-2. Termes de recherche utilisés comprennent : distance.

Chaque référence potentiellement pertinente a été examinée pour confirmer qu'elle comportait des données pertinentes et les données pertinentes sont extraites dans l'examen. Cet examen contient des recherches publiées jusqu'au 22 juin 2020.

Préparé par : Chatura, Prematunge. Groupe des sciences émergentes, ASPC. phac.emergingsciencesecretariat-secretariatdessciencesemergentes.aspc@canada.ca

Evidence Snapshot:

Rapid Review on SARS-CoV-2 Aerosol Transmission – Update 2

Context

A wide range of evidence supporting SARS-CoV-2 aerosol transmission potential, in different settings and conditions, appears in the scientific literature. The current update includes 46 new studies, pre-published and published, between November 6, 2020 and March 12, 2021.

New Findings

- Twelve new reports of SARS-CoV-2 outbreaks/cluster investigations attributed to aerosol transmission including: inside a post-travel quarantine hotel, nursing home, hospital hematology unit, passenger bus, restaurant, fitness facilities, department store, and apartments arranged in a vertical line in an apartment building. In most outbreaks/clusters, the index cases were pre-symptomatic or early symptomatic and mask use was infrequent or improper.
- An experimental study on SARS-CoV-2 viability and decay within aerosols reported dependence on environmental conditions in order of influence: simulated sunlight exposure levels (midday summer, midday spring, indoor/night tested) > temperature (10-40°C) > humidity (20-70%). A 90% reduction in infectious virus took 4.8 minutes with midday summer sunlight exposure but took more than 2 hours under no sunlight exposure (i.e., indoors or at night) at 40^0C and 20% relative humidity.
- Viral RNA was detected in exhaled breath samples when COVID-19 patients were oropharyngeal, nasopharyngeal, and/or salivary swab positive at the time of sampling.
- Twenty-eight new biological monitoring studies examined SARS-CoV-2 contamination in environmental air samples. Two notable studies included significant SARS-CoV-2 aerosols produced by a mildly symptomatic individual during a short car ride. The other estimated 8.75 [95% CI 1.21-63.43; p=0.058] greater odds of SARS-CoV-2 in air samples collected from active case households compared to hospital rooms, which was attributable to differences in air exchanges and ventilation between the two settings.

Considerations

Scientific evidence on aerosol transmission of SARS-CoV-2 is increasing. SARS-CoV-2 infectious dose, characterization of case attributes and environmental conditions that change aerosol transmission risk are not well defined within the available literature.

Aperçu des éléments de preuve :

Revue rapide sur la transmission par les aérosols du SRAS-CoV-2 – Mise à jour 2

Contexte

On trouve, dans la littérature scientifique, une vaste gamme d'éléments de preuve qui appuient la transmission potentielle du SRAS-CoV-2 par les aérosols, dans différents contextes et dans différentes conditions. Cette mise à jour inclut 46 nouvelles études, tant publiées qu'en préimpression, diffusées entre le 6 novembre 2020 et le 12 mars 2021.

Nouvelles constatations

- Douze nouveaux rapports associés à des enquêtes sur des éclosions ou des grappes de SRAS-CoV-2 attribuées à la transmission par les aérosols, y compris dans un hôtel où se trouvaient des voyageurs en quarantaine, dans une maison de soins infirmiers, dans l'unité d'hématologie d'un hôpital, dans un autobus avec passagers, dans un restaurant, dans des installations de conditionnement physique, dans un grand magasin et dans des appartements à la verticale dans une tour d'habitation, ont été examinés dans la présente revue rapide. En les regardant, on peut voir que les cas index inclus dans ces rapports en étaient aux stades présymptomatiques ou symptomatiques précoces de l'infection et que le masque ou le couvre-visage avait soit été peu porté ou mis de façon inadéquate.
- Une étude expérimentale sur la viabilité et la désintégration du SRAS-CoV-2 dans les aérosols a révélé une dépendance aux conditions environnementales suivantes, par ordre d'influence : concentrations d'exposition simulées à la lumière du soleil (mi-journée, l'été, mi-journée, au printemps, intérieur/nuit) > température (entre 10 et 40 °C) > humidité (entre 20 et 70 %). Il a ainsi fallu 4,8 minutes à 40 °C avec une exposition à la lumière du soleil en mi-journée pour obtenir une réduction de 90 % des virus infectieux alors que, sans exposition à la lumière du soleil (c.-à-d. à l'intérieur ou la nuit), il a fallu plus de 2 heures à 40 °C, avec une humidité relative de 20 %, pour obtenir la même réduction.
- L'échantillonnage a permis de détecter la présence d'ARN viral dans l'air expiré chez différents patients atteints de COVID-19 ayant reçu des résultats positifs après des prélèvements oropharyngés, nasopharyngés ou salivaires.
- Vingt-huit nouvelles études de suivi biologique ont examiné la contamination par le SRAS-CoV-2 dans des échantillons d'air ambiant. Deux études notables ont également mentionné qu'une personne légèrement symptomatique avait produit une quantité importante d'aérosols du SRAS-CoV-2 alors qu'elle effectuait un court trajet en voiture. Une étude a comparé des échantillons d'air ambiant prélevés dans des chambres d'hôpital et chez des ménages en quarantaine où se trouvaient des cas actifs et estimé à plus de 8,75 [IC à 95 %, 1,21 à 63,43; P = 0,058] la probabilité de résultats positifs dans les échantillons d'air prélevés dans les ménages par rapport aux chambres d'hôpital, un

résultat qui a été attribué aux différences dans les échanges d'air et la ventilation entre les deux milieux.

Facteurs dont il faut tenir compte

Les preuves scientifiques sur la transmission par les aérosols du SRAS-CoV-2 sont de plus en plus nombreuses. La dose infectieuse du SRAS-CoV-2, la caractérisation des caractéristiques des cas et les conditions environnementales qui modifient le risque de transmission par les aérosols ne sont cependant pas bien définies dans la documentation disponible.

Référence : Groupe des sciences émergentes de l'Agence de la santé publique du Canada. Revue rapide sur la transmission par les aérosols du SRAS-CoV-2– Mise à jour 2. Rapport complet disponible auprès de : **phac.ocsoevidence-bcscdonneesprobantes.aspc@canada.ca**

Evidence Snapshot:
SARS-CoV-2 Contact Tracing

Context

Contact tracing is one of several public health measures (PHMs) used to control the COVID-19 pandemic. When cases are too high, there is not enough capacity for contact tracing to contain the epidemic. As regions transition from restrictive PHMs (e.g., lift lockdown), the potential and limits of new and traditional contact tracing techniques to prevent resurgence of the pandemic must be fully understood. The evidence brief identified relevant literature to assess the strategic use of effective and efficient methods for contact tracing.

Key Findings

There were 23 articles in the review: seven rapid or systematic reviews with studies up to December 2020; and two empirical and 14 modelling studies posted November 2020 through February 10, 2021. The key findings were:

- Studies have shown that as transmission decreases and restrictive PHMs (e.g., lockdowns, closures and restricted movement) are lifted, a strong contact tracing system with sufficient capacity is needed to avoid a resurgence (5% vs. <50% chance of a resurgence when sufficient contact tracing capacity is and is not in place, respectively).
- For contact tracing to be effective, timely isolation of cases (≤3 days after onset of symptoms) and quarantine of at least 60-90% of people exposed to the case is necessary.
- Models show decreased effectiveness of contact tracing when system capacity is exceeded, as case contacts are not traced, or there are delays in tracing and initiating quarantine, all of which may lead to ongoing transmission.
- Increasing efficiency and effectiveness of contact tracing can be achieved with bidirectional contact tracing, the use of electronic data management tools and contact tracing apps. Apps require that high proportions of population use the app (estimates from 56% to up to 100%) to result in improved epidemic control.

Considerations

The limitations of the evidence include a lack of empirical studies and high reliance on the findings of modeling studies and reviews based on pre-pandemic experience. Overall, evidence indicates that contact tracing systems can effectively contain the COVID-19 pandemic when they have the capacity to rapidly isolate identified cases and quarantine the majority of their contacts, to limit transmission potential within a community.

Aperçu des éléments de preuve : Recherche des contacts pour le SRAS-CoV-2

Contexte

La recherche des contacts est l'une des nombreuses mesures de santé publique qui ont été utilisées pour contrôler la pandémie de COVID-19. Lorsque le nombre de cas est trop élevé, la capacité de dépistage des contacts n'est cependant pas suffisante pour contenir l'épidémie. Ainsi, au fur et à mesure que les régions passent à des mesures de santé publique moins restrictives (p. ex., fin du confinement), il faut s'assurer de bien comprendre le potentiel et les limites des techniques de recherche des contacts pour pouvoir prévenir toute résurgence de la pandémie. La synthèse en bref a permis d'identifier des documents pertinents qui permettront d'utiliser stratégiquement différentes méthodes efficaces et efficientes de recherche des contacts.

Principales constatations

Vingt-trois articles ont été inclus dans cette synthèse, soit sept revues rapides ou systématiques (portant sur des études publiées jusqu'en décembre 2020), deux études empiriques et quatorze études de modélisation publiées entre novembre 2020 et le 10 février 2021. Les principales constatations qui en découlent sont les suivantes :

- Les études ont montré qu'à mesure que la transmission diminue et que les mesures de santé publique restrictives (p. ex., confinement, fermetures et déplacements restreints) sont levées, un système de recherche des contacts solide et suffisamment puissant est nécessaire pour éviter une résurgence de la pandémie (la probabilité de résurgence atteint 5 % les capacités pour effectuer la recherche des contacts sont disponibles comparativement à < 50 % lorsque ces capacités ne sont pas disponibles).
- Pour que la recherche des contacts soit efficace, il faut cependant s'assurer d'isoler rapidement les cas (≤ 3 jours après l'apparition des symptômes) et de mettre en quarantaine au moins 60 à 90 % des personnes exposées à ces cas.
- Les modèles montrent une diminution de l'efficacité de la recherche des contacts lorsque les capacités du système de soins de santé sont dépassées, car la recherche des contacts n'est alors plus effectuée ou est retardée, ce qui entraîne également un retard dans la mise en quarantaine et peut donc permettre une transmission continue du virus.
- Il est cependant possible d'augmenter l'efficience et l'efficacité de la recherche des contacts grâce à la recherche bidirectionnelle, ainsi qu'à l'utilisation d'outils électroniques de gestion des données et d'applications de recherche des contacts. Pour que ces applications puissent être utilisées de façon adéquate et permettre d'obtenir un meilleur contrôle de l'épidémie, il faut cependant s'assurer qu'une importante proportion de la population les utilise (estimations variant entre 56 % et 100 %).

Facteurs dont il faut tenir compte

Les limites associées aux éléments de preuve comprennent un manque de preuves empiriques et une forte dépendance aux conclusions tirées des études de modélisation ou des examens fondés sur l'expérience prépandémique. Dans l'ensemble, les éléments de preuve indiquent que les systèmes de recherche des contacts peuvent permettre de contenir efficacement la pandémie de COVID-19 lorsqu'ils sont utilisés pour isoler rapidement les cas identifiés et mettre la majorité de leurs contacts en quarantaine, ce qui permettra de limiter le potentiel de transmission du virus dans la collectivité.

Référence : Groupe des sciences émergentes de l'Agence de la santé publique du Canada. Synthèse en bref sur la recherche des contacts pour le SRAS-CoV-2. 8 février 2021. Rapport complet disponible auprès de : **phac.evidence-donnees.probantes.aspc@canada.ca**

Evidence Snapshot:

Evidence Brief of COVID-19 Infectious Period in Immunosuppressed/Immunocompromised Individuals

Context

The infectious period is an important clinical and epidemiologic parameter in the management of COVID-19 patients and has been estimated to be approximately 10-13 days in immunocompetent COVID-19 cases. The objective of this brief was to review the evidence on the infectious period for immunosuppressed and immunocompromised COVID-19 cases.

Key Findings

The evidence brief identified 19 studies, including 12 cohort studies and 7 longitudinal case series, published before February 5, 2021. All but two studies relied on RT-PCR testing to monitor viral shedding. The key findings were:

- Patients with immunosuppression due to hematologic cancers have been shown to shed replication-competent SARS-CoV-2 for up to 2 months, median 25 days (range 8-61 days). In cancer patients overall, median time to viral RNA clearance ranged from 12-50 days with an overall range of 9-78 days.
- In solid organ transplant patients undergoing immunosuppressive therapy, time to viral RNA clearance ranged from 9-66 days. Kidney transplant recipients had mean viral RNA shedding of 28.4 ± 9.3 days, similar to another study that reported high viral loads at day 30.
- In patients with HIV, viral RNA clearance occurred over a median of 18 days (IQR 7-28) but remained detectable in some patients >40 days post symptom onset. Lower CD4 cell counts in HIV patients were associated with longer time to viral clearance.
- Overall, longer time to viral clearance was associated with more severe disease and more comorbidities, however this was not significant in all studies.

Considerations

Immunosuppressed and immunocompromised individuals with COVID-19 appear to have longer and highly variable infectious periods compared to immunocompetent individuals. The evidence is limited by the use of RT-PCR to assess infectivity as this test cannot distinguish between infectious and non-infectious viral particles. A gap in research is how infectious period is affected by immune-modulating drugs for non-cancer diseases. Prospective studies and the use of culture are needed to better inform when to de-isolate immunosuppressed and immunocompromised patients recovering from COVID-19 infection.

Reference: Emerging Science Group of the Public Health Agency of Canada. Evidence Brief of COVID-19 Infectious Period in Immunosuppressed/Immunocompromised Individuals. February 17, 2021. Full report available from: **phac.evidence-donnees.probantes.aspc@canada.ca**

février 17, 2021

Aperçu des éléments de preuve :

Synthèse en bref sur la période infectieuse de la COVID-19 chez les personnes immunodéprimées ou immunodéficientes

Contexte

La période infectieuse est un paramètre clinique et épidémiologique qui joue un rôle important dans la prise en charge des patients atteints de COVID-19 et cet état de fait est encore plus vrai dans le cas des patients immunocompétents atteints de COVID-19 puisque leur période infectieuse a une durée estimative de 10 à 13 jours. La présente synthèse vise donc à examiner les éléments de preuve sur la période infectieuse des patients immunodéprimés et immunodéficients atteints de COVID-19.

Principales constatations

La synthèse en bref a identifié 19 études, soit 12 études de cohorte et 7 séries de cas longitudinales, qui ont été publiées avant le 5 février 2021. Toutes ces études, à l'exception de deux, ont utilisé des tests RT-PCR pour surveiller l'excrétion virale. Les principales constatations qui en découlent sont les suivantes :

- Les patients dont l'immunosuppression est due à des cancers hématologiques ont excrété le virus SARS-CoV-2 réplicatif pendant un maximum de deux mois avec une médiane de 25 jours (plage de 8 à 61 jours) Dans l'ensemble, chez les patients atteints de cancer, le délai médian avant la clairance de l'ARN viral variait de 12 à 50 jours, avec une plage globale allant de 9 à 78 jours.
- Chez les patients qui ont subi une greffe d'organe entier et suivent une thérapie immunosuppressive, le temps qui s'est écoulé avant la clairance de l'ARN viral variait entre 9 et 66 jours. Le temps moyen d'excrétion de l'ARN viral du SRAS-CoV-2 dans un groupe de patients ayant subi une greffe de rein était de 28,4 ± 9,3 jours, ce qui est similaire aux données d'une autre étude qui a déclaré des charges virales élevées le jour 30.
- Chez les patients atteints de VIH, la clairance virale de l'ARN a atteint 18 jours en moyenne (EI 7 à 28), mais le virus est demeuré détectable chez certains patients plus de 40 jours après l'apparition des symptômes. Un lien a été établi entre un nombre plus bas de cellules CD4 chez les patients atteints du VIH et une plus longue période avant la clairance virale.
- Dans l'ensemble, une plus longue période de clairance virale est donc associée à une forme plus grave de la maladie et à un plus grand nombre de comorbidités, même si cet élément de preuve n'a pas été jugé significatif dans toutes les études.

Facteurs dont il faut tenir compte

Comparativement aux personnes immunocompétentes, les personnes immunodéprimées et immunodéficientes atteintes de la COVID-19 semblent avoir eu des périodes infectieuses plus longues et beaucoup plus variables. La preuve présentée est cependant limitée par l'utilisation du test RT-PCR pour évaluer l'infectivité, puisque ce test ne permet pas de faire de distinction entre les particules virales infectieuses et non infectieuses. La recherche comporte également une lacune, à savoir la manière dont la période infectieuse est affectée par les médicaments immunomodulateurs utilisés dans les cas de maladies non cancéreuses. Des études prospectives et l'utilisation de cultures seront nécessaires pour mieux savoir à quel moment ne plus isoler les patients immunodéprimés et immunodéficients qui se remettent d'une infection à la COVID-19.

Référence : Groupe des sciences émergentes de l'Agence de la santé publique du Canada. Synthèse en bref sur la période infectieuse de la COVID-19 chez les personnes immunodéprimées ou immunodéficientes. 17 février 2021. Rapport complet disponible auprès de : **phac.evidence-donnees.probantes.aspc@canada.ca**

Aperçu des éléments de preuve : **Synthèse en bref sur la charge virale et la probabilité de transmission pendant la période infectieuse du SRAS-CoV-2**

Contexte

L'identification des personnes infectieuses est essentielle à la prévention et au contrôle efficaces de la COVID-19. La présente synthèse en bref examine le lien entre la charge virale et la probabilité de transmission pendant la période infectieuse du SRAS-CoV-2. La valeur du seuil de cycle (Ct), qui correspond au nombre de cycles requis pendant la RT-PCR pour atteindre le seuil de détection pour une certaine cible génétique, est souvent utilisée comme indicateur de la charge virale (puisqu'une faible valeur Ct correspond à une charge virale plus élevée).

Principales constatations

La synthèse en bref comprend 27 études, soit 2 revues systématiques, 22 études d'observation, 1 étude de surveillance et 2 études de modélisation publiées avant le 31 mars 2021. Il s'agissait d'études portant notamment sur le lien entre la charge virale et la preuve d'un virus réplicatif (n = 15) et l'association entre la charge virale et le risque de transmission (n = 12). Les principales constatations qui en découlent sont les suivantes :

- Des charges virales élevées (Ct inférieur à 30 ou supérieur à 10^6 copies/ml) ont été signalées pendant la période présymptomatique, ainsi que jusqu'à 8 à 10 jours après l'apparition des symptômes. C'est précisément pendant cette période que le risque de transmission est le plus grand. Les échantillons dont la valeur Ct est ≤ 25 ont indiqué la présence d'un virus réplicatif à un taux supérieur à 90 %.
- Les cas index qui avaient une faible charge virale (indiquée par une valeur Ct supérieure à 35) présentaient un faible risque de transmission (environ 8 %).
- Dans de rares cas, on pouvait tout de même détecter un risque de transmission chez ces personnes plus de 10 jours après l'apparition des symptômes ou lorsque leurs valeurs Ct étaient supérieures à 35, mais ces cas sont plus susceptibles d'être atteints de la forme grave de la maladie ou d'être immunodéprimés.

Facteurs dont il faut tenir compte

Dans la plupart des cas, la charge virale et les jours qui ont suivi l'apparition des symptômes sont de bons prédicteurs du potentiel de transmission. Les preuves sont cependant limitées par la grande hétérogénéité des méthodes d'échantillonnage, des tests de détection et des cibles génétiques utilisés dans les différentes études. Une lacune importante dans la recherche porte sur le lien potentiel entre la charge virale et la transmissibilité accrue des variants préoccupants du SRAS-CoV-2. Des recherches futures seront donc nécessaires pour combler ce manque de connaissances.

Evidence Snapshot:

Evidence Brief of SARS-CoV-2 Risks in Arenas

Context

COVID-19 outbreaks related to arenas and ice sports have highlighted the need to understand how transmission is occurring and what environmental and behavioural factors may be altered to lower the risk of transmission. To address this, the available literature was summarized.

Key Findings

Thirteen publications available as of February 12, 2021 were included: four of outbreaks in arena sports (hockey, curling), two cross-sectional studies on transmission in non-arena based sports, four guidance documents for resumption of hockey, and three reviews on SARS-CoV-2 with respect to cold temperatures. The key findings were:

- Hockey provides favourable conditions for SARS-CoV-2 transmission because of both on-ice activities: heavy breathing on ice and the bench due to high intensity physical activity, close proximity of players and coaches, dry and cold air in the arena, and segregated air mass caused by ~10 foot barriers around the ice resulting in poor air circulation. And off-ice activities: due to time spent in close proximity to others before and after on-ice activities.
- Evidence on transmission during non-arena sports found lower risk of COVID-19 among outdoor sports compared to indoor sports, and non-contact sports compared to contact sports. For indoor sports, wearing a mask had a significant protective association.
- Strategies to reduce risk for all indoor ice activities include limiting the number of individuals in the arena, screening of individuals and increasing the use of sanitizers, minimizing the sharing of equipment, and using masks and social distancing when not on the ice, as well as lessening time of both before and after on-ice activities.

Considerations

Published empirical evidence is limited, despite many jurisdictions reporting cases or outbreaks traced to hockey teams or curling, as the nature of these sports makes it difficult to establish with certainty where transmission has occurred. However, it appears basic public health measures can reduce the risk of COVID-19 transmission in ice arenas.

Aperçu des éléments de preuve :

Synthèse en bref sur les risques associés au SRAS-CoV-2 dans les arénas

Contexte

Les éclosions de COVID-19 associées aux arénas et aux sports sur glace ont fait ressortir la nécessité de comprendre comment s'effectue la transmission et les facteurs environnementaux et comportementaux qui peuvent être modifiés pour réduire le risque de transmission. La littérature disponible à cet égard a donc été résumée dans la présente synthèse en bref.

Principales constatations

Treize publications disponibles en date du 12 février 2021 ont été incluses, soit quatre études portant sur des éclosions dans les arénas (hockey, curling), deux études transversales sur la transmission dans des sports pratiqués à l'extérieur des arénas, quatre documents d'orientation sur la reprise du hockey et trois revues sur le lien entre le SRAS-CoV-2 et les températures froides. Les principales constatations qui en découlent sont les suivantes :

- Le hockey offre des conditions favorables à la transmission du SRAS-CoV-2 en raison des activités pratiquées sur la glace, de la respiration forte, tant sur la glace et sur le banc en raison de l'intense activité physique, de la proximité des joueurs et des entraîneurs, de l'air sec et froid que l'on retrouve dans les arénas, ainsi que de la masse d'air séparée que créent les barrières d'environ 3 mètres (10 pieds) de hauteur tout autour de la glace et favorisent une mauvaise circulation de l'air. Les activités en dehors de la glace, notamment le temps passé à proximité d'autres personnes, tant avant qu'après les activités sur glace, sont aussi des conditions favorables à la transmission du virus.
- Les preuves sur la transmission pendant la pratique des sports à l'extérieur des arénas ont révélé un risque plus faible de COVID-19 lorsque les sports étaient pratiqués en plein air plutôt qu'à l'intérieur, et le même type de lien a pu être établi entre les sports sans contact et les sports de contact. En ce qui concerne les sports pratiqués à l'intérieur, le port d'un masque ou d'un couvre-visage a semblé offrir un important niveau de protection.
- Les stratégies visant à réduire le risque de transmission associé à l'ensemble des activités sur glace pratiquées à l'intérieur comprennent le fait de limiter le nombre de personnes pouvant se trouver dans l'aréna, d'effectuer le dépistage des personnes et d'améliorer l'utilisation des désinfectants, de minimiser le partage de l'équipement, de favoriser le port des masques ou des couvre-visages et d'assurer le respect de la distanciation sociale lorsque les personnes ne sont pas sur la glace, ainsi que de réduire le temps passé dans l'aréna, tant avant qu'après les activités sur glace.

Facteurs dont il faut tenir compte

Les données empiriques publiées sont limitées, malgré le fait que de nombreuses administrations signalent des cas ou des éclosions liés aux équipes de hockey ou de curling, car la nature de ces sports ne permet pas d'établir facilement avec certitude le lieu où la transmission s'est produite. Il semble toutefois que le respect des mesures de base en matière de santé publique puisse réduire le risque de transmission de la COVID-19 dans les arénas.

Evidence Snapshot:

Evergreen Rapid Review on COVID-19 Vaccine Attitudes and Uptake – Update 8

Context

Vaccination is a key public health strategy for the prevention and control of COVID-19. Update 8 of this living rapid review summarizes 205 studies on COVID-19 vaccine uptake globally, and vaccine attitudes in the Canadian general population and pre-defined priority populations. Evidence on priority populations includes studies from Australia, New Zealand, USA, and the UK to complement areas where there was little Canadian research.

New Findings

There were 40 new studies identified from June 1-July 1, 2021 including 6 new studies from Canada. Key results from studies conducted after January 2021 found that:

- Intention to vaccinate in Canada continues to increase and was 84-88% across the country in June 2021.
- In June, 89% of Canadians reported they intend to receive a second dose, 9% have already had their second dose, 1% probably will not, and 1% were unsure.
- One study indicated that 48% of Canadians were uncomfortable about receiving a different brand of vaccine as their second dose, whereas 46% were comfortable and 6% were unsure.
- Financial incentives were not reported to increase the likelihood of accepting a vaccine in a study conducted in Manitoba, however two studies indicate text messaging reminders are effective.
- Parental and child vaccine intentions continue to be highly correlated with each other, with parents who were intending to take a vaccine more likely to intend to vaccinate their children. In a group of 70 parents or guardians of children aged 12-17 from Manitoba, 15% and 13% were not sure or would not vaccinate their children, respectively. Similar to the general population, parents from lower-income households, who are younger, less educated, have a history of not accepting other vaccines, who are female, and ethnic minorities were more likely to reject a vaccine for their children.
- Vaccine passports have high support in Quebec with 72% of residents in favour.
- In February, Israel implemented the "green pass" which could be acquired post-vaccination or with a recent negative test. This resulted in a 22% increase in vaccine uptake after three days.

Considerations

Since November 2020, Canadians have indicated an increasing intention to vaccinate. Most of the evidence on vaccine intention has been based on self-reported results from surveys, so may be limited by response and social desirability bias. Since the vaccine rollout began, 29 studies on vaccine uptake have been identified. Uptake trends were in line with trends reported in intention to vaccinate studies.

Aperçu des éléments de preuve

Revue rapide et évolutive sur les attitudes à l'égard des vaccins et de l'adoption des vaccins contre la COVID-19 – Mise à jour 8

Contexte

La vaccination est une stratégie de santé publique clé pour la prévention et le contrôle de la COVID-19. La mise à jour 8 de la présente revue rapide évolutive résume 205 études sur l'adoption du vaccin contre la COVID-19 à l'échelle mondiale et les attitudes à l'égard du vaccin dans la population canadienne en général que dans des populations prioritaires prédéterminées. Les données probantes sur les populations prioritaires en Australie, en Nouvelle-Zélande, aux États-Unis et au Royaume-Uni ont également été incluses pour compléter les domaines dans lesquels il y avait peu de recherche au Canada.

Nouvelles constatations

Entre le 1er juin et le 1er juillet 2021, 40 nouvelles études ont été recensées, dont six nouvelles études provenaient du Canada. Les études effectuées après janvier 2021 ont notamment révélé ce qui suit :

- Au Canada, l'intention de se faire vacciner a continué d'augmenter et se situait entre 84 et 88 % dans l'ensemble du pays en juin 2021.
- En juin, 89 % des Canadiens ont déclaré avoir l'intention de recevoir une deuxième dose, 9 % ont déjà reçu leur deuxième dose, 1 % ne le feront probablement pas et 1 % étaient incertains.
- Une étude a indiqué que 48 % des Canadiens étaient mal à l'aise à l'idée de recevoir une marque différente de vaccin comme deuxième dose, tandis que 46 % étaient à l'aise et 6 % étaient incertains.
- Une étude menée au Manitoba a révélé que les incitations financières n'augmentaient pas la probabilité de se faire vacciner, mais deux études indiquent que les rappels par messagerie texte sont efficaces.
- L'intention de se faire vacciner des parents et des enfants sont fortement corrélées les unes avec les autres, puisque les parents qui avaient l'intention de se faire vacciner étant plus susceptibles de vouloir faire vacciner leurs enfants. Dans un groupe de 70 parents ou tuteurs d'enfants âgés de 12 à 17 ans du Manitoba, 15 % et 13 % n'étaient pas sûrs ou ne feraient pas vacciner leurs enfants, respectivement. Tout comme dans la population en général, les parents qui sont dans des ménages à faible revenu, qui sont plus jeunes et moins instruits, qui ont déjà refusé d'autres vaccins, qui sont des femmes ou des membres de minorités ethniques, sont ceux qui étaient plus susceptibles de refuser un vaccin pour leurs enfants.
- Le passeport vaccinal bénéficie d'un soutien important au Québec, 72 % des résidents y étant favorables.
- En février, Israël a mis en place le « laissez-passer vert » qui peut être acquis après la vaccination ou avec un test négatif récent. Cela a entraîné une hausse de 22 % de l'adoption du vaccin après trois jours.

Facteurs dont il faut tenir compte

Depuis novembre 2020, les Canadiens ont dit être de plus en plus nombreux à vouloir se faire vacciner. La plupart des données probantes sur l'intention de se faire vacciner étaient fondées sur les résultats autodéclarés provenant de sondage, ce qui veut dire qu'elles peuvent être limitées par la réponse et le biais de désirabilité sociale. Depuis le début du déploiement du vaccin, 29 études sur l'adoption du vaccin ont été recensées. Les tendances en ce qui concerne l'adoption du vaccin étaient conformes aux tendances déclarées dans les études sur l'intention de se faire vacciner.

Référence : Groupe des sciences émergentes de l'Agence de la santé publique du Canada. Revue rapide et évolutive sur les attitudes à l'égard des vaccins et de l'adoption des vaccins contre la COVID-19 : mise à jour 8. Juillet 2021. Rapport complet disponible en écrivant à : **phac.ocsoevidence-bcscdonneesprobantes.aspc@canada.ca**

Evidence Snapshot:

Evergreen Rapid Review on COVID-19 Vaccine Attitudes and Uptake in Canada – Update 9

Context

Vaccination is a key public health strategy for the prevention and control of COVID-19. Update 9 of this living rapid review summarizes 62 studies on COVID-19 vaccine uptake and attitudes in Canada. Previous versions of this report (1-8) included vaccine uptake globally, vaccine attitudes in the Canadian general population and pre-defined priority populations from Australia, New Zealand, USA, and the UK to complement areas where there was little Canadian research.

New Findings

There were 9 new studies identified from July 1-August 1, 2021 and key results from studies conducted in the last 4 months were highlighted. This included:

- Two July studies indicated 86-91% of Canadians have either received a vaccine or wish to get a vaccine as soon as possible, a slight increase from May and June.
- A study that explored the relationship between race and intention to vaccinate found that 21% of Canadians were vaccine hesitant with higher levels among Black (33%) and non-Black visible minorities (25%) compared to White Canadians (19%). Black Canadians aged 25-34 had the highest levels of vaccine hesitancy (54%). Drivers of vaccine hesitancy among Black Canadians were the inability to take paid time off, concern that vaccines cause autism, and vaccine safety concerns in general.
- In Saskatchewan, those with Indigenous status were more vaccine hesitant than non-Indigenous (RRR 1.65, 95% CI: 1.01-2.70) and those who were born outside of Canada or who had lived in Canada less than 20 years were more vaccine hesitant than those born in Canada (RRR 3.14, 95% CI: 1.56-6.34).
- A longitudinal study from Quebec demonstrated that 87% of parents intend to vaccinate their children, up 1% from June.
- 76% of those unwilling or unsure about vaccination were planning on resuming everything they did before COVID-19 with no hesitation, compared to 34% of people after their first dose and 27% of people after both doses of vaccine.
- Two studies reported 66% of Canadians want full vaccination as a requirement to allow people to cross the USA-Canada border and 69% want to wait until at least 75% of Canadians are fully vaccinated before opening the border.

Considerations

Since November 2020, Canadians have indicated an increasing intention to vaccinate. This is based on self-reported results from surveys, so may be limited by response and social desirability bias. Since the vaccine rollout began, only one study on vaccine uptake has been identified. Uptake trends were in line with trends reported in intention to vaccinate studies.

Emerging Evidence on COVID-19

Rapid Review of Infectious Period

Introduction

What is the length of the infectious period for SARS-CoV-2?

The infectious period (also known as the communicability period) is defined as the time during which an infected person can transmit an infectious agent to another person. The infectious period and its relationship to exhibiting symptoms is an important clinical and epidemiologic parameter to understand for the control of any infectious disease.

Infectious period estimates have been determined from a combination of epidemiological and clinical investigations that together inform when an infected person can or is likely to transmit the virus. To establish a person is infected, most studies report the use of RT-PCR to diagnose cases of COVID-19 and to monitor viral shedding over time. However, detection of viral RNA by RT-PCR does not provide proof of infectivity and virus particles are likely to be shed from infected tissue for a period of time after an infection has been cleared by the host immune system (Jefferson et al., 2020). To establish if viable virus has been isolated in a sample, replication of virus is established most commonly in cell culture and indicates that infective virus is present. In this review few studies have employed culture methods (or animal inoculation) because it is slow, costly, and is not as sensitive as RT-PCR. The results of epidemiological studies, RT-PCR, qRT-PCR and culture results together provide evidence on when a case is likely infective and capable of transmitting the virus.

This rapid review covers the evidence for the infectious period of pre-symptomatic, asymptomatic, and symptomatic COVID-19 cases as inferred by culturable virus shedding, viral RNA detection, epidemiological data, and predictive models. Samples studied are most commonly nasopharyngeal swabs, however fecal/rectal swabs and eye swabs have also been studied for the presence of SARS-CoV-2. Respiratory transmission is considered most common, and more evidence is needed to determine importance of other modes of transmission including fecal-oral, fecal-fomite or fecal-respiratory given viable SARS-CoV-2 has been found in feces.

This is an evergreen rapid review of infectious period and contains key studies captured by the PHAC emerging sciences daily COVID-19 literature scan up to August 31, 2020.

Key Points

Overall, the best available evidence indicates infectious period for most symptomatic cases is considered to start on average 2.5 days before developing symptoms, peak around day 4 of symptoms and decrease to low levels within 8-10 days after the start of symptoms for a total of 10-13 days. The asymptomatic infectious period has been found to be similar. Longer infectious periods have been documented in more severe or immunocompromised cases (18-32 days post symptom onset).

Pre-symptomatic Infectious Period, N=25 studies

- Viable virus has been cultured from respiratory samples of pre-symptomatic cases 1-6 days before symptom onset as determined by medical observation (Table 1). Viable virus has also been cultured from gastrointestinal samples; for example a rectal sample showed evidence of active SARS-CoV-2 viral replication three days prior to symptom onset (Qian et al., 2020).
- Studies utilizing RT-PCR to detect viral RNA from respiratory samples also suggest that shedding occurs on average 2.5 days (1-7 range) prior to symptom onset.

Asymptomatic Infectious Period, N=25 studies

- Viable virus and viral RNA detected in a cohort of asymptomatic cases was highest during the first week of infection and declined in subsequent weeks (Quicke et al., 2020). Infectious virus was not detected by plaque assay in nasopharyngeal swabs from individuals with less than 100,000 RNA copies/swab.
- There has been little consensus about whether asymptomatic and mildly symptomatic infections differ in viral shedding time (Table 2). Based on the current evidence, the total infectious period of asymptomatic cases appears to be similar or shorter than that of mildly symptomatic cases. Across studies, similar viral loads have been reported for asymptomatic, pre-symptomatic, and symptomatic cases.

Symptomatic Infectious Period, N=107 studies

- Viable virus, culture results, N=18 primary research studies and 2 systematic reviews:
  - For mild cases, the best estimate for the infectious period, measured from self-reported symptom onset using virus culture from respiratory samples, is 8-10 days with a peak in viral load during the first week of illness (Table 3).
  - Cases of prolonged viable viral shedding (18-32 days) have been documented using virus culture in a few studies. Many of these studies are still in preprints and include single cases or small sample sizes (Table 3). These cases are typically individuals with severe infection, who are either immunocompromised, or have multiple chronic underlying health conditions.
  - There are a few studies that have cultured SARS-CoV-2 from the fecal/rectal samples of a confirmed case (Table 3). A recent study of inoculated ferrets has confirmed the presence of infectious SARS-CoV-2 in fecal and urine specimens from days 11, 13 and 15 of illness (Jeong et al., 2020).
- Viral RNA detection, RT-PCR results, N=88 primary research studies and 6 systematic reviews:
  - Most studies report time from self-reported symptom onset or test positive diagnosis to time viral infection has been cleared, determined via RT-PCR. Positive RT-PCR results are not proof of infectiousness.

- Viral RNA presence varies widely by sample type. Respiratory swabs typically become negative within 14-20 days of self-reported symptom onset, while stool samples remain positive a few days to four weeks longer than respiratory samples. Evidence of SARS-CoV-2 RNA has also been identified in eye swabs up to 22 days post onset of self-reported symptoms.
- Extended periods of viral RNA shedding have been reported (up to 83 days) in respiratory samples, with shedding frequently outlasting the duration of symptoms. However, concentrations of viral RNA measured in upper respiratory samples has been shown to decline after symptom onset and there has been no evidence of transmission in clinically recovered individuals with persistent detection of viral RNA nor has there been viable virus isolated from such cases.
- Prolonged viral RNA shedding has been shown to be positively associated with severity of COVID-19 and older age in multiple studies (Table 3). However, a recent meta-regression identified that the reported average of four days longer duration of viral RNA shedding in severe cases was not statistically significant (Byrne et al., 2020). The length of viral RNA shedding does not significantly differ between male and female.

<u>Recurrence of Viral Shedding in Convalescent Period, N=55 studies</u>

- Recurrence of viral RNA shedding in the convalescent period after meeting discharge criteria (defined at the time as two consecutive negative RT-PCR tests) has been reported in multiple case reports and observational studies (Table 4). These cases are not thought to be re-infection with a new strain of the virus, instead are considered to have not fully cleared the original SARS-CoV-2 infection.
  - Recurrence typically occurs within seven days of discharge.
  - Following recurrence, patients remained viral RNA positive for approximately 1-8 days and typically remained asymptomatic.
  - Although this is an active area of study and numerous new studies have been published, to date, only one study has provided evidence of viable virus in a recurrent case (Quicke et al., 2020). No evidence of transmission during the recurrence of viral RNA detection has been reported.
- Additional research is needed to improve our understanding of RT-PCR results and how to interpret those results with respect to infectious period and risk of transmission. Particularly in cases with prolonged RT-PCR positive test results. As a result, the CDC has stopped recommending two consecutive negative RT-PCR tests to determine when to end isolation and precautions for COVID cases.

<u>Reinfection, N=2 studies</u>

- Since August 25, 2020, good evidence that reinfection can occur has been reported (Table 5):
  - A patient from Hong Kong was reinfected 142 days after initial infection and this was documented with compelling epidemiological, clinical, serological evidence as well as genomic analyses. (To, Hung, et al., 2020).

    - There is also strong evidence for a case of re-infection in the United States (Tillet et al., 2020).
- At this time, knowledge gaps exist on whether clinical course and epidemiological characteristics including infectious period of re-infection cases are different from the initial infection.
- Additional research is needed to understand the role of immunity in protection against SARS-CoV-2 post infection.

Overview of the Evidence

To date, there have been numerous publications related to the infectious period of COVID-19. The majority of these publications are case reports and observational studies based on contact tracing; these study designs are at high risk of bias and thus are considered low quality. Many of these are pre-prints and have not undergone a peer-review process. Prospective cohorts are of lower risk of bias and are considered higher quality research, but there are few of this study design contributing to this question. Overall, the outcomes should be interpreted with caution, estimates are changing as new research becomes available and there are many knowledge gaps that new research addressing these gaps could significantly change our understanding of SARS-CoV-2 infection in humans.

Outcomes from key studies are summarized in the evidence tables: 1) pre-symptomatic, 2) asymptomatic, 3) symptomatic, and 4) recurrence of viral shedding. Within these, key information including study type and specific methods used (e.g. culture, serial RT-PCR results, epidemiological data, or modeling) are specified along with the infectious period estimates and risk factors.

There is substantial variation in the methodological approach utilized and how infectious period was defined across studies. Research based on case series and contact tracing investigations alone is considered very low quality. These study designs suffer from low sample size, selection bias and recall bias (e.g. self-report symptom onset). Their results should be interpreted with caution, as results are likely to change with additional research.

Several knowledge gaps exist for infectious period. Detection or confirmation of viable virus rather than RNA is underpinned by few observations. The relationship between transmission potential and RT-PCR results is not well defined. Additional research on post infection immunity, recurrence of RNA positive tests and the likelihood and epidemiological characteristics of reinfection are needed to understand if and/or when a person is potentially infectious after the initial acute infection. This research is fundamental to understanding the transmission dynamics of SARS-CoV-2.

CONTENTS

BACKGROUND INFECTIOUS PERIOD

The infectious period (also known as the communicability period) is defined as the time during which an infected person can transmit an infectious agent to another person. The infectious period and its relationship to exhibiting symptoms is an important epidemiological parameter to understand for the control of any infectious disease. For COVID-19, there is evidence that SARS-CoV-2 can be shed by an infected person before they exhibit symptoms (pre-symptomatic) (e.g., (Arons et al., 2020; Hoehl et al., 2020; Pan, Zhang, Yang, Poon, & Wang., 2020)) and by infected persons who never develop noticeable symptoms (asymptomatic) (e.g., (Alshami et al., 2020; Y. Lu et al., 2020; Z. Zhang et al., 2020)). There are also studies that suggest viral shedding may persist in the convalescent phase or may re-emerge after the virus has been undetectable for a period of time (e.g., (Hoang, Dao, & Gautret, 2020; Q. Hu et al., 2020)). This report covers the evidence for these different periods and studies that attempt to estimate the entire infectious period for COVID-19. Studies will be further divided by methods for determining viral shedding and the question of how detection of viral RNA by RT-PCR compares to that of culture and what inferences can be made for these different results.

Infectious period estimates have been determined from a combination of epidemiological and clinical investigations that together inform when an infected person can or is likely to transmit the virus. To determine if a person is infected, most studies report the use of RT-PCR to diagnose cases of COVID-19 and to monitor viral RNA shedding over time. However, detection of viral RNA by RT-PCR does not provide proof of infectivity and virus particles are likely to be shed from infected tissue for a period of time after an infection has been cleared by the host immune system (Jefferson et al., 2020). To establish if viable virus has been isolated, replication of virus from the sample is established most commonly in cell culture and indicates that infective virus is present. In this review few studies have utilized culture methods (or animal inoculation) because it is slow, costly, and is not as sensitive as RT-PCR. The results of epidemiological studies, RT-PCR, qRT-PCR and culture results together provide evidence on when a case is likely infective and capable of transmitting the virus.

Variability in the measurement of infectious period is also present across studies. The majority of studies measure time from diagnosis or symptom onset until clearance of viral RNA. Thus, there are no measurements prior to diagnosis. Epidemiological research, mainly in the form of cluster investigations and testing close contacts of cases regardless of their clinical status has provided evidence that virus shedding can occur prior to symptom onset (Z. Du et al., 2020; X. He et al., 2020). The heterogeneity across definitions and how infectious period is determined in each study is summarized in the detailed evidence tables.

PRE-SYMPTOMATIC INFECTIOUS PERIOD

Table 1 lists twenty-five studies that provide estimates of the pre-symptomatic infectious period, identified through case series, contact tracing investigations, and modeling. Many of these case reports and contact tracing studies originate from China and show evidence of COVID-19 transmission from people who are in their incubation period. SARS-CoV-2 has been successfully isolated from pre-symptomatic cases, which further provides evidence that pre-symptomatic transmission occurs. However, the vast majority of evidence is based on case reports and cluster investigations which are subject to recall bias as the cases and their contacts are responsible for providing information about exposure and symptom onset time. Additionally, with widespread transmission of COVID-19 in an epidemic area it is possible that infections described in these studies could have been caused by other unrecognized sources.

Pre-symptomatic infectious period across studies suggests a person likely sheds SARS-CoV-2 on average 2.5 days (1-7 range) prior to symptom onset based on respiratory samples (Hoehl et al., 2020; Z. Liu et al., 2020; Nissen et al., 2020; Pan et al., 2020; Sakurai et al., 2020). Estimates from contact tracing studies also suggest an average pre-symptomatic infectious period of 2-3 days (1-12.3 range) (X. He et al., 2020; S. Hu et al., 2020; R. Huang, Xia, Chen, Shan, & Wu, 2020; Kong et al., 2020; J. Li et al., 2020; Rothe et al., 2020; W. E. Wei et al., 2020). Evidence of active SARS-CoV-2 virus replication from a rectum sample three days prior to symptom onset has also been presented (Qian et al., 2020). A study of long-term care residents found that viable virus could be cultured up to six days before symptom onset and reported similar cycle threshold values (i.e. viral load) for asymptomatic, pre-symptomatic, and symptomatic cases (Arons et al., 2020).

There are few studies that take measurements prior to diagnosis/symptom onset. More evidence is needed to improve the certainty of the estimates for pre-symptomatic infectious period of COVID-19.

Table 1: Studies evaluating the pre-symptomatic infectious period of COVID-19 (N=25)

Reference	Study Type	-Population & Setting -Time Period	IP determined via: Culture, serial RT-PCR results, Epi data, or Model	Key Outcomes
Culture & RT-PCR Studies				
(Arons et al., 2020)	Outbreak investigation	-Residents of a skilled nursing facility in Washington, US -April 3, 2020 end date	Culture & RT-PCR	Nasopharyngeal and oropharyngeal swabs -48 (63%) of residents that participated in point-prevalence surveys tested positive. -24 were pre-symptomatic and 2 were asymptomatic as determined by standardized symptom-assessments completed

				by nurses. -Viable virus was isolated from specimens collected six days before to nine days after onset of symptoms.
(Hoehl et al., 2020)	Case series	-Travelers from Wuhan to Germany - February 1, 2020	Culture & RT-PCR	Throat Swab -2 patients were asymptomatic RT-PCR test positive. One day later 1 of the cases demonstrated a faint rash and minimal pharyngitis. -SARS-CoV-2 was successfully isolated from the 2 cases, indicating potential infectiousness while pre-symptomatic. -These findings suggest that infectiousness may occur at least 1 day before symptom onset.
(Nissen et al., 2020) *Preprint*	Case report	-36 year old healthcare worker in Sweden -April 2 – 17, 2020	Culture & RT-PCR	Nasopharyngeal and oropharyngeal swabs - Observed cytopathic effect via cell culture, immunofluorescence for dsRNA and rRT-PCR determined that the SARS-CoV-2 virus from two samples (taken on day 3 and day 1 before symptom onset) were infectious in two independent experiments.
(Qian et al., 2020)	Case report	-Patient receiving surgery for rectal cancer in China -January 16, 2020 onward	Culture & RT-PCR	Rectal tissue and throat swabs -On January 16, 2020, the patient underwent rectal surgery. On day 3 postoperatively, the patient presented with fever and cough and he was subsequently diagnosed with COVID-19 via RT-PCR. In March, a retrospective study was conducted on the patient's surgically removed tissue. Ultrathin sections of rectal tissues were prepared, and virus particles were found in the cytoplasm of intestinal epithelial cells. To further confirm the SARS-CoV-2 -specific infection and replication in the rectum, immunohistochemistry and immunofluorescence using the rabbit anti-SARS-CoV-2 NP antibody was used. -This is the first report of direct evidence of active replication of SARS-CoV-2 in a patient's rectum during the incubation period.
(Z. Liu et al., 2020)	Prospective cohort	-Pre-symptomatic carriers in China (n=16)	RT-PCR	Sputum and throat swabs -The median period between positive SARS-CoV-2 RNA

		-Timeline not reported		detection and symptom onset was calculated as 2 days (1-5 range).
(Sakurai et al., 2020)	Retrospective cohort	-Asymptomatic (n=90) and pre-symptomatic (n=11) cases hospitalized in Japan from the Diamond Princess cruise ship -February 19 - 26, 2020	RT-PCR	Specimen type not reported -11 patients were pre-symptomatic, and developed symptoms a median of four days (3-7 range) after the first positive RT-PCR test. -The asymptomatic cases experience a median duration of SARS-CoV-2 viral RNA shedding of 9 days (3-21 range) between the first positive PCR test and the first of 2 serial negative PCR tests.
Epidemiological data studies				
(Pan et al., 2020)	Contact tracing study	-Two individuals tracked due to exposure to an infected patient in China -Timeline not reported	RT-PCR & Epi data	Respiratory swab -Cases were serially tested prior to onset of symptoms. -Cases showed positive RT-PCR results one day before onset, suggesting that infectiousness may occur before symptom onset.
(J. Li et al., 2020)	Contact tracing study	-Three family clusters in China -January 21 – February 9, 2020	Epi data	- The three index cases transmitted the infection to 28 family members 2-10 days before illness onset.
(Kong et al., 2020)	Contact tracing study	-Ten cases in China -January 8 – 27, 2020	Epi data	-The last two generations were infected in public places, 3 and 4 days prior to the onset of illness in their infectors.
(R. Huang et al., 2020)	Contact tracing study	-Family cluster of confirmed infection in China -January, 2020	Epi data	-Tracing within a family cluster (n=11) and exposure dates demonstrated a median pre-symptomatic infectious period of four days (3-5 range).
(Rothe et al., 2020)	Contact tracing study	-Cluster of cases from pre-symptomatic contact in Germany -January 19- 29, 2020	Epi data	-Transmission occurred from a pre-symptomatic case to 4 contacts. -The tracing results show a median pre-symptomatic infectious period of two days (1-3 range).
(W. E. Wei et al., 2020)	Contact tracing study	-Seven clusters in Singapore	Epi data	-Pre-symptomatic transmission was evident in 4 clusters with a median infectious period of two days (1-3 range).

		-January 23 – March 16, 2020		-Transmission exposure was not ascertained for the other 3 clusters.
(S. Hu et al., 2020) *Preprint*	Contact tracing study	-1,178 SARS-CoV-2 infected individuals and their 15,648 contacts in China -January 13 – April 2, 2020	Epi data	-Forty-three pre-symptomatic transmission events were recorded in 23 clusters. -Infectiousness was estimated to peak 1.8 days before symptom onset, with 95% of transmission events occurring between 7.6 days before and 7.3 days after the date of symptom onset. -The proportion of pre-symptomatic transmission was estimated to be 62.5%.
(X. He et al., 2020)	Contact tracing study	-77 infector–infectee transmission pairs from Vietnam, Malaysia, Japan, China, Taiwan, USA, Singapore -December 18, 2019 – March 5, 2020	Epi data	-Authors assumed an incubation period distribution of mean 5.2 days to infer that infectiousness started from 12.3 days (5.9-17 95%CI) before symptom onset and peaked at symptom onset (-0.9-0.9 95%CI). -Observed that only <0.1% of transmission would occur before 7 days, 1% of transmission would occur before 5 days and 9% of transmission would occur before 3 days prior to symptom onset. -In a sensitivity analysis, infectiousness was shown to peak at 2 days before to 1 day after symptom onset. -Estimated that 44% (30-57% 95%CI) of secondary cases were infected during the index cases' pre-symptomatic stage.
(Chun, Baek, & Kim, 2020) *Preprint*	Literature review	-72 infector-infectee transmission pairs in South Korea -January 23 – March 31, 2020	Epi data	-The mean and median estimates were 1.31 days (0.38–2.55 95%CI) and 0.68 days (-0.09–1.73 95%CI) after symptom onset, respectively, with the peak at 0.72 days before symptom onset. -The pre-symptomatic transmission proportion was 37% (16–52% 95%CI).
(Z. Du et al., 2020) *Preprint*	Literature review	-468 infector–infectee pairs identified via contact tracing in China -January 21 – February 8,	Epi data	-59 of 468 infector-infectee pairs indicated that the infectee had symptoms earlier than the infector. -These negative serial intervals suggest that pre-symptomatic transmission may have occurred.

		2020		
(Casey et al., 2020) *Preprint*	Literature review	-17 studies reporting serial interval or generation time from Hong Kong, Tianjin, pooled data from Hong Kong and Shenzhen, Singapore, Mainland China excluding Hubei, mixed sources, Shenzhen, northern Italy and Wuhan -December 1 – April 15, 2020	Epi data	-Subtracted incubation period from serial interval or generation time to infer pre-symptomatic infectious period and to estimate the proportion of pre-symptomatic transmission. -The pooling of serial interval estimates for transmission time relative to symptom onset gave a mean pre-symptomatic infectious period of 0.67 days (0.63 median). -The pooling of 5 generation time-based estimates gave a mean pre-symptomatic infectious period of 1.62 days (1.32 median). -Pre-symptomatic transmission was estimated to be 56.1% based on serial interval estimates and 65.5% based on generation time estimates.
(Prakash, 2020) *Preprint*	Literature review	-Individuals reported in the literature (n=1251) -No limit on country -No timeline reported	Epi data	-The peak of infectiousness was 2 days after the infection. -Estimated that 68.4% (67.0-69.7% 95%CI) of infections are caused by pre-symptomatic infectors.
Modeling studies				
(Nishiura, Linton, & Akhmetzhanov, 2020)	Bayesian Predictive Model	-28 infector-infectee pairs -No limit on country -February 12, 2020 end date	Modeled	-Accounting for right truncation and analyzing all pairs, authors estimated a serial interval of 4.0 days (3.1-4.9 95%CI). -This interval is shorter than preliminary estimates of the incubation period of approximately 5.0 days. -This suggests that pre-symptomatic transmission may make up a substantial proportion of secondary transmission.
(Tindale et al., 2020) *Preprint*	Statistical Model	-Outbreak cases in Tianjin, China, and Singapore -January 19 – February 27, 2020	Modeled	-Period of pre-symptomatic transmission was inferred from estimates of serial interval and incubation periods for populations in Tianjin and Singapore. -Average pre-symptomatic infectious periods were 2.55 days (1.2-3.3 range) in Singapore and 2.89 days (2.79-8.2 range) in Tianjin.
(Zhu, 2020) *Preprint*	SEIR model	-Wuhan outbreak in China	Modeled	-Authors propose a new epidemic model called SEIR-HC, with 2 different social circles. Using the model alongside an

		-April 15, 2020 end date		optimization algorithm, the spread process of the outbreak in Wuhan city is reproduced and the propagation characteristics and unknown data are estimated. -A pre-symptomatic infectious period of 1.01 day was estimated by taking the difference between the latent period and the incubation period.
(Siwiak, Szczesny, & Siwiak, 2020) *Preprint*	SIR metapopulation model	-Entire pandemic (Global) -January 22 – March 26, 2020	Modeled	-Built a modified SIR metapopulation transmission mode parameterized analytically according to the literature, and fitted missing parameters to the observed dynamics of the virus spread. -Estimated a pre-symptomatic infectious period of 4.6 days.
(Peak et al., 2020) *Preprint*	SEIR model	-Confirmed cases in Massachusetts, US -Timeline not specified	Modeled	-Pre-symptomatic infectious period was modelled assuming a serial interval of 4.8 -The mean time of infectiousness onset was 0.77 days before symptom onset (1.98 days before, 0.29 days after 95%CI)
(H. Yuan et al., 2020) *Preprint*	Two-layered SEIQR model	-Imported and confirmed local cases in Hong Kong -January 18 – February 29, 2020	Modeled	-Epidemiological parameters of COVID-19 were estimated. -The pre-symptomatic transmission period before symptom onset was 3.49 days (0.48-5.80 95%CI).
(S. Zhao, 2020)	Novel likelihood-based framework	-Confirmed cases -Country and timeline not specified	Modeled	-Estimate the mean pre-symptomatic transmission period to be 2.2 days (95%CI: 1.3−4.7). -Approximate that 32.2% (10.3−73.7 95%CI) of secondary infections may be due to pre-symptomatic transmission.

ASYMPTOMATIC INFECTIOUS PERIOD

Table 2 lists twenty-five studies that provide estimates of the asymptomatic infectious period, identified through case series and contact tracing investigations. Asymptomatic cases can transmit COVID-19 but there have been few studies investigating the infectious period of asymptomatic cases as they rarely undergo testing. Furthermore, there have been few studies that investigate live viral shedding from asymptomatic carriers via culture. The majority of studies identify asymptomatic cases through contact tracing and determine the length of viral RNA shedding via RT-PCR

from the first day of a positive RT-PCR test to the first day of consecutive negative results. Caution is warranted when interpreting these results as RT-PCR positivity is not indicative of infectiousness and the duration of viral detectability likely overestimates the infectious period.

The best available evidence come from a cohort of asymptomatic cases that detected viable virus and viral RNA through infection. The viral load was highest during the first week of infection and declined in subsequent weeks (Quicke et al., 2020). Further, infectious virus was not detected in nasopharyngeal swabs from individuals with less than 100,000 RNA copies/swab, indicating that low levels of viral RNA correspond to low levels of infectious virus.

Some studies comparing asymptomatic and symptomatic cases show that symptomatic cases demonstrate longer viral RNA shedding periods (Alshami et al., 2020; Y. H. Lee et al., 2020; S. Lee et al., 2020; W. Li et al., 2020; Y. Li et al., 2020a; Y. Lu et al., 2020; Noh et al., 2020; Saurabh et al., 2020; Valente et al., 2020; X. Wei et al., 2020; Z. Zhang et al., 2020), while other studies show no difference between the groups (Lombardi et al., 2020; Xiong et al., 2020) or the opposite association (Long et al., 2020). Similar viral loads have been reported for asymptomatic, pre-symptomatic, and symptomatic cases. Thus, the total infectious period of asymptomatic cases is likely similar or shorter than that of symptomatic cases. The length of viral RNA shedding in asymptomatic cases is not significantly associated with age or sex.

Table 2: Studies evaluating the asymptomatic infectious period of COVID-19 (N=25)

Reference	Study Type	-Population & Setting -Time Period	IP determined via: Culture, RT-PCR Serial testing, Epi data, or Model	Key Outcomes
Culture & RT-PCR Studies				
(Quicke et al., 2020) *Preprint*	Longitudinal surveillance study	-Asymptomatic staff (n=454) at 5 skilled nursing facilities (prevalence varied considerable between facilities) in Colorado, USA	Culture (Plaque assay) & RT-PCR	<u>Nasopharyngeal swabs</u> -N1 viral RNA level was positively correlated with the amount of infectious virus detected via plaque assays. -Infection length ranged from 1- 4 weeks, as determined by detection of viral RNA via qRT-PCR for the SARS-CoV-2 N1 gene. -Levels of viral RNA and infectious virus were highest during the first week of infection and declined in subsequent weeks. -Infectious virus was not detected in individuals with less than 100,000 N1 RNA copies/swab. -One staff member had a weak positive result detected via a single passage plaque assay three weeks after initial diagnosis.

		-Timeline not reported		
(Lavezzo et al., 2020)	Prospective cohort	-Survey 1= 2,812 residents and Survey 2 =2,343 residents in Italy -February 21 – March 7, 2020	RT-PCR	Nasopharyngeal swabs -Found no statistically significant difference in the viral load of symptomatic versus asymptomatic infections. -Found that the viral load tends to peak around the day of symptom onset and for most of the subjects tends to decline after symptom onset.
(W. Li et al., 2020)	Prospective cohort	-Asymptomatic (n=3), pre-symptomatic (n=6), and symptomatic (n=9) cases in China -January 29 – February 5, 2020	RT-PCR	Respiratory and anal swabs - The median duration of viral shedding was shorter in pre-symptomatic patients (11.5 days) than in asymptomatic (28 days) and mild symptomatic cases (31 days).
(Y. H. Lee et al., 2020)	Prospective cohort	-Asymptomatic and mild cases (n=632) in South Korea -March 2 – April 12, 2020	RT-PCR	Oral and nasal swabs -Symptomatic patients had a longer period between diagnosis and negative RT-PCR results than asymptomatic patients: 21.8 days (7.6 SD) vs. 19.1 days (7.5 SD), $p<0.0001$. -Respiratory symptoms had statistically significant correlation to the RNA shedding period ($p<0.0001$). However, there were no statistically significant differences related to gastrointestinal symptoms, headache, fever, and other symptoms. There were also no statistically significant differences according to sex, age, or underlying conditions.
(Saurabh et al., 2020)	Prospective cohort	-Asymptomatic (n=44) and symptomatic	RT-PCR	Oropharyngeal and nasopharyngeal swab -The asymptomatic individuals had median virus persistence duration of 8.87 days (95% CI: 7.65–10.27) and 95 percentile duration of 20.70 days (95% CI:

		(n=7) cases in India -March 19 – May 21, 2020		16.08–28.20). -Around one-fourth asymptomatics (10/44) demonstrated SARS-CoV-2 persistence beyond 2 weeks. -The virus persistence duration for symptomatic individuals was 10.98 days (8.38–14.44 95%CI). This was not found to be significantly longer than that of asymptomatic individuals (P = 0.222). -Age (<60 years) and local transmission were found to be significantly associated with longer virus persistence among asymptomatic individuals on univariate regression but not in multivariate analysis.
(Long et al., 2020)	Prospective cohort	-Asymptomatic cases (n=37) and matched symptomatic cases (n=37) in China -April 10, 2020 end date	RT-PCR	Nasopharyngeal swabs -The median duration of viral RNA shedding in the asymptomatic group was 19 days (15-26 IQR). -The asymptomatic group had a significantly longer duration of viral RNA shedding than the symptomatic group (log-rank P = 0.028). -Data suggest that asymptomatic individuals had a weaker immune response to SARS-CoV-2 infection.
(Y. Lu et al., 2020)	Retrospective cohort	-Hospitalized children with mild and ordinary COVID-19 (n=110) in China -January 30 – March 10, 2020	RT-PCR	Respiratory swab -The median duration of viral RNA shedding was 15 days (11–20 IQR, 5-37 range). -The duration of viral shedding in symptomatic patients was statistically longer (p<0.001) than that in asymptomatic patients: 17 days (12-23 IQR) vs. 11 days (9-13 IQR).
(Alshami et al., 2020) *Preprint*	Retrospective cohort	-Laboratory-confirmed COVID-19 subjects who were quarantined in	RT-PCR	Nasopharyngeal and oropharyngeal swab -69 patients (54%) did not exhibit any symptoms. -For the patients that did experience symptoms, the median time to resolution was 5 days. -The median time to viral clearance was significantly longer (p=0.011) in the symptomatic patients than the asymptomatic patients: 17 days (12.4-21.6

		a government-designated facility following travel outside the kingdom (n=128) in Saudi Arabia -March 16 – April 18, 2020		95%CI) vs. 11 days (8.7-13.3 95%CI).
(Noh et al., 2020)	Retrospective cohort	-Hospitalized patients (n=199) in South Korea, 26.6% were asymptomatic -Timeline not reported	RT-PCR	Specimen type not reported -Duration of viral shedding was defined as time from diagnosis to the day before first negative conversion of two consecutive negative results of RT-PCR. -Mean duration of viral shedding was 24.5 days (± 4.8 SD). -Duration of viral shedding was longer in symptomatic patients than in asymptomatic patients: 25.2 days (± 4.9 SD) vs. 22.6 days (± 4.0 SD), $p < 0.01$. -Symptomatic patients with chest pain released the virus significantly longer than those without: 30.0 (± 4.7 SD) days vs. 25.0 days (± 4.8 SD), $p = 0.01$). -Patients who complained of sputum also experienced prolonged viral RNA shedding: 26.8 days (± 4.8 SD) vs. 24.6 days (± 4.8 SD), $p = 0.03$.
(S. Lee et al., 2020)	Retrospective cohort	-Symptomatic and asymptomatic patients (n=303) in Korea -March 6 – 26, 2020	RT-PCR	Nasopharynx, oropharynx, and sputum swab -The median time from diagnosis to the first negative viral RNA conversion was 17 (1.07, SE) days for asymptomatic patients and 19.5 (0.63, SE) days for symptomatic (including pre-symptomatic) patients ($p=0.07$).
(Xiong et al., 2020)	Retrospective cohort	-Hospitalized pediatric cases (n=244) -January 21 –	RT-PCR	Nasopharyngeal aspirate -The duration between positive and negative nasopharyngeal aspirate were similar in patients with COVID-19, regardless of whether they were asymptomatic or symptomatic (mean of 8.2 days vs 8.9 days; $P = 0.434$),

		March 20, 2020		suggesting a similar duration of viral shedding.
(Lombardi et al., 2020) *Preprint*	Retrospective cohort	-Health care workers in Italy -February 24 – March 31, 2020	RT-PCR	Nasopharyngeal swab -Of 138 subjects with a positive viral RNA test, 41/138 (29·7%) were asymptomatic. -Median time from first positive to a negative test did not differ between symptomatic subjects and asymptomatic cases, 23 days (18-26 95%CI) vs. 23 days (19-29 95%CI). -Median time of viral shedding was not statistically associated with gender or age.
(Kim et al., 2020)	Retrospective cohort	-Laboratory-confirmed hospitalized COVID-19 patients in South Korea -February 4 – April 7, 2020	RT-PCR	Nasal-throat swab -10/71 laboratory confirmed cases, as determined by RT-PCR, were asymptomatic. -The median time to first negative RT-PCR test after diagnosis was 4.5 days (2.5–9 range). -Authors suggest that 14-day quarantine at home after diagnosis may be adequate for asymptomatic carriers.
(Y. J. Liu et al., 2020)	Retrospective cohort	-Asymptomatic (n=35) and subclinical (n=18) pediatric cases in China -Timeline not reported	RT-PCR	Nasopharyngeal swabs -The mean time to clearance of SARS-CoV-2 nucleic acid in nasopharyngeal swabs was 9±4 days.
(M.S. Han et al., 2020)	Retrospective cohort	-Mildly symptomatic (n=9) and asymptomatic children (n=3) in South Korea -March 8 –	RT-PCR	Nasopharyngeal, fecal, and saliva swabs -Viral RNA load in the nasopharyngeal swabs peaked early at median 7.56 $\log^{10}$ copies/mL and decreased over time ($p<0.001$ for trend). The positivity of the specimens was 75% during week 2 and 55% during week 3. -In comparison, the median initial fecal RNA load was 7.68 $\log^{10}$ copies/mL and remained steadily high ($p = 0.148$ for trend) for >3 weeks. Fecal positivity remained >80%.

		April 28, 2020		-The median RNA load in fecal samples was significantly higher than that for nasopharyngeal swab specimens during week two (p = 0.006) and week 3 (p = 0.006). -The RNA load in saliva declined rapidly with time (p = 0.003 for trend). Positivity in saliva samples was 80% in week one but dropped sharply to 33% in week 2 and 11% in week 3. -Symptomatic children had higher initial RNA load in nasopharyngeal swab specimens than asymptomatic children (p = 0.048). There was no significant differences in feces or in saliva and no correlation between RNA load and age.
(Shen et al., 2020)	Retrospective cohort	-Pediatric patients (seven mild & two asymptomatic) in China -January 8 – February 26, 2020	RT-PCR	Specimen type not reported -6 children had a family exposure and could provide exact dates of close contract with someone confirmed to have COVID-19. -The time from exposure to negative RT-PCR results in asymptomatic cases (n=2) was 10 days and 14 days.
(Z. Zhang et al., 2020) *Preprint*	Case series	-56 COVID-19 patients without symptoms at admission (33 later displayed symptoms) and 19 age-matched symptomatic patients from China -January 23 – April 1, 2020	RT-PCR	Respiratory and anal swab -Among 56 patients without symptoms at admission, 23 remained asymptomatic throughout the follow-up period. -Infectious period in this study was defined as the period from the first day of positive nucleic acid test to the first day of continuous negative test during hospitalization. -They also provide estimates for the mean days from symptom onset to RNA negative-conversion. -The infectious period of asymptomatic patients (n=19) was statistically shorter than pre-symptomatic patients (n=30) 9.6 days (±5.3 SD) vs. 13.6 (±6.6 SD), p=0.03. -The symptomatic patients also had a shorter infectious period, 9.71 days (±4.3 SD), compared to pre-symptomatic cases (p=0.05), but a similar time between illness onset and negative conversion, 16.6 (±5.6 SD) and 16.6 (±7.5 SD).
(Mesoraca et	Case series	-Asymptomatic	RT-PCR	Respiratory and fecal swabs

al., 2020)		and mild patients (n=15) in Italy -March 4 – April 20, 2020		-Of the 10 patients with fecal sample negative in the first 10 days, 6 samples became positive 2 weeks after their first positive respiratory tract test. -In four cases, fecal samples showed positive viral RNA shedding 25 days more than their respiratory tract samples.
(W. Du et al., 2020)	Case series	-Asymptomatic (n=5) and mild (n=5) pediatric cases in China -January 23 – March 9, 2020	RT-PCR	Respiratory and fecal samples -The median time from onset to negative RT-PCR results in respiratory tract and fecal specimens was 9 days and 34.43 days, respectively.
(Shin et al., 2020)	Case report	-11 year old asymptomatic girl from South Korea -March 12 – May 13, 2020	RT-PCR	Nasopharyngeal swabs -Child had positive SARS-CoV-2 RNA detection for 62+ days with no symptoms during the entire period.
(Mao, Wan, He, Hu, & Chen, 2020)	Case series	-Asymptomatic cases (n=2) in China -January 27 – February 21, 2020	RT-PCR	Throat swab -Discovered that after 14 days of isolation, 2 asymptomatic cases were still viral carriers of COVID-19. -1 case produced positive RT-PCR results up to 19 days post start of isolation.
(Y. Li et al., 2020a) *Preprint*	Case series	-Asymptomatic cases (n=38) in China -February – March, 2020	RT-PCR	Pharyngeal swabs -The median viral shedding time was 6 days with a minimum of 2 days and maximum of 17 days between first nucleic positive test and last nucleic positive test. - The authors note that this shedding period is shorter than that noted in other studies of symptomatic cases, suggesting shorter infectivity for asymptomatic cases.
(Valente et al., 2020)	Case series	-Pediatric hospitalized	RT-PCR	Nasopharyngeal and conjunctival swab -Two asymptomatic cases became negative after three days post symptom

		patients (n=27) in Italy, 4 were asymptomatic, 15 showed respiratory symptoms, and 8 had gastrointestinal symptoms -March 16 – April 15, 2020		onset while a symptomatic case tested negative after 6 days, while remaining positive on nasopharyngeal swabs. -Additionally, the nasopharyngeal swab was negative on average 8 days (range, 2-17 days) from onset of symptoms, whereas conjunctival swab became negative in all patients on average in 4 days (range, 3-6 days).
Epidemiologic studies				
(Z. Hu et al., 2020)	Serial testing and cluster tracing study	-Cases with asymptomatic infection (n=24) in China -January 28 – February 9, 2020	RT-PCR & Epi data	<u>Pharyngeal swab</u> -Observed asymptomatic transmission to the cohabiting family members, which even caused severe COVID-19 pneumonia. -The median asymptomatic communicable period, defined as the interval from the first day of positive nucleic acid tests to the first day of continuous negative tests, was 6 days (2-12 IQR) in cases that did not develop symptoms but had some evidence of COVID-19 in CT scan (n=19), and 4 days (2-15 IQR) in cases that did not develop symptoms and had normal CT scan.
(Ma et al., 2020) *Preprint*	Literature review	-Cases that contained the data that allowed for estimation of at least 1 parameter in China, Japan, Singapore, South Korea, Vietnam, Germany, and	Epi data	-Among 49 asymptomatic cases the median infectious period was 11.66 days (9.9-13.3 range) -Infectious period was approximated as serial interval minus the upper limit of latent period. In these analyses, the date of diagnosis was used as the day of onset for asymptomatic cases.

		Malaysia -February 20, 2020 end date		

SYMPTOMATIC INFECTIOUS PERIOD

Table 3 lists one hundred and seven studies that evaluate the symptomatic infectious period of COVID-19, identified through systematic reviews/meta-analyses, case series, observational studies, and modeling. Key studies report robust evidence of infectiousness via culture, evaluation of risk factors for prolonged viral shedding (e.g., sex, age, severity), evidence of differences in viral RNA shedding between different specimen types (fecal vs. respiratory) and models that estimate the entire infectious period.

Studies that report virus culture only provide measurements from symptom onset and are likely to underestimate the total infectious period, as they do not take pre-symptomatic infectiousness into account. They are also based on limited sample size. For mild cases, the best available estimates for the infectious period measured from symptom onset is 8-10 days determined using virus culture (Arons et al., 2020; Bullard et al., 2020; Folgueira et al., 2020; La Scola et al., 2020; Perera et al., 2020; Singanayagam et al., 2020; van Kampen, Jeroen J. A. et al., 2020; Wölfel et al., 2020), with high viral loads observed in the first five days and a viral peak at four days post onset (Wölfel et al., 2020).

Prolonged viable virus shedding have been reported in a few studies, mainly still in preprint with small sample sizes. Case reports, some of which detail immunocompromised cases, demonstrate viable virus up to 18-22 days self-reported post symptom onset (Decker et al., 2020; Gniazdowski et al., 2020; W. D. Liu et al., 2020; van Kampen, Jeroen J. A. et al., 2020). Even longer durations (up to 32 days) have been reported in a small sample of severe cases (Folgueira et al., 2020). One study confirmed the presence of infectious SARS-CoV-2 in urine and faecal specimens from days 11, 13, and 15 of severe/critical illness by demonstrating infection in inoculated ferrets (Jeong et al., 2020).

There are a few studies that have cultured SARS-CoV-2 from the fecal/rectal samples of confirmed cases (Qian et al., 2020; F. Xiao et al., 2020; Y. Zhang et al., 2020). However, more evidence is needed to determine the likely frequency and duration of shedding viable virus via the fecal route and whether fecal-oral, fecal-fomite or fecal-respiratory transmission occurs.

The majority of serial testing studies measure infectious period via RT-PCR from the date of self-reported symptom onset or first RT-PCR positive result to the first of two negative consecutive RT-PCR results. Caution is warranted when interpreting these results as RT-PCR positivity is not indicative of infectiousness and the duration of viral detectability likely overestimates the infectious period.

Estimates from RT-PCR show prolonged shedding of viral RNA, frequently outlasting the duration of symptoms. A recent meta-analysis estimated that the mean duration of RT-PCR positivity in respiratory samples from symptom onset to recovery or death was 13.4 days (95%CI: 10.9-15.8) (Byrne et al., 2020). Concentration of viral RNA measured in upper respiratory samples are shown to decline after symptom onset (Kujawsk et al., 2020; Lavezzo et al., 2020; Quicke et al., 2020; Wölfel et al., 2020; van Kampen et al., 2020; B. E. Young et al., 2020b; L. Zou et al., 2020). There have also been extended periods of viral RNA shedding reported (up to 83 days) in respiratory samples (e.g. J. Li, Zhang, Liu, & Song, 2020; N. Li, Wang, & Lv, 2020; Park et al., 2020; Shin et al., 2020).

Viral RNA presence has varied widely by sample type. Stool samples initially test positive by RT-PCR several days after the onset of symptoms on average and remain positive longer than respiratory samples (Cai et al., 2020; Z. Chen et al., 2020; Du et al., 2020; Hua et al., 2020; Ling et al., 2020; Lyu et al., 2020; Mesoraca et al., 2020; Santos et al., 2020; F. Xiao et al., 2020; Y. Xing et al., 2020; C. L. H. Xu et al., 2020; N. Zhang et al., 2020). Evidence of SARS-CoV-2 RNA viral shedding has also been identified in eye swabs (Hu et al., 2020; Valente et al., 2020; Xia et al., 2020). In one study, eye swabs were continuously positive for two weeks after nasopharyngeal swabs turned negative on day 22 (Y. Hu et al., 2020). Whereas conjunctival swabs became negative in pediatric patients sooner than nasopharyngeal swabs (4 days vs. 8 days) in another study (Valente et al., 2020). In a study of 17 COVID-19 patients, no evidence of viral RNA shedding was found in tears throughout the course of disease (Seah et al., 2020).

Individual or disease characteristics that determine the length of viral RNA shedding have been investigated, including cancer, severity, age, symptomology. Further, the duration of viral RNA shedding was shown to be inversely correlated with plasma levels of T-cell cytokines IL-1β and IL-17A at the initial phase of infection (P. H. Lee et al., 2020). There is also variable evidence for neutralizing antibodies and the association with COVID-19 severity and viral clearance (Jeewandara, et al., 2020; Ru et al., 2020).

There are three studies that investigate SARS-CoV-2 shedding from animals. An experimental challenge trial in rhesus macaques reported the isolation of viable virus up to three days post infection, while viral RNA shedding continued up to 17 days post infection (Munster et al., 2020). A case series of large felines from the Bronx zoo reported the isolation of viable virus in two animals, five days after clinical signs had ceased (Bartlett et al., 2020). An experimental challenge trial of cats found that nasal swabs were positive for viral RNA at days 1 through 10 post challenge, with maximal quantities observed from days 1 through 5 post challenge (Gaudreault et al., 2020).

Due to an abundance of case reports, not all case reports reporting serial testing have been included in this table.

Table 3: Studies evaluating the symptomatic infectious period of COVID-19 in humans and animals. (N=107)

Reference	Study Type	-Population & Setting -Time Period	IP determined via: Culture, RT-PCR Serial testing, Epi data, or Model	Key Outcomes
Culture & RT-PCR studies				
(Jeong et al., 2020)	Prospective cohort	-Five COVID-19 patients from Korea and groups of ferrets -February 25 – March 5, 2020	Culture & RT-PCR	Respiratory and fecal swabs -Viable SARS-CoV-2 virus was isolated from three respiratory specimens taken from COVID-19 patients at 11 and 15 days of illness. -Viral loads in urine, saliva, and stool samples were almost equal to or higher than those in naso/oropharyngeal swabs. -To confirm the presence of infectious SARS-CoV-2 in urine and faecal specimens, two urine specimens (from day 11 and 13 of illness) and one faecal specimen (day 15 of illness) were selected for ferret infection experiments. All urine and stool specimen-treated ferrets showed evidence of infection.
(B. E. Young et al., 2020a) *Preprint*	Prospective cohort	-Hospitalized patients (n=100) in Singapore -January 22 – March 6, 2020	Culture & RT-PCR	Respiratory swabs -Viral culture from respiratory samples was positive for 14 of 73 patients. -PCR cycle threshold value ≤30 predicted viral isolation by culture -Average duration of viral RNA shedding was 16.7 days (95% CI 15·2-18·3) and did not differ significantly by disease severity or use of lopinavir-ritonavir.
(Wölfel et al., 2020)	Prospective case series	-Nine hospitalized confirmed patients with mild symptoms in Germany -Cases discovered January 27, 2020	Culture & RT-PCR	Respiratory swab -Live virus was isolated from upper respiratory swabs via viral culture during the first seven days following symptom onset. No isolates were obtained from samples after the eighth day despite the ongoing presence of viral RNA. -Viral RNA shedding was demonstrated in sputum and upper respiratory samples up to 22 and 20 days, respectively. -Viral load peaked on day four post onset at 7.11×10^8 RNA

				copies per throat swab. The average viral RNA load was 6.76 × 10^5 copies per whole swab until day five. Swab samples taken after day five had an average viral load of 3.44 × 10^5 copies per swab and a detection rate of 39.93%. Stool swab -Live virus was not isolated from stool samples despite the presence of on-going viral RNA (detected up to 21 days post symptom onset).
(van Kampen, Jeroen J. A. et al., 2020) *Preprint*	Retrospective cohort	-Hospitalized COVID-19 patients (n=129, 89 intensive care, 40 medium care) in the Netherlands -March 8 – April 8, 2020	Culture & RT-PCR	Upper and lower respiratory swabs -Infectious virus shedding was detected in 62 respiratory samples of 23/129 patients (17.8%). -The median duration of infectious viral shedding was 8 days (5-11 IQR, 0-20 range) and the probability of detecting infectious virus dropped below 5% after 15.2 days (13.4-17.2 95%CI) post symptom onset. -Infectious virus shedding dropped to undetectable levels when viral RNA load threshold was below 7 $\log^{10}$ RNA copies/mL and once serum neutralizing antibodies were present. These associations were significant in uni- and multivariate analysis.
(Folgueira et al., 2020) *Preprint*	Retrospective cohort	-Samples (n=106) from 105 patients in Spain -Timeline not reported	Culture	Respiratory samples -In 49/106 samples (46.2%) a cytopathic effect was detected in culture. -In mild cases, viral viability was maintained up to 10 days post symptom onset. -In severe cases, viral viability was maintained up to 32 days post symptom onset. -Compared to mild cases, severe cases presented infective virus in a significantly higher proportion in samples with moderate or low viral load, ($p < 0.01$).
(La Scola et al., 2020)	Retrospective cohort	-183 samples from 155 patients in France -February 27 – March	Culture & RT-PCR	Nasopharyngeal and sputum swabs -SARS-CoV-2 could not be isolated from samples collected after day eight of symptom onset.

		12, 2020		- Suggest that patients with Ct values ≥34 are no longer infectious and are suitable for discharge.
(Singanayagam et al., 2020)	Retrospective cohort	-324 samples, 81 culture positive in the United Kingdom -January – May, 2020	Culture & RT-PCR	Respiratory swabs -Detection of cultivable virus peaked around the time of symptom onset. Median duration of virus shedding as measured by culture was 4 days (1–8, IQR) from symptom onset. -Ten days after symptom onset, the probability of culturing virus declined to 6.0% (0.9–31.2%, 95%CI) -There was no difference in cycle threshold values between those with asymptomatic, mild-to-moderate, or severe illness. There was no significant difference between age groups.
(Perera et al., 2020)	Retrospective cohort	-Respiratory specimens (n=68) from 35 COVID-19 patients in Hong Kong -Timeline not reported	Culture & RT-PCR	Respiratory swabs -Virus was isolated from 16 patients. -Viable SARS-CoV-2 were rarely detectable beyond 8 days after onset of illness in mild cases. However, viral RNA was detectable for many weeks by reverse transcription PCR.
(Gniazdowski et al., 2020) *Preprint*	Retrospective cohort	-Patients' specimens (n=161) that were positive by molecular testing in the United States -March 11 – May 11, 2020	Culture & RT-PCR	Oropharyngeal swabs -To assess recovery of infectious virus they evaluated a randomly selected subset of 29 patients, many of which had chronic underlying conditions (n=27). - Four patients had viable virus recovered from respiratory specimens collected up to 22 days after the first positive result. -Infectious virus shedding was not associated with a specific outcome as one patient was never admitted, one was hospitalized but mild, and two had severe disease. - Recovery of infectious virus was associated with persistence of symptoms in all but one patient. -Complete viral genome sequencing showed these patients were carrying the same virus over time (no reinfection).
(Bullard et al.,	Retrospective	-RT-PCR SARS-CoV-2	Culture & RT-	Nasopharyngeal and endotracheal swabs

2020)	cross-sectional study of samples submitted to lab	positive samples (N=90) in Canada -Timeline not reported. Samples taken from day of symptom onset (Day 0) up to 21 days post symptom onset	PCR	-Of 90 RT-PCR SARS-CoV-2 positive samples analyzed, SARS-CoV-2 was successfully cultivated from 26 (28.9%). -Positive cultures were only observed up to day 8 post symptom onset. -The probability of obtaining a positive viral culture peaked on day 3 post symptom onset. -Infectivity was significantly reduced when RT-PCR Cycle threshold values were greater than 24.
(Kujawski et al., 2020)	Case series	-First 12 confirmed patients in the United States -January 20 – February 5, 2020	Culture & RT-PCR	Respiratory swab -Viral culture was successful for all 9 patients tested, with positive results from respiratory samples at 9 days post symptom onset. Viral isolation was not attempted on later specimens. -All 12 patients had SARS-CoV-2 RNA detected in respiratory specimens, typically for 2–3 weeks post symptom onset. -SARS-CoV-2 RNA was detected for a max of 36 days post onset, long after symptoms had fully resolved. -Serum and stool specimens also demonstrated positive viral shedding for a maximum of eight and 25 days, respectively.
(Decker et al., 2020)	Case report	-Sixty-two year old male mild COVID-19 patient with a recent heart transplantation in Germany -March 13, 2020 onward	Culture & RT-PCR	Throat swabs -Patient had no clinical symptoms after 20 days since initial presentation, but virus culture of throat swabs on day 18 and 21 confirmed active SARS-CoV-2 viral replication. -Under continued immunosuppression, SARS-CoV-2 viral RNA remained detectable up to day 35 with copy numbers similar to onset of infection.
(W. D. Liu et al., 2020)	Case report	-50 year old woman in Taiwan -Timeline not reported	Culture & RT-PCR	Throat swab and sputum samples -SARS-CoV-2 could be isolated from cultures in throat swab collected upon admission, and all sputum specimens collected within 18 days after symptoms onset. -Viral RNA was detectable via RT-PCR up to 63 days post symptom onset.

(Y. Zhang et al., 2020)	Case report	-One laboratory-confirmed COVID-19 severe case in China -January 16 – February 1, 2020	Culture	Stool swab -SARS-CoV-2 was isolated from a stool specimen of a case who experienced symptom onset on January 16, 2020 and was sampled on February 1, 2020. -The interval between sampling and onset was 15 days.
(F. Xiao et al., 2020)	Case series	-Fatal COVID-19 case and 28 other feces specimens in China -January, 2020	Culture & RT-PCR	Nasopharyngeal, oropharyngeal, and fecal swabs -The viral load was higher in feces than in respiratory samples collected at multiple time points (17–28 days after symptom onset). -Isolation of virus from feces samples collected at later time points was not successful, despite ongoing viral RNA shedding. -Authors also collected feces specimens from 28 patients. 12, including the case mentioned above, were positive for viral RNA. Isolation of SARS-CoV-2 virus was successful for 2 patients.
(Sun et al., 2020)	Case report	-72 year old man in China -January 25 – March 6, 2020	Culture & RT-PCR	Urine -Viral load in urine was low but detectable at day 12 and day 42 post infection, but not at day 30. -In order to prove that the isolated virus was infectious to susceptible cells, RT-PCR positive urine specimens from day 12 post infection was serially diluted in infection media and inoculated onto Vero E6 cells. -Cytopathic effects were clearly observed after 3 days, raising the possibility of fecal/urine-respiratory transmission.
(Mancuso et al., 2020) *Preprint*	Population-based prospective cohort	-COVID-19 cases (n=1162) in Italy -February 26 – April 22, 2020	RT-PCR	Nasopharyngeal swabs -Median time of viral RNA clearance determined via RT-PCR was 36 days (28-45 IQR) from symptom onset. -The time to viral clearance increased with age and hospitalization, although this was not statistically significant.
(K. Wang et al., 2020)	Prospective cohort	-Hospitalized patients (n=68) in China	RT-PCR	Nasopharyngeal and sputum swabs -The median duration of viral RNA shedding from sputum

		-February 10 – March 20, 2020		specimens was significantly longer than from NPS: 34 days (24-40 IQR) vs. 19 days (14-25 IQR), p<0.001. -Elderly age was an independent factor associated with prolonged virus shedding time of SARS-CoV-2 (HR 1.71, 1.01-2.93). - In nine patients, the viral RNA was detected in sputum after NPS had turned negative.
(Yu et al., 2020)	Prospective cohort	-Recovered cases (n=75) in China -March 9 – 14, 2020	RT-PCR	Respiratory samples -Of the 75 cases, 12 took <30 days to yield 2 consecutively negative results from for SARS-CoV-2 RNA, 57 took 31 to 60 days; and 1 recruit took >60 days to fulfil this criterion. -The mean 27.15 days (24.72-29.58 95%CI).
(Shrestha et al., 2020)	Prospective cohort	-Healthcare workers (n=230) in Cleveland, United States -March 16 – April 20, 2020	RT-PCR	Nasopharyngeal swab -Among patients with non-severe COVID-19, viral loads in upper respiratory specimens peaked by two or three days from symptom onset and decrease rapidly thereafter. - In individuals with non-severe illness, transmission potential of COVID-19 is greatly diminished by 7-10 days since the onset of symptoms.
(Y. Xing et al., 2020) *Preprint*	Prospective cohort	-Pediatric cases (n=3) in China -January 17 – February 23, 2020	RT-PCR	Throat swab -Median infectious period from symptom onset to viral clearance was 13.5 days (11-16 range). Fecal swab -Median infectious period from symptom onset to viral clearance was 29 days (24-34 range).
(Yu, Zhang et al., 2020)	Retrospective matched-pair cohort study	-Hospitalized patients with COVID-19 pneumonia, 64 confected with influenza A/B and 64 influenza negative in China	RT-PCR	Throat swabs -The median duration of viral shedding time from admission was longer for patients with influenza coinfection (17.0 days) than for those without influenza coinfection (12.0 days) (P< .001).

		-January 28 – March 17, 2020		
(Spagnuolo et al., 2020) *Preprint*	Retrospective cohort	-Hospitalized patients (n=280) in Italy -February 25 – May 19, 2020	RT-PCR	Nasopharyngeal swabs - Study shows that delayed SARS-CoV-2 clearance in moderate/severe COVID-19 is associated with older age and a more severe disease, but not with early use of corticosteroids.
(X. Zheng et al., 2020)	Retrospective cohort	-Hospitalized patients (n=80) in China, 28 severe, 52 common type -January 17 – March 9, 2020	RT-PCR	Throat and fecal swabs -The longest observed duration of viral shedding for throat-swab and fecal sample in COVID-19 patients was 43 and 46 days after symptom onset, respectively. -There was no correlation between the duration of viral shedding and the severity of COVID-19.
(F. Hu et al., 2020)	Retrospective cohort	-Hospitalized patients (n=190) in China -January 8 – February 9, 2020	RT-PCR	Throat swabs -Time from onset to admission ($P < 0.001$), and administration of corticosteroid ($P = 0.002$), arbidol ($P = 0.008$) and oseltamivir ($P < 0.001$) were independently associated with duration of viral shedding.
(Bahar et al., 2020) *Preprint*	Retrospective cohort	-Pediatric cases (n=6369) that underwent testing in the United States -March 13 – June 21, 2020	RT-PCR	Nasopharyngeal swabs - Median duration of viral shedding (RT-PCR positivity) was 19.5 days and RT-PCR negativity from positivity was 25 days. -Patients aged 6-15 years demonstrated longer durations of viral shedding, compared to patients aged 16-22 years (median=32 vs. 18 days, p=0.015).
(X. Chen et al., 2020)	Retrospective cohort	-Hospitalized patients (n=284) in China -January 20 – March 15, 2020	RT-PCR	Throat swabs -The median duration of viral RNA shedding was 12 days (8–16 IQR) after the symptom onset. -Older age, time lag from illness onset to hospital admission, diarrhea, corticosteroid treatment and lopinavir/ritonavir were significantly and independently associated with prolonged viral RNA shedding.
(Y. Shen et al., 2020)	Retrospective cohort	-Confirmed cases (n=325) in China	RT-PCR	Nasopharyngeal, urine, feces, and blood samples -Median times from onset to negative detection of nucleic acid

		-January 20 – February 29, 2020		by nasopharyngeal swab was 8 days. -Longer duration of viral shedding in blood and feces was detected among patients with mild disease using glucocorticoid. -Median time from illness onset to negative viral detection was longer in severe and critical patients compared with mild patients. -Among 22 mild patients without antiviral treatment, median times from illness onset to negative viral detection in nasopharyngeal swab, urine, feces, and blood samples were 9, 7, 10, and 9.5 days, respectively.
(N. Li et al., 2020)	Retrospective cohort	-Confirmed cases with prolonged viral shedding, >30 days (n=36) in China -February 11 – April 11, 2020	RT-PCR	-Prolonged viral RNA shedding even after symptomatic relief was common, and the median duration of viral RNA shedding was 53.5 days (47.75-60.5 IQR). -The longest duration of viral RNA shedding could be 83 days. -Compared to the late-onset group, the patients with early onset had longer durations of viral shedding and more severe illnesses.
(Korkmaz et al., 2020)	Retrospective cohort	-Hospitalized children (n=81) in Turkey -March 5 – May 5, 2020	RT-PCR	Naso-oropharyngeal swabs -The median time to turn SARS-CoV-2 RNA negative in the RT-PCR test was 5 (3–10) days. - The time to turn negative was significantly longer for those aged five years or younger than others (P=0.037).
(T. Z. Li et al., 2020)	Retrospective cohort	-Hospitalized patients (n=101) in China -January 21 – March 15, 2020	RT-PCR	Throat swab -The median duration of viral RNA shedding from onset was 11 days (8-14.3 IQR). -In univariate analysis, disease severity, corticosteroid use, fever, and time from onset to hospitalization were associated with prolonged viral RNA shedding. -In multivariate analysis, disease severity did not show a significant association.
(X. Du et al.,	Retrospective	-Cases stratified by age,	RT-PCR	Specimen type not reported

2020)	cohort	sex, and severity (n=161) in China -January 20 – March 1, 2020		-Median duration of viral carriage of all cases (n=161) was 20 days (range 6-30). -Median duration of viral carriage in males was 21 days (16.5-29 IQR) in males (n=89) vs. 20 days (16-26.8 IQR) in females (n=72). There was no significant difference between the sexes (p>0.05). -Median duration of viral carriage for cases older or equal to 60 was statistically longer (p<0.01) than cases between 0-59 years old: 28 days (19-33 IQR) vs. 20 days (16-26 QR). -Median duration of viral carriage for cases considered severe (n=37) was statistically longer (p<0.01) than non-severe cases (n=124): 27 days (19-33 IQR) vs. 20 days (16-26 IQR).
(Tang Xiao et al., 2020) *Preprint*	Retrospective cohort	-Cases stratified by age and gender (n=301) in China -January 21 – February 11, 2020	RT-PCR	Upper respiratory swabs (throat and/or nasal swabs) -The median period from symptoms onset to negative RT-PCR test result was 20 days (17–24 IQR, 7–44 range, N=216). -Female patients (n=147) had a shorter median period from positive to negative SARS-CoV-2 RT-PCR test results than male patients (n=154): 19 days (17–24 IQR) vs. 21 days (17–25 IQR). This finding was not statistically significant (p=0.189). -The median period from symptom onset to negative RT-PCR results was significantly longer in older (≥65years, n=110) patients that younger (<65, n=191): 22 days (19–26 IQR) vs. 19 days (IQR, 17–23), p=0.015.
(Voinsky et al., 2020)	Retrospective cohort	-Patients (n=5,769, 3,370 men and 2,399 women) in Israel -April 28, 2020 end date	RT-PCR	Throat swab -Time from first positive to first negative PCR test result was significantly longer (p<0.05) for patients aged >30 years. Recovery periods were: Male<30: 13.84 (±5.67 SD) Male >30: 14.69 (±6.0 SD) Female <30: 13.66 (±5.87 SD) Female >30: 14.24 (±6.16 SD)
(Sharma et al.,	Retrospective	-Hospitalized cases	RT-PCR	Nasopharyngeal swabs

2020) *Preprint*	cohort	(n=234) in India -March 20 – April 30, 2020		-Mean duration of viral RNA detectability was 10.2 days (6.4 SD). -Duration was significantly lower in cases aged less than 40 years old compared to those aged 40-59 and >60 years old: 9.1 days (5.2 SD) vs. 11.3 days (6.1 SD) vs. 16.4 days (13.3 SD), p=0.001.
(G. Wu et al., 2020) *Preprint*	Retrospective cohort	-Confirmed hospitalized patients in China -January 23 – March 8, 2020	RT-PCR	Upper respiratory swab -Mean time of viral RNA shedding from symptom onset to first negative among common patients (n=93) was 15.1 days (± 7.23 SD). -Severe patients (n=41) had a statistically longer (p=0.00) shedding period of 20.56 days (±6.59 SD). Lower respiratory swab -Mean time of viral shedding was 27.45 days (±10.06 SD) for common patients and 29.78 days (±10.11 SD) for severe patients. There was no statistical difference between the groups (p=0.328). Fecal swab -In the digestive tract, the mean time of viral shedding was 22.6 days (±7.69 SD) for common patients and 27.24 days (±7.86 SD) for severe patients, which was statistically longer (P = 0.01).
(F. Xing et al., 2020) *Preprint*	Retrospective cohort	-Hospitalized patients (n=229) in China -January – March, 2020	RT-PCR	Nasopharyngeal swab -The time between diagnosis and first negative test result of common patients was 25.5 days (±11.3 SD) and 37.1 (±14.4 SD) for severe patients. This was statistically significant (p<0.001).
(Zeng et al., 2020)	Retrospective cohort	-Hospitalized COVID-19 patients (n=149) in China -January 20 – March 26, 2020	RT-PCR	Throat swabs -The median duration from illness onset to the second SARS-CoV-2 RNA negative result was 20 days (16-24 IQR). -Patients admitted to the intensive care unit had longer viral shedding period from illness onset than non-ICU patients: 30 days (22-33 IQR) vs. 19 days (15.8-22 IQR), p<0.0001.
(Fu et al., 2020)	Retrospective	-Hospitalized adult	RT-PCR	Throat swab or nasopharyngeal swab

Preprint	cohort	COVID-19 patients (n=3129) in China -January 18 – March 31, 2020		-The viral RNA shedding durations in critically ill patients were significantly longer than non-critically ill patients: 24.0 days (18.9-29.1 95%CI) vs. 18.0 days (16.8-19.1 95%CI). -Non-critically ill patients (n=330) had persistent viral shedding beyond 30 days post-onset. -A lower IgM/IgG antibody titer in 4 weeks after illness onset may be a risk factor of persistent infection.
(P. H. Lee et al., 2020)	Retrospective cohort	-Hospitalized patients (n=201) in Singapore -January 22 – April 5, 2020	RT-PCR	Respiratory swabs -Duration of viral shedding was not significantly associated with sex, age, presence of comorbidities, baseline investigations, prolonged fever, pneumonia, need for supplemental oxygen or use of experimental antiviral agents. - Median duration of viral RNA shedding was significantly longer in patients requiring invasive mechanical ventilation. -Duration of viral RNA shedding was inversely correlated with plasma levels of T-cell cytokines IL-1β and IL-17A at the initial phase of infection.
(Talmy et al., 2020)	Retrospective cohort	-Israel Defense Forces soldiers with mild COVID-19 (n=219) in Israel -March 20 – May 5, 2020	RT-PCR	Oropharyngeal and nasopharyngeal swabs -The median time of viral RNA duration from symptom onset in this group of young and healthy adults was 21 days (15-27 IQR, 4-45 range).
(Corsini Campioli et al., 2020)	Retrospective cohort	-Hospitalized cases (n=251) in the United States -February 1 – May 15, 2020	RT-PCR	Nasopharyngeal swabs -The median time from symptom onset to negative RT-PCR result was 23 days, and did not differ by symptoms.
(T. Y. Yang et al., 2020)	Retrospective cohort	-Hospitalized cases (n=50) in China -February 2 – 13, 2020	RT-PCR	Nasopharyngeal swabs -The duration of viral shedding was significantly longer in cases presenting with gastrointestinal symptoms compared to pulmonary symptoms (10.22 days ± 1.93 vs 8.15 days ± 1.87, P

				< 0.01).
(Jeewandara et al., 2020) *Preprint*	Retrospective cohort	-Severe (n=6), moderate (n=5) and mild/asymptomatic illness (n=13) and also those who had mild illness but with prolonged shedding of the virus (n=21) in Sri Lanka -April, 2020	RT-PCR	Respiratory swabs -The median duration of virus shedding in this whole cohort was 25 days (15-38 IQR) -Ten individuals had shedding longer than 50 days. -Those who had prolonged shedding of the virus, had neutralizing antibodies appearing faster and at higher levels than those who cleared the virus earlier.
(Jiang et al., 2020)	Retrospective cohort	-Hospitalized patients with liver injury (n=76) and without liver injury (n=55) in China -January 19 – February 20, 2020	RT-PCR	Specimen type not reported -Liver injury was related to increased length of viral shedding duration (mean difference: 3.0, 95% CI: 1.0–4.9).
(Carmo et al., 2020)	Retrospective cohort	-Patients (n=210) in Portugal -March 1 – April 30, 2020	RT-PCR	Nasopharyngeal and oropharyngeal swabs -In the group of patients with 2 consecutive negative tests, the first negative RT-PCR test was achieved a mean of 24.8 days (7-46 range) after the first positive test. -In men, the first negative test took 24 days (7-46 range) and in women it took 25 days (9-44 range), p>0.05. -69 patients were discharged home and had mild illness. Mild illness patients maintained viral RNA for a longer period of time. 47 were inpatients who had moderate to severe illness. In the patients discharged home, the number of days until the first negative test was 26.3 days (±8.5 SD) and in the inpatient group it was 22.5 days (±9.3 SD), p=0.027. -The inpatients aged over 65 took longer (23.9 days (± 9.7)) than those aged under 65 days (18.3 (± 9.7 SD)), to reach the first negative test, p=0.026.

(D. Shi et al., 2020) *Preprint*	Retrospective cohort	-Inpatients with laboratory confirmed COVID-19 (n=246) in China -January 27 – March 24, 2020	RT-PCR	Nasopharyngeal or pharyngeal swab -Duration of viral shedding was defined as the duration from illness onset to the date of first negative result of viral shedding. -The median duration of viral shedding was 24 days (6-63 range). -Soluble interleukin-2 receptor >710 U/mL, Lactate dehydrogenase >250 U/L and severe COVID-19 were related to prolongation of viral shedding, p<0.05.
(Qingxian et al., 2020) *Preprint*	Retrospective cohort	-Cases stratified by body mass index in China -January 11 – February 16, 2020	RT-PCR	Nasal Swab -The median time from onset to viral clearance was not significantly different (p=0.14) between different body mass indexes: Normal: 14 days (9-18 IQR), Underweight: 14·5 (10-21 IQR), Overweight: 15 (10-22 IQR), Obese: 14 (9-20 IQR).
(Moriconi et al., 2020)	Retrospective cohort	-Hospitalized cases (n=100) in Italy -March 16 – April 15, 2020	RT-PCR	Pharyngeal and nasal swabs -Patients with obesity showed a longer duration for obtaining a negative oropharyngeal or nasal swab (19 ± 8 vs. 13 ± 7, days, p = 0.002).
(Xiao, Fu, & Yang, 2020) *Preprint*	Retrospective cohort	-Non-severe COVID-19 patients with hypertension (n=24) and without hypertension (n=24) in China -January 23 – February 15, 2020	RT-PCR	Nasopharyngeal swabs -The mean period from symptom onset to negative conversion was 17 days (5.5 SD) and 15 days (3.6 SD) for patients with and without hypertension (p=0.021).
(C. Cao et al., 2020)	Retrospective cohort	-Patients (n=157), 63 (40.1%) with GI symptoms in China -Timeline not reported	RT-PCR	Nasopharyngeal swabs -There was no significant difference in mean viral shedding duration between patients with and without GI symptoms. -Total: 12.4 days (6.4 SD) vs. GI symptoms: 13.0 days (6.1 SD) vs. no-GI symptoms: 12.0 days (6.7 SD), p=0.3509.
(H. Wang et al.,	Retrospective	-Hospitalized patients	RT-PCR	Throat swabs

2020)	cohort	(n=95) in China -January 15 – March 2, 2020		-This study suggests that NCD4LR is a potential and useful biomarker for predicting the virus negative conversion time in COVID-19 patients. -The median negative conversion time (interval between symptom onset and the first of two consecutive negative virus tests) among all patients was 19 days (11–27 IQR). -Patients with high neutrophil to CD4+ lymphocyte ratio showed a relatively longer negative conversion time compared to patients with a lower neutrophil to CD4+ lymphocyte ratio: 24 days (18-33 IQR) vs. 13 days (9-21 IQR) ($p < 0.001$).
(J. Han et al., 2020)	Retrospective cohort	-Hospitalized cases (n=185) in China -January 21 – May 8, 2020	RT-PCR	Respiratory swabs -The median duration of viral RNA shedding was 17 days from illness onset; the longest duration was 51 days, and the shortest duration was 4 days.
(G. Zheng et al., 2020)	Retrospective cohort	-Pediatric cases (n=52) in China -Timeline not reported	RT-PCR	Oropharyngeal swabs -The time from admission to first negative RT-PCR test was 12 days (8.0-16.8 IQR).
(Woodruff et al., 2020)	Retrospective cohort	-First 100 patients in the Mayo Clinic FL Positive COVID Registry in the United States -May 15, 2020 end date	RT-PCR	Nasopharyngeal swabs -The mean time for onset of symptoms to undetectable viral RNA was 21.5 days. -Based on this data, the authors suggest more cautious guidelines for isolation.
(J. Xu et al., 2020)	Retrospective cohort	-Critically ill adult patients (n=239) in China -January 12 – February 3, 2020	RT-PCR	Respiratory and serum samples -The median duration of the negative conversion of SARS-CoV-2 RNA was 30 (range 6-81) days in 49 critically ill survivors that were identified.
(Nakamura et al., 2020) *Preprint*	Retrospective cohort	-Patients with a history of cancer (n=32) in Japan -January 31 – May 25, 2020	RT-PCR	Nasopharyngeal swab - The median period between illness onset and the first effective negative SARS-CoV-2 RNA PCR result was 22 days (interquartile range, 18–25) in survivors. -Viral shedding was detected in one case up to 56 days post

				onset.
(Infante et al., 2020)	Retrospective cohort	-Patients with hematological malignancies (n=26) in Spain -March 8 – April 8, 2020	RT-PCR	Nasal swab -Median duration of viral shedding was 32.7 days (10-70, range).
(Berghoff et al., 2020)	Retrospective cohort	-Patients with cancer (n=4) in Austria -March 21 – May 4, 2020	RT-PCR	Nasal swab -Viral clearance was achieved in three of the four patients 14-56 days after testing positive.
(J. Shi et al., 2020)	Retrospective cohort	-Hospitalized cases (n=99) in China -January 19 – February 17, 2020	RT-PCR	Respiratory and stool samples -One patient tested SARS-CoV-2 negative within 5 days, 9 patients tested negative within 10 days, and 49 tested negative within 20 days from illness onset. A subset of 12 patients had detectable levels of the virus up to 30 days from symptom onset. -The shedding time was significantly increased if fecal SARS-CoV-2 RNA test results was positive. Male sex, immunoglobulin use, APACHE II score, and lymphocyte count were independent factors associated with a prolonged duration of SARS-CoV-2 shedding.
(Ling et al., 2020)	Retrospective cohort	-66 patients that had recovered after treatment (convalescent patients) in China -January 20 – February 10, 2020	RT-PCR	Oropharyngeal swab -The median time from the onset of symptoms to first negative RT-PCR results was 9.5 days (6.0–11.0 IQR). Fecal swab -Stool specimens were negative for SARS-CoV-2 RNA following a median duration of 11.0 days (9.0–16.0 IQR) after symptom onset. -43 (65%) patients had a longer viral RNA duration in stool swabs than for throat swabs, with a median delay of 2.0 days (1.0–4.0 IQR).

				Urine swab -Results for only 4 (6.9%) urine samples were positive for viral nucleic acid out of 58 cases. -Viral RNA was still present in 3 patients' urine specimens after throat swabs were negative. Patients undergoing glucocorticoid treatment had delayed viral clearance compared to those who were not.
(Hua et al., 2020)	Retrospective cohort	-Hospitalized children (n=35) in China -Up to April 20, 2020	RT-PCR	Fecal swab -Fecal SARS-CoV-2 RNA detection was positive in 91.4% (32/35) cases and some children had viral excretion time over 70 days. -Viral clearance time was not different between groups treated with different antiviral regiments.
(J. Huang et al., 2020) *Preprint*	Retrospective cohort	-Hospitalized patients (n=33) in China -January 27 – April 10, 2020	RT-PCR	Throat, sputum, and stool swabs -The median time from symptom onset to undetectable viral RNA in throat swab, sputum, and stool samples was 18.5 days (13.25-22 IQR), 22 days (18.5-27.5 IQR), and 17 days (11.5-32 IQR) days, respectively. -Compared to throat swabs, viral loads in sputum and stool declined significantly slower ($p<0.05$). -3 patients showed a detectable recurrence of viral RNA in sputum when tested 2 weeks after discharge from the hospital.
(P. Liu et al., 2020)	Retrospective cohort	-Hospitalized pediatric COVID-19 cases (n=9) in China -January 19 – April 10, 2020	RT-PCR	Nasopharyngeal swabs -The median duration of viral RNA shedding from the day of illness onset to the last positive was 13 days (6–24 range). Oropharyngeal swabs -3 of 9 patients had oropharyngeal swabs that were SARS-CoV2 RNA-positive for a median duration of 4 days (3–10 range). Stool swabs -8 patients had SARS-CoV-2 shedding in their stools for a median duration of 43 days (28–66 range). All had persistent viral shedding in their stools after discharge, with a median duration from the day of discharge to the day of last positive

				collected stool at follow-up of 22.5 days (4–46 range). -SARS-CoV-2 RNA was not detected in the serum or urine samples.
(N. Zhang et al., 2020)	Retrospective cohort	-Hospitalized patients (n=23) in China -January 20 – February 23, 2020	RT-PCR	Upper respiratory and fecal swabs -A longer virus shedding period was found in fecal samples compared to the upper respiratory samples (22 days vs 10 days), although the viral RNAs in upper respiratory samples were generally detectable earlier. - The viral titers of respiratory swabs peaked at 6–9 days post symptom onset and at 14–18 days for fecal samples. - In one critically ill patient, all samples were negative until 21 days post symptom onset, when the fecal sample was positive.
(Lyu et al., 2020)	Retrospective cohort	-Discharged patients (n=6) in China -January 23 – March 9, 2020	RT-PCR	Throat, sputum, and fecal swabs -Stool samples were positive in 6 discharged patients with negative throat and sputum swabs. -The stool samples were positive up to 52 days from onset.
(Gombar et al., 2020)	Retrospective cohort	-Patients (n=87) and healthcare workers (n=63) with COVID-19 in Stanford, California, United States -March 3 – April 30, 2020	RT-PCR	Respiratory swabs -For patients, the median time from first positive RT-PCR test to first negative test was 25 days. There was no demonstrable difference with healthcare workers who had a median time of 23 days.
(Rivera-Izquierdo et al., 2020)	Case series	-Symptomatic health professionals (n=76) in Spain -March 11 – April 13, 2020	RT-PCR	Specimen type not reported -The median time from start of symptoms to negative PCR was 31 days. -The duration of viral shedding was longer in females compared to males (33 vs. 21 days, p=0.025) and cases aged 55+ years compared to those <55 (33 vs. 28 days, p=0.207).
(Warabi et al., 2020)	Case series	-Hospitalized cases (n=2) in Japan -April 30 – May 14,	RT-PCR	Nasopharyngeal swabs -The average time from the onset of symptoms until the virus was no longer detectable was 31.6 days (11.8 SD, 17-53 range).

		2020		- In two patients who had mental retardation and psychiatric disorders, the viral shedding period continued for 44 days and 53 days, respectively. These two patients did not voluntarily brush their teeth. -The authors propose that tooth brushing and gargling remove viral nucleic acid and improve the accuracy of PCR testing.
(B. E. Young et al., 2020b)	Case series	-First 18 patients diagnosed with SARS-CoV-2 infection in Singapore -January 23 – February 3, 2020	RT-PCR	Nasopharyngeal swabs - Viral shedding was prolonged for 7 days or longer among 15 cases (83%). -The median duration of viral shedding from first to last positive nasopharyngeal swab collected was 12 days (range, 1-24), with decreasing viral loads overtime. - Virus was also detectable in the stool (4/8) and blood (1/12) by PCR but not urine.
(L. Zou et al., 2020)	Case series	-Symptomatic patients (n=17) in China -January 7 – 26, 2020	RT-PCR	Nose and throat swabs -Higher viral loads (inversely related to Ct value) were detected soon after symptom onset, with higher viral loads detected in the nose than in the throat.
(Tepasse et al., 2020)	Case series	-65 and 66 year old males in Germany -Timeline not reported	RT-PCR	Pharyngeal swabs -The virus levels tended to further increase during the disease course and there was no indication of virus clearance at all. -Viremia peaked shortly before death in both patients; furthermore there was no sign of viral clearance at 22 and 30 days after development of first symptoms or rather 22/26 days after first detection of SARS-CoV-2 RNA in pharyngeal swabs.
(Wongsawat et al., 2020)	Case series	-Three pediatric cases in China -Timeline not reported	RT-PCR	Nasopharyngeal and throat swabs -RT-PCR tests for viral RNA turned negative on days 15, 23, and 27 of illness for each child, respectively.
(Navaneethan & LehnerNoguera,	Case report	-43 year old female with past medical history of Crohn's	RT-PCR	Nasopharyngeal swab - Case had a repeat RT-PCR testing for SARS-CoV-2 by nasopharyngeal swab twice and was finally negative after 22

2020)		disease in Florida, United States -Timeline not reported		days of initial presentation.
(Ru et al., 2020) *Preprint*	Case series	-Confirmed cases (n=4) in China -January 17 – April 27, 2020	RT-PCR	Nasopharyngeal, blood, and stool samples -The mean time for RNA shedding was 36.5 days with one case demonstrating shedding up to 68 days post symptom onset. - Viral clearance was observed along with high level of neutralizing antibody in three cases. -In the case of prolonged viral shedding, the authors suggest that neutralizing antibody in was not high enough to clear the virus completely.
(Benotmane et al., 2020) *Preprint*	Case series	-Hospitalized kidney transplant recipients with non-severe (n = 21) and severe (n =19) COVID-19 in France -March 4 – April 7, 2020	RT-PCR	Nasopharyngeal swabs and plasma sample -Ten recipients (25%) displayed persistent viral shedding 30 days after symptom onset.
(Tajima et al., 2020)	Case report	-71 year old man in Japan -February 5 – March 20, 2020	RT-PCR	Nasopharyngeal swabs -Despite becoming asymptomatic after having some mild symptoms of COVID-19, case had SARS-CoV-2 RNA detected in saliva specimens for 37 days after onset.
(De Vriese & Reynders, 2020)	Case series	-Hemodialysis patients (n=7) in Belgium -March 14 – April 7, 2020	RT-PCR	Nasopharyngeal swab - In four survivors, the nucleic acid conversion time, defined as the interval from symptom onset to first negative RT-PCR result, was 34, 37, 37, and 44 days. -Cycle threshold values, an inverse measure of nucleic acid concentration, were lowest in the first week of infection and remained relatively stable thereafter.
(Zhou et al., 2020)	Case series	-Hematological patients concomitant with COVID-19 (n=9) in	RT-PCR	Throat swabs - Positive viral load in 4 survivors lasted longer than 45 days.

		China -February 1 – March 31, 2020		
(Dong et al., 2020)	Case series	-Hospitalized patients with complete data of peripheral blood lymphocyte subsets (n=18) in China -January 30 – February 21, 2020	RT-PCR	Respiratory and stool samples -Cases with viral RNA shedding ≥ 15 days had significantly decreased lymphocytes, T cell and its subsets compared to those who remained positive for less than 15 days.
(Cai et al., 2020)	Case series	-Pediatric cases (n=10) in China -January 19 – February 3, 2020	RT-PCR	Nasopharyngeal/throat swab -Results from all 10 patients were available. The median infectious period from symptom onset to viral clearance was 12 days (8-15 IQR, 6-22 range). Fecal swab -Fecal swabs from 10 patients demonstrated a median infectious period from symptom onset to viral clearance of 24 days (18-30 range).
(Z. Chen et al., 2020)	Case series	-Hospitalized children (n=32) in China -January 15 – March 15, 2020	RT-PCR	Respiratory and fecal samples -The average durations of viral RNA in respiratory samples and gastrointestinal samples were 15.8 days (n=25) and 28.9 days (n=16), respectively. -Viral RNA shedding duration in faeces significantly decreased with age: 39.8 days, 27.5 days and 20.4 days in infants and preschool children, school children, and adolescents respectively.
(Park et al., 2020)	Case series	-Hospitalized patients (n=6) in South Korea -February 14 – March 26, 2020	RT-PCR	Nasopharyngeal/oropharyngeal swabs -Six patients were analyzed. -The median duration of SARS-CoV-2 viral detection after hospitalization was 34 days (22-67 range). -After resolution of symptoms/signs, SARS-CoV-2 RNA was detected for a median of 26 days (9-48 range).

				-One patient had persistent detection until day 67 of hospitalization, which was 30 days after symptom resolution. -This is the longest duration of respiratory SARS-CoV-2 detection reported to date.
(J. Li et al., 2020)	Case report	-71 year old woman in China -January 27 – April 22, 2020	RT-PCR	Oropharyngeal swab -A 71 year old woman experienced viral shedding of SARS-CoV-2 RNA for 60 days post symptom onset. -Viral shedding continued 24 days after complete resolution of symptoms.
(M. C. Yang et al., 2020)	Case series	-Three generation family cluster with 6 infected individuals in Taiwan -February 9 – April 6, 2020	RT-PCR	Throat swabs -Among this cluster, the longest throat swab conversion time for SARS-CoV-2 RNA was 37 days, and the estimated course of disease from symptoms to negative throat swab was 59 days.
(Y. Hu et al., 2020)	Case report	-70 year old man in China -Timeline not reported	RT-PCR	Nasopharyngeal and eye swabs -Reported positive detection of SARS-CoV-2 combined with herpes simplex virus type 1 and human herpesvirus type 6B virus nucleic acid in tear and conjunctival secretions of a non-conjunctivitis COVID-19 patient with obstruction of common lacrimal ducts. -Nasopharyngeal swabs were positive for 22 days but eye swabs were still continuously positive for 2 weeks after nasopharyngeal swabs turned negative.
(Q. Shen et al., 2020)	Case series	-Nine pediatric patients (7 mild & 2 asymptomatic) in China -January 8 – February 19, 2020	RT-PCR	Specimen type not reported -6 children had a family exposure and could provide exact dates of close contact with someone confirmed to have COVID-19.
Epidemiologic studies				
(X. He et al., 2020)	Contact tracing study	-77 infector-infectee pairs in China	Epi data	-Viral dynamics reported by the authors (assuming an incubation period of mean 5.2 days) suggested an infectious

		-December 18, 2019 – March 5, 2020		period that started 12.3 days days prior to symptoms and decline quickly within 7 days from onset. -Authors inferred that infectiousness peaked on or before symptom onset.
(You et al., 2020)	Contact tracing study & SIR Model	-169 cases in China - March 31, 2020 end date	Epi data	-A total of 198 chains of transmission together with dates of symptoms onset and 139 dates of infections were identified among 14,829 confirmed cases. -A total of 169 cases in the collected data were able to identify the dates of infection. -The infectious period had an average of 13.96 days (5.20 SD).
(Cheng et al., 2020)	Contract tracing study	-Cases of confirmed COVID-19 (n=100) and 2761 close contacts in Taiwan -January 15 – April 2, 2020	Epi data	- The overall secondary clinical attack rate was 0.7% with the attack rate being higher among contacts whose exposure to the index case started within 5 days of symptom onset than those who were exposed later.
Modeling studies				
(Lin et al., 2020)	Systematic review of transmission-dynamic models	-Fifty-two articles involving 75 mathematical or statistical models from China -December 1, 2019 – February 21, 2020	Modeled	- The median infectious period was 9.94 days (3.93–13.50 IQR).
(Tang et al., 2020) *Preprint*	SEAIR model	-Cumulative reported COVID-19 infected cases in Ontario, Canada -February 26 – April 21, 2020	Modeled	-Recovery rate parameter estimate of symptomatic infected individuals was 0.1957 (0.0111 SD). -By taking the inverse of this estimate an infectious period of 5.11 (SD 0.31) can be inferred.
(Lourenco et al., 2020)	SIR model	-Death cases in the United Kingdom	Modeled	-Calibrated a susceptible-infected-recovered (SIR) model to data on cumulative reported SARS-CoV-2 associated deaths

Preprint		-January 27 – March 16, 2020		from the United Kingdom (UK). -Median infectious period estimated to be between 3-5 days (posterior model estimate).
(R. Li et al., 2020) *Preprint*	Mathematical model	-Documented cases in China -January 10 – 23, 2020	Modeled	-Applied model-inference framework to the observed outbreak before the travel restrictions imposed on 23 January 2020 -A total of 801 documented cases throughout China. -Median infectious period estimated to be 3.47 days (posterior estimated from model for documented cases).
(Zhu, 2020) *Preprint*	SEIR model	-Confirmed cases in China -April 15, 2020 end date	Modeled	-Mean infectious period estimated to be 12.53 days, SD±11.4. -The parameter was estimated using a Weibull distribution.
(Wan et al., 2020)	SEIR model	-Wuhan outbreak in China -January 22 – February 12, 2020	Modeled	-Analyzed the epidemic dynamics and trend of 2019-nCoV in Wuhan from data collected from the official website of Hubei Provincial Health Committee. -The data showed that the infectious time of the infected person (I) is 14 days.
(Peirlinck, Linka, Sahli Costabal, & Kuhl, 2020)	Integrated global network and SEIR model	-Outbreak in China -January 21 – April 4, 2020	Modeled	-A mean infectious period of 17.82±2.95 days was estimated from model using case data of 30 provinces in China.
(Goyal et al., 2020) *Preprint*	Mathematical model	-Confirmed cases. Location not specified -Timeline not reported	Modeled	-People with SARS-CoV-2 are usually infectious for fewer that two days in agreement with peak viral load several days after infection and that transmission is unlikely below a certain viral load.
Reviews				
(Walsh et al., 2020)	Systematic review	-No restriction on setting -Studies published between December 30 – May 12, 2020	Culture & RT-PCR	-Conclude there is a relatively consistent trajectory of SARS-CoV-2 viral load over the course of COVID-19 from respiratory tract samples, however the duration of infectivity remains uncertain.
(Byrne et al., 2020)	Scoping review and Meta-	-No restriction on setting	RT-PCR	-A meta-analysis of 15 estimates approximated a mean time from symptom onset to 2 negative RT-PCR tests was 13.4 days

Preprint	analysis	-Studies published between December 1 – April 1, 2020.		(95%CI: 10.9-15.8), but was shorter when studies included children or less severe cases (~5.8 days shorter). -Maximum duration of detection ranged from approximately 20-49 days, with the longest duration associated with fecal samples. -A meta-regression approach showed that severe cases tended to have longer duration of viral RNA shedding (estimated to be 4.0 days longer), but the effect was not significant.
(Cevik et al., 2020) *Preprint*	Systematic review and Meta-analysis	-No restriction on setting -Studies published between January 1, 2003 - June 6, 2020	Culture & RT-PCR	Respiratory swabs -Mean SARS-CoV-2 RNA shedding duration in upper respiratory tract (URT), lower respiratory tract (LRT), stool and serum were 17.0, 14.6, 17.2 and 16.6 days, respectively. -Maximum duration of SARS-CoV-2 RNA shedding reported in URT, LRT, stool and serum were 83, 59, 35, 42 and 60 days, respectively. -Pooled mean duration of SARS-CoV-2 RNA shedding was positively associated with age (p=0.002), but not gender (p = 0.277). -Viral load in the URT peaked the first week of illness. -No study to date had cultured live virus beyond day nine of illness despite persistently high viral loads.
(Santos et al., 2020)	Systematic review & meta-analysis	-No restriction on setting -Based on data compiled from 36 pediatric cases from studies published from January 1 – April 19, 2020	RT-PCR	-More children had viral shedding in stools after 14 days of symptoms onset compared to respiratory samples (risk ratio = 3.2, 95% confidence interval 1.2–8.9, I2 = 51%). -Viral RNA shedding was longer in fecal samples with a mean difference of approximately 9 days compared with respiratory samples.
(Jefferson et al., 2020)	Systematic review	-No restriction on setting	RT-PCR	-They identified eight studies that report on the duration of viral shedding as assessed by PCR for SARS-CoV-2 RNA.

Preprint		-Studies published up to August 18, 2020		-The minimum duration of RNA shedding detected by PCR was seven days reported and the maximum duration of shedding was 35 days after symptom onset. Six out of eight studies reported RNA shedding for longer than 14 days.
(C. L. H. Xu et al., 2020)	Systematic review	-No restriction on setting -Based on data compiled from 69 pediatric cases from studies published up to May 8, 2020	RT-PCR	-The duration of viral RNA shedding through the respiratory tract was up to 24 days from symptom onset with a mean of 11.1 ± 5.8 days. -The mean duration of viral shedding through the gastrointestinal tract was 23.6 ± 8.8 days from symptom onset. -In 89% of cases, viral shedding through the gastrointestinal tract persisted up to 4 weeks after nasopharyngeal or throat swabs became negative.
Animal studies				
(Bartlett et al., 2020) *Preprint*	Case series	-Two Malayan tigers, two Amur tigers, and three lions in the Bronx zoo, United States -March, 2020	Culture & RT-PCR	Fecal swabs - The index case shed viral RNA for 14 days, including 5 days beyond the cessation of clinical signs. -In contrast, the asymptomatic tiger shed viral RNA for only 5 days. -The tiger with the longest duration of viral fecal shedding (24 days) was asymptomatic during this time. -Fecal shedding was also prolonged in two lions persisting for more than 30 days. - Virus was isolated from feces of two animals: 5 days after clinical signs ceased and the last day of clinical signs.
(Munster et al., 2020)	Experimental challenge trial	-Adult rhesus macaques inoculated with SARS-CoV-2 in the United States -N/A	Culture & RT-PCR	Bronchoalveolar swab -Infectious virus was isolated from bronchoalveolar lavage fluid collected on one and three days post infection in adult rhesus macaques. Throat swab -Viral loads were high in throat swabs following inoculation. In 1 animal throat swabs were positive on 1 and 10 days post infection but not on any of the sampling dates in between.

				Rectal Swab -One animal showed prolonged shedding of viral RNA in rectal swabs from 7-17 days post infection but infectious virus could not be isolated from these swabs.
(Gaudreault et al., 2020) *Preprint*	Experimental challenge trial	-Male cats (n=10) in the United States -N/A	RT-PCR	Nasal swabs -SARS-CoV-2 RNA was detected in nasal swabs of the principal infected cats at 1 through 10 days post challenge, with maximal quantities observed from 1 through 5 days post challenge

RECURRENCE OF VIRAL SHEDDING IN CONVALESCENT PERIOD

Table 4 lists studies that provide evidence of the intermittent recurrence of viral RNA detection in the convalescent (asymptomatic or post-symptomatic) period of COVID-19 infection. Case reports and follow-up studies have reported on the recurrence of viral RNA detection in patients through post-discharge/recovery quarantine, re-hospitalization, and re-discharge/recovery. To date, only one study has provided evidence of culturable viral shedding during the recurrence of viral RNA detection (Quicke et al., 2020). No evidence of transmission has been reported.

The majority of discharged patients experiencing a recurrence in RT-PCR RNA positivity did so within seven days following consecutive negative test results. Following recurrence, patients remained viral RNA positive for approximately 1-8 days and typically remain asymptomatic (Chen et al., 2020; Lan et al., 2020; McGrath et al., 2020; Quicke et al., 2020; To et al., 2020b; Wong et al., 2020; Wu et al., 2020;Yuan et al., 2020).

Risk factors for recurrence of viral RNA positivity included elevated low-density lipoprotein cholesterol (LDL-C) on admission, the number of pulmonary lobes with infiltration lesions on imaging, CT imaging abnormalities, productive cough, and chest congestion with dyspnea in the convalescent phase (Jin et al., 2020; Yan et al., 2020).

It is unclear whether such recurrence in RT-PCR test results is indicative of prolonged intermittent viral RNA shedding or whether recurrence (virus replication starts again) or reinfection (a new infection occurs) is possible in the convalescent phase. However, recent studies utilizing culture methods have found that redetections of viral RNA are associated with no, or very low levels of infectious virus (Chang et al., 2020; Kang, 2020; Korea CDC, 2020; J. Lu et al., 2020; Quicke et al., 2020).

Table 4: Studies evaluating recurrence of viral shedding in the convalescent period of COVID-19 infection (N=55)

Reference	Study Type	-Population & Setting -Time Period	IP determined via: Culture, RT-	Key Outcomes

			PCR Serial testing, Epi data, or Model	
Culture & RT-PCR studies				
(Korea CDC, 2020)	Prospective cohort	-Re-positive cases (n=285) in South Korea -Up to May 15, 2020	Culture & RT-PCR	Specimen type not specified -Epidemiological investigation and contact investigation was completed for 285 of 447 re-positive cases. -No secondary cases among contacts were reported for re-positive cases. -Viral cell culture testing of 108 re-positive cases all had negative results. -The cycle threshold values in RT-PCR during re-positive period was found to be above 30 in 89.5% of cases.
(Chang et al., 2020)	Prospective cohort	-Discharged cases (n=64) in China -January 28 – April 30, 2020	Culture & RT-PCR	Throat swabs -As part of the regular follow-up, patients that were discharged were followed up every week to obtain their throat swabs. -Four of the patients re-tested positive. -The throat swabs were sent to test for the presence of a live pathogen. The swabs were plated on Vero cells to measure cytopathy and viral replication using qPCR of cell lysates after infection. They failed to detect any cytopathy or presence of viral replication in the infected cells. -Data also showed that patients with persistent viral RNA presence (>16 days) had more severe disease outcomes.
(J. Lu et al., 2020) *Preprint*	Prospective cohort	-Discharged COVID-19 cases (n=619) in China -January 23 – February 25, 2020	Culture & RT-PCR	Respiratory samples -87/619 discharged cases tested re-positive via RT-PCR. -Cases re-tested as SARS-CoV-2 viral RNA positive at a mean of 6.7 days (3-10 range) post-discharge. -77/87 re-positive cases were asymptomatic and ten cases had unproductive cough. -No infective viral strain could be obtained by culture and no full-length viral genomes could be sequenced for re-positive cases.
(Quicke et al., 2020)	Longitudinal surveillance	-454 asymptomatic staff at 5 skilled nursing	Culture (Plaque assay)	Nasopharyngeal swabs -Six individuals had recurrent positive results after 1-2 weeks of

Preprint	study	facilities in Colorado, United States (prevalence varied considerable between facilities) -Timeline not reported	& RT-PCR	undetectable viral RNA. After redetection, viral RNA was detectable for up to one week. -These redetections of viral RNA were associated with no, or very low levels of infectious virus.
(Kang, 2020)	Literature review	-Patients released from quarantine (n=8,922) in South Korea -April 8 – 29, 2020	Culture & RT-PCR	-292 (3.3%) of the 8,922 patients released from quarantine retested positive. -The largest proportion of re-positive cases were between 20-29 years old (24%). -It took an average of 13.5 days (1-35 range) to retest positive after being initially cleared as negative. -Re-positive cases were asymptomatic or only had minor symptoms such as cough, sputum, fever, and sore throat. -Cultivation tests were all negative when researchers tried to confirm if there was any viable virus in the samples of the re-positive cases.
(J. Zheng, Zhou, & Chen, 2020) *Preprint*	Prospective cohort	-Hospitalized patients (n=285) in China -January 20 – March 14, 2020	RT-PCR	Nasopharyngeal swab -27 (9.5%) previously discharged patients tested positive for SARS-CoV-2 in their nasopharyngeal swab. Patients were readmitted after a median duration of seven days (IQR 5-8) since initial discharge. -Age, sex, epidemiological history, clinical symptoms and underlying diseases were similar between patients that experiences reoccurrence and those that did not ($p>0.05$). -Prolonged duration of viral RNA shedding and higher Ct values during the first hospital admission were associated with redetection.
(B. Yuan, Liu, & Yang, 2020) *Preprint*	Prospective cohort	-Recovered and isolated patients that underwent retesting (n=182) in China -Timeline not reported	RT-PCR	Nasopharyngeal swabs and anal swabs -Twenty (10.99 %) patients out of the 182 re-tested had positive results. -Fourteen were positive via nasopharyngeal swabs and 6 were positive via anal swabs; none were found positive for both swabs.

				-More females retested positive than men (13 vs. 7). -No severe patients retested positive. -Most cases turned negative again in subsequent test.
(Abdullah et al., 2020)	Prospective cohort	-Discharged cases (n=138) in Brunei -Timeline not reported	RT-PCR	Nasopharyngeal and throat swabs -Out of 138 discharged patients, 27 (19.6%) re-tested positive after discharge. -On readmission, six (22.2%) patients had mild symptoms which resolved without specific treatment. -Contact tracing carried out after re-testing positive did not detect any new cases linked to these 27 patients. - Time from re-positive to negative was 7.0 ± 5.6 days.
(Yan et al., 2020)	Prospective cohort	-Discharged hospitalized cases (n=337) in China -February 23 – March 14, 2020	RT-PCR	Throat swabs -21/337 (6.2%) COVID-19 patients were SARS-CoV-2 nucleic acid re-positive, and 4 /337(1.2%) patients were suspected positive. -The median day interval between the discharge to nucleic acid re-positivity was 7.5 days (IQR, 6–13), ranging from 6 to 13 days. -Risk factors of nucleic acid re-positivity included the number of pulmonary lobes with infiltration lesions (odds ratio[OR], 1.14; 95% CI, 1.09–1.19), the distribution of pulmonary lesions (OR, 0.16; 95% CI, 0.13–0.19), patchy shadowing accompanied with consolidation in CT imaging (OR, 9.36; 95% CI, 7.84–11.17), respiratory symptoms of cough accompanied with expectoration (OR, 1.39; 95% CI, 1.28–1.52), and chest congestion accompanied by dyspnea (OR, 1.42; 95% CI, 1.28–1.57).
(X. Wei et al., 2020) *Preprint*	Retrospective cohort	-Mild to moderate COVID-19 cases admitted to shelter hospitals (n=231) in China -February 17 – March 7, 2020	RT-PCR	Respiratory swab -The median time of SARS-CoV-2 RNA negative conversion was shorter in the asymptomatic group (n=34) than in the symptomatic group (n=197): 15 days (11.5-17 IQR) vs. 32 days (23-39 IQR), $p<0.05$. -25/221 (11.3%) discharged patients retested positive for SARS-CoV-2 nucleic acids. There was no significant difference in the rate or time of nucleic acid re-positivity between the symptomatic and

				the asymptomatic groups.
(Miyamae et al., 2020)	Retrospective cohort	-Asymptomatic /mild cases (n=23) aboard the Diamond Princess cruise ship -February 18 – 25, 2020	RT-PCR	Oropharyngeal and nasopharyngeal swab -The median duration of SARS-CoV-2 viral RNA shedding was 19 days (6-37 range) from initial viral detection. -Eight cases (35%) had another positive RT-PCR RNA result after testing negative previously.
(Q. Hu et al., 2020) *Preprint*	Retrospective cohort	-Confirmed COVID-19 patients (n=211) in China, among which were 181 mild and moderate cases and 40 severe and critical cases -January 23 – March 3, 2020	RT-PCR	Nasopharyngeal swab -SARS-CoV-2 IgG and IgM antibody concentration and re-detectable positive nucleic acid testing was investigated with antibody testing results of 74 recovered patients within seven days following discharge. -Nasopharyngeal swabs revealed positive SARS-CoV-2 RNA in up to 52.7% of recovered patients after discharge, whose IgG level showed to be significantly lower than that of patients with negative RNA results (P = 0.009). -The protective effect of IgG remains to be investigated.
(J. Chen et al., 2020) *Preprint*	Retrospective cohort	-Discharged hospitalized patients (n=1067) in China -February 24 – March 31, 2020	RT-PCR	Throat swab -Eighty one (7.6%) patients had a repeat positive SARS-CoV-2 RNA result within nine days (3-18 range) following discharge. -For patients with recurrent RT-PCR positivity, the median duration from illness onset to onset of complete RNA negative was33 days (6-82.0 range). -Time from illness onset to recurrence was 50 days (21-95 range).
(Y. Zou et al., 2020)	Retrospective cohort	-Inpatients with confirmed COVID-19 (n=257) in China -January 1 – March 10, 2020	RT-PCR	Throat swabs -Among 257 patients, 53 had a recurrence of positive viral RNA results after have consecutive negative results. -Recurrently positive RT-PCR test results in patients with three consecutive negative results (5.4%) were significantly decreased compared with those in patients with 2 consecutive negative results (20.6%). -Patients reported positive RT-PCR test results within 1-12 days after meeting the discharge criteria.

(W. Zhao et al., 2020)	Retrospective cohort	Children who had been hospitalized for COVID-19 (n=14) in China -Cases discharged between January 21 – April 18, 2020	RT-PCR	Nasopharyngeal swab -Seven (50%) children experienced reactivation, including 2 children who experienced a second reactivation after discharge. -Among those who experienced reactivation of SARS-CoV-2 viral RNA shedding, the median time was 14 days (7-17 range) days from discharge to the first recurrence of a positive SARS-CoV-2 test result.
(B. M. Liu et al., 2020)	Retrospective cohort	-71 confirmed cases of COVID-19 who were discharged from hospital in China. All were hospital employees or their family members. -February 6 – March 26, 2020	RT-PCR	Oropharyngeal swabs -During convalescence, RNA detection results of 35.2% patients (25/71) turned negative to positive. -The longest RNA reversed phase time was 7days.
(To et al., 2020)	Retrospective cohort	-1 patient of a cohort of 23 in Hong Kong -January 22 – February 12, 2020	RT-PCR	Posterior oropharyngeal swab -1 patient showed negative viral RNA tests on days 21 and 22 after symptom onset, with rebound of viral positivity on days 23 and 24, followed by 5 days of undetectable viral load.
(J. Wu et al., 2020) *Preprint*	Retrospective cohort	-Recovered and discharged COVID-19 patients (n=14) in China -January 23 – March 30, 2020	RT-PCR	Nasopharyngeal swab -Of the 14 patients, six (42.86%) were positive for SARS-CoV-2 RNA after discharge. -Cases presented with a mild cough, diarrhea, runny nose, but no fever at readmission. -The time to RT-PCR positive conversion ranged from 3–15 days after the first discharge. -The time to RT-PCR negative conversion ranged from 1-16 days (average 7.5 days) after readmission. -No worsening outcomes or active transmission to close contacts were found for the readmitted contacts.
(Wong et al., 2020)	Retrospective cohort	-Discharged patients (n=106) in Brunei	RT-PCR	Nasopharyngeal -Of 106 patients that had a follow-up swab taken between 11 - 18

Preprint		-April 12, 2020 end date		days post discharge, 21 (19.8%) were found to be re-positive. -Only 1 case reported symptoms post-discharge. -RT-PCR results were negative again in 16 patients within 1-3 days following readmission. -These findings suggest that reinfection is not plausible, but rather prolonged intermittent viral RNA shedding is more likely. -The highest re-positive rate was observed in patients aged 53 and above (38.5%), followed by those with moderate to critical conditions (33.3%) and lopinavir/ritonavir treatment (30.3%).
(L. Wang et al., 2020) *Preprint*	Retrospective cohort	-Discharged patients (n=399) in China -January 19 – March 15, 2020	RT-PCR	Respiratory and anal swabs -35patients (8.8%) showed recurrent positive RT-PCR test results following discharge. -The median interval from the first negative RT-PCR to the recurrent positive RT-PCR was 10 days (7–16 IQR).
(X. Chen, Shui, Li, & Zhang, 2020) *Preprint*	Retrospective cohort	-Discharged patients (n=758) hospitalized in 17 hospitals in China -February 25 – March 15, 2020	RT-PCR	Throat swab -59 patients (7.78%) had recurrent positive RT-PCR test results following discharge. -Time from onset of symptoms to last time of positive results of RT-PCR ranged from 14 to 61 days. -The time from quarantine (discharge) to last time of positive results ranged from 1 to 19 days.
(H. Cao, Ruan, Liu, & Liao, 2020)	Retrospective cohort	-COVID-19 patients (n=108) in China -February 10 – April 13, 2020	RT-PCR	Nasal and throat swabs -8 cases were readmission patients because their PCR test results were positive again following discharge. -On their second admission all cases were symptom free and had normal chest CT. -Two patients were subsequently discharged while six were still hospitalized at time of writing as they had not yet cleared virus. The course of two patients had persisted more than 90 days since first symptom onset.
(S. Chen et al., 2020)	Retrospective cohort	-Discharged patients (n=1282) in China	RT-PCR	Nasopharyngeal and anal swabs -Of 1,282 discharged patients enrolled in this study, 155(12.1%)

Preprint		-January 14 – March 10, 2020		tested positive for SARS-CoV-2 RNA during 14 days' follow-up. -The median time of recurrence of SARS-CoV-2 RNA was 7 days (IQR4-9). -Compared to negative group, the patients from re-positive group were a younger and had a higher proportion of moderate cases. -None of the re-positive patients showed symptoms or blood abnormalities during the second admission to hospital. -The median time of all re-positive patients turned viral RNA negative was 8.0 days (IQR4-14). -None of close contacts (n=202) derived from re-positive patients (n=67) developed to COVID-19 patients.
(Su et al., 2020) *Preprint*	Retrospective cohort	-Discharged patients (n=938) in China -January 18 – May 11, 2020	RT-PCR	Nasal and pharyngeal swab - Of 938 discharged patients, a total of 58 (6.2%) had reappeared positive nucleic acid test results. -Factors associated with re-positive results were coronary artery disease and hypertension.
(L. Chen et al., 2020) *Preprint*	Retrospective cohort	-Confirmed cases (n=15) in China -February 10 – March 31, 2020	RT-PCR	Nasopharyngeal swab -Reviewed the data of 15 recurrent-positive patients and 107 control patients with non-recurrent, moderate COVID-19. - The rate of recurrent-positive disease in the hospital was 1.87%. Recurrent-positive patients were significantly younger than control patients, 43 years (35-54 range) vs. 60 years (43-69) P=0.011. -The length of stay in hospital before recurrence was significantly longer in recurrent-positive patients than in control patients, 36 days (34-45 range) vs 15 days (7-20 range) p=0.001. -The time required for the first conversion of RT-PCR results from positive to negative was significantly longer in recurrent-positive patients than in control patients, 14 days (10-17 range) vs 6 days (3-9 range) p=0.011. -Serum COVID-19 antibody levels were significantly lower in recurrent-positive patients than in control patients.

(Mei et al., 2020)	Retrospective cohort	-Convalescent cases (n=651) in China -January 11 – April 4, 2020	RT-PCR	Nasopharyngeal and oropharyngeal swabs -During follow-up, 23 (3%) of 651 patients tested positive on a retest for SARS-CoV-2 by RT-qPCR. -In this retest-positive group, 12 patients (52%) had moderate, nine (39%) severe, and two (9%) critical conditions during their previous hospitalisation. -The median duration from hospital discharge to a positive retest was 15·0 days (range 4–38, IQR 11·0–16·5; appendix). -Among this retest-positive group, 15 patients (65%) were asymptomatic at the time of the retest whereas eight (35%) had at least one symptom associated with active COVID-19.
(C. Liu et al., 2020)	Retrospective cohort	-Discharged cases (n=51) in China -January 23 – March 28, 2020	RT-PCR	Oropharyngeal swabs -17.6% discharged patients, in which only 33.3% patients complained clinical symptoms.
(Qiao et al., 2020)	Retrospective cohort	-Confirmed severe/critical cases (n=15) in China -January – March, 2020	RT-PCR	Respiratory samples -Most patients showed no clinical symptoms and negative nucleic acid tests during follow-up after discharge. -One patient had an itchy throat, her CT scan showed a light density shadow in the right lower lobe of the lung, and the nucleic acid was re-positive.
(Jin et al., 2020) *Preprint*	Retrospective cohort	-Hospitalized adult COVID-19 patients (n=133) in China -February – April 30, 2020	RT-PCR	Oropharyngeal swab -32.4% of patients were positive for SARS-CoV-2 RNA after initial discharge. The mean recurrence time from the first discharge was 18.22 days. Following readmission, the mean length of stay was 14.2 days. -Univariable and multivariable Cox regression showed that the low-density lipoprotein cholesterol (LDL-C) dyslipidemia on admission was associated with the recurrence of COVID-19 during the follow-up period.
(Habibzadeh et al., 2020)	Retrospective cohort	-Patients (n=35) intending to donate	RT-PCR	Nasopharyngeal swab - Reverse transcription polymerase chain reaction test was positive

		plasma in Iran -March, 2020		in 9 (5 male, 4 female) of 13 recovered patients - a positive rate of almost 70%. - The second RT-PCR test was found positive in these patients after a median of 29 (range 22 to 54) days after initiation of their symptoms/illness and 18 (range 15 to 48) days after complete resolution of their symptoms.
(Bongiovanni et al., 2020)	Retrospective cohort	-Recovered patients (n=1146) in Italy -March 9 – June 30, 2020	RT-PCR	Nasopharyngeal swab -125 (10.9%) had a recurrence of COVID-19 infection. - The mean time to clinical recovery and two negative nasopharyngeal swabs was 27.7 days (95% CI 11-51); after that, the mean time to recurrence was 19.9 days (3-43, 95%CI). - After a mean time of 14.8 days (95% CI 6-36), 102 subjects (81.6%) had two additional negative nasopharyngeal swabs and were considered clinically recovered for the second time. -During follow-up, 11 patients (8.8%) died. Patients who died were older than others (mean age 86.4 years, 95% CI 77-92) and 8 of them (72.7%) had clinical symptoms at the time of recurrence (4 fever and 4 respiratory failure).
(Y. Li et al., 2020b) *Preprint*	Retrospective cohort	-Nasal swabs (n=484) from patients with COVID-19 in China -January – April, 2020	RT-PCR	Nasal swabs -Serum levels of lipoprotein-associated phospholipase A2 were significantly higher in re-positive COVID-19 cases compared to healthy controls and hospitalized COVID-19 patients.
(Peng et al., 2020)	Retrospective cohort	-Hospitalized patients (n=79) in China -January – May, 2020	RT-PCR	Oropharyngeal swab -The median duration of positive nucleic acid test (NAT) results for SARS-CoV-2 was 16.5 (12.0-22.0, IQR) days. -Two weeks after discharge, 5.6% survivors experienced a recurrence of the positive nucleic acid test results.
(Hao et al., 2020)	Case-control study	-Patients with confirmed COVID-19 (n=104), with short and long viral shedding times (cases & controls) in China	RT-PCR	Respiratory swabs -Median viral shedding time from confirmed diagnosis to ≥2 consecutive negative RT-PCR results was 11 days (1-39 range). -Recurrent positive RT-PCR results in respiratory specimens after ≥2 consecutive negative results were observed in 24 patients. The

		-January 19 – March 3, 2020		probabilities of positive RT-PCR results in the next test after 1 or 2 consecutive negative results were 30.5% and 16.4%, respectively. With an increase from 2 to 3 consecutive negative results, the rate of recurrent positive RT-PCR RNA results decreased sharply to 4.8%. -A series of ≥3 consecutive negative results was deemed suitable by authors as a criterion for the end of viral RNA shedding.
(S. Cao et al., 2020) *Preprint*	Citywide screening program	-9,899,828 persons in China -January 23 – April 8, 2020	RT-PCR	Nasopharyngeal and pharyngeal swab - 107 of 34,424 previously recovered patients with a history of COVID-19 diagnosis were re-positive (relapse rate, 0.31%).
(McGrath et al., 2020) *Preprint*	Case series	-4 cases of COVID-19 in healthcare workers in Ireland -March – April, 2020	RT-PCR	Nasopharyngeal and oropharyngeal swabs -All three cases completed 14 day periods of self-isolation with full resolution of symptoms. -Each had distinct episodes of recurrent symptoms following initial resolution and had persistently positive SARS-CoV-2 PCR results, ranging up to 60 days post onset of illness.
(D. Chen et al., 2020)	Case report	-46 year old woman in China -January 17 – February 9, 2020	RT-PCR	Oropharyngeal swab -Reports a confirmed case of COVID-19 whose oropharyngeal swab test of SARS-CoV-2 RNA turned positive in convalescence. -Case developed symptoms on January 17 2020 and on January 24 2020 tested positive for SARS-CoV-2 RNA. -Viral RNA tests were negative on January 28 2020 and January 30 2020, but became positive again on February 2 2020. She was later discharged on February 9 2020.
(H. Zheng, Tan, Ma, & Meng, 2020) *Preprint*	Case report	-37 year old woman in China -January 12 – March 10, 2020	RT-PCR	Oropharyngeal swab -RT-PCR test results were positive during the first menstrual period before admission (February 2 2020). -Case was hospitalized on February 4 2020. -RT-PCR test results turned negative during hospitalization (ten and 12 days after admission) then turned positive again during the second menstrual period (February 24 & 25 2020), which

				occurred after hospital discharge. -The RT-PCR test on March 10 2020 was negative. -Authors suggest sex hormones may play an important role in SARS-CoV-2 infection.
(Lan et al., 2020)	Case series	-One hospitalized patient and 3 patients (all medical personnel) quarantined at home with COVID-19 in China -January 1 – February 15, 2020	RT-PCR	Throat swab -Patients were evaluated with real-time reverse transcriptase–polymerase chain reaction (RT-PCR) tests for COVID-19 nucleic acid to determine if they could return to work. -After discharge or discontinuation of quarantine, the patients were asked to continue the quarantine protocol at home for 5 days. -RT-PCR tests were positive 5-13 days later. Patients had three repeat tests performed over the following 4-5 days and all were positive despite all cases being asymptomatic.
(J. Yuan et al., 2020) *Preprint*	Case series	-Discharged patients with COVID-19 recovery (n=25) in China -January 23 – February 21, 2020	RT-PCR	Respiratory swabs -All cases had previously tested negative on 2 consecutive RT-PCR tests but were re-hospitalized due to the recurrence of viral RNA. -Patients presented with recurring RNA within 3.0 (2-7 range) days after hospital discharge. The median time from their last negative result to turning positive was 6.0 (4-10 range) days. -All patients were asymptomatic at time of recurrence. -Cases were treated with Chinese herbal medicine and within a few days were all negative for viral RNA.
(Z. Zhang et al., 2020) *Preprint*	Case series	-56 COVID-19 patients with symptoms at admission (33 later displayed symptoms) and 19 age-matched symptomatic patients in China -January 23 – April 1, 2020	RT-PCR	Respiratory and anal swab -Among 56 patients without symptoms at admission, 23 remained asymptomatic throughout the follow-up period. -For asymptomatic cases viral RNA reappeared after discharge (Ct value >40) in nasopharyngeal and anal samples 54 and 42 days, respectively, post initial admission. -For pre-symptomatic cases viral RNA reappeared 81 and 40 days post initial admission and in symptomatic cases reappeared 62 and 42 days post initial admission.

(Peng, Wang, Zhang, & Lu, 2020)	Case series	-Seven discharged patients in China -January 22 – March 8, 2020	RT-PCR	Throat and anal swabs -7 cases retested positive for SARS-CoV-2 following discharge. -All 7 patients had shorter hospital stays, lower medical costs, and milder symptoms in their second hospital visit compared to their first hospitalization.
(Loconsole et al., 2020)	Case report	-46 year old woman in China -January 17 – February 17, 2020	RT-PCR	Oropharyngeal swab -Patient had consecutively negative test results on day 12 and 14 following symptom onset. -A recurrence of viral positivity occurred 17 days following symptom onset. -Test results were negative again on days 20, 22, and 32. -Patient was not symptomatic at time of recurrence.
(Pan et al., 2020) *Preprint*	Case series	-Confirmed cases (n=64) in China -January 23 – March 31, 2020	RT-PCR	Stool and pharyngeal swab -There were 64 confirmed patients and 17 patients present re-positive testing after discharge. -The interval between first negative test and first time of re-positive test was 11.82 days (±3.42).
(J. Huang & Zheng et al., 2020) *Preprint*	Case series	-Patients (n=414) in China -January 11 – April 23, 2020	RT-PCR	Nasopharyngeal swabs -16.7% of recovered patients had re-positive PCR results one to three times, despite being in strict quarantine. -Younger patients with mild pulmonary respiratory syndrome had higher risk of PCR positivity recurrence.
(Martinez Alonso, Fábio de O. et al., 2020) *Preprint*	Case report	-26 year old man in Brazil -April 21 – June 18, 2020	RT-PCR	Oropharynx and nasopharynx swabs -On April 21, 2020 the man experienced a headache with no respiratory symptoms. Two days later he tested positive by RT-PCR. -On May 5, 2020 viral RNA was no longer detected. -One month later, the symptoms returned more acutely and included fever, cough, headache, myalgia, arthralgia, anosmia and fatigue, and lasted for almost two weeks. -SARS-CoV-2 RNA detection reversed to positive June 8, 2020. -On June 22, 2020, IgA/IgM and IgG antibodies were detected in

				serum and only N gene was detected by RT-qPCR.
(Tian et al., 2020)	Case series	-Convalescent cases (n=20) in China -May 22, 2020 end date	RT-PCR	Oropharyngeal swab -Of 147 patients, 20 convalescent cases (13.6%) tested re-positive for viral RNA in respiratory specimens 7 to 47 days after discharge. -All cases remained asymptomatic.
(Dou et al., 2020)	Case report	-34 year old man with a history of type 2 diabetes in China -January 27 – April 13, 2020	RT-PCR	Oropharyngeal swab - The patient had a recurrence of positive SARS-CoV-2 ribonucleic acid (RNA) after recovering. - Despite this, he displayed no obvious clinical symptoms and improved chest CT. - Members of his family and other close contacts did not experience any symptoms.
(F. Liu et al., 2020)	Case report	-35 year old man in China -January 30, 2020 onward	RT-PCR	Nasopharyngeal swabs - Case tested re-positive to viral RNA even after apparent recovery (normal CT imaging, no clinical symptoms, negative SARS-CoV-2 on stool sample and negative serum IgM test) from COVID-19. -Viral shedding duration lasted for 65 days and the time from symptom onset to disappearance was up to 95 days.
(F. He et al., 2020)	Case report	-39 year old woman with systemic lupus erythematosus in China -January 21 – April 11, 2020	RT-PCR	Throat swab -On the 8th day of her home isolation (March 5), she reappeared symptoms of dry cough, arthralgia, and headache without fever. -On March 7, her symptoms were relieved. And the retests of SARS-CoV-2 viral RNA for 3 consecutive days were all negative from Mar 7 to Mar 9, and on follow up until April 11.
(González-Calvo, Bores-García, Barba-Martín, & Gallego-Lema, 2020)	Case report	-64 year wold woman in Iran -February 16 – March 22, 2020	RT-PCR	Nasopharyngeal swab -After a few weeks, relapse occurred, as indicated by symptoms of acute meningoencephalitis. Results of COVID-19 RT-PCR testing from her cerebrospinal fluid, nasopharyngeal and tracheal aspiration specimens became positive again, but COVID-19 serum antibodies were negative.
(Alonso et al., 2020)	Case report	-26 year old man in Brazil -April 21 – June 29, 2020	RT-PCR	Respiratory swab -Having a mild infection, the patient remained in isolation for 14

				days at home, recovering after 3 days of symptoms onset. -On 6 June (a month later), symptoms returned more acutely and included fever, cough, headache, myalgia, arthralgia, anosmia, and fatigue, and lasted for 2 weeks. SARS-CoV-2 RNA detection reversed to positive on June 8 and remained positive in another testing on 16 June, although SARS-CoV-2 antibodies remained negative. -On June 22, IgA/IgM and IgG antibodies were detected in serum and only N gene was detected by RT-qPCR and finally, on 29 June, no viral genes were further detected. -Absence of detectable antibodies in the first episode may have allowed for a new infection, rather than a recurrence. However, as the authors did not investigate viral genetics at different times, such a statement is hypothetical.
(Duggan et al., 2020)	Case report	-82 year old male with a history of advanced Parkinson's disease, insulin-dependent diabetes, chronic kidney disease, and hypertension in the United States -April – May, 2020	RT-PCR	Specimen type not reported -Case presented to the emergency department (ED) in early April with one week of fever and shortness of breath. -In early May 2020 two subsequent RT-PCRs for SARS-CoV-2 were negative and he was discharged. - Ten days post-discharge (48 days after first presentation), he re-presented to the emergency department with fever and hypoxia and a positive RT-PCR result. - RT-PCR for SARS-CoV-2 on hospital days 11 and 12 which both resulted as negative.
(Ye et al., 2020)	Case report	-72 year old female in China -January 30, 2020 onward	RT-PCR	Nasopharyngeal swab - The case was admitted to hospital isolation after being infected with COVID-19 as part of a family cluster on January 30, 2020. -The patient recovered and was discharged on February 19. - Because of a low humoral immune response, the chronic lymphocytic leukemia patient could not effectively clear the SARS-Cov-2 infection and suffered from recurrence twice during the 69-day follow-up.

(Alfano et al., 2020)	Case report	-72 year old man with end stage renal disease in Italy -March, 2020	RT-PCR	Nasal/oropharyngeal swab -After 41 days from the primary infection, the clinically recovered patient experienced symptomatic reactivation of SARS-COV-2 infection with immunoglobulin M seroconversion. - He was discharged home on day seven from re-admission with a negative PCR result on the oropharyngeal/nasal swab.

REINFECTION

Table 5 lists studies that provide evidence of reinfection with COVID-19.

Since August 25, 2020, evidence that reinfection can occur has been published. Epidemiological, clinical, serological and genomic analyses provide good evidence of reinfection in a patient from Hong Kong 142 days after initial infection (To, Hung, et al., 2020). There is also strong evidence for a case of re-infection in the United States (Tillet et al., 2020). Additional research is needed to understand the role of immunity in protection against SARS-CoV-2 post initial acute infection, the clinical and epidemiological characteristics of reinfection, and whether recurrent cases can be infectious and the likelihood that they may experience clinical disease.

Table 5: Studies evaluating reinfection with COVID-19 (N=2)

Reference	Study Type	-Population & Setting -Time Period	IP determined via: Culture, RT-PCR Serial testing, Epi data, or Model	Key Outcomes
(To, Hung, et al., 2020)	Case report	-33 year old male in Hong Kong -March – August, 2020	RT-PCR & Whole Genome Sequencing	Respiratory samples -Immunocompetent case tested re-positive for SARS-CoV-2 viral RNA 142 days after the first symptomatic episode. -While re-positive, there was serological evidence of elevated C-reactive protein and SARS-CoV-2 IgG seroconversion. -Viral genomes from first and second episodes belonged to different clades/lineages, confirming reinfection. Epidemiological data, including a recent trip from Spain, supports the virological results.
(Tillet et al., 2020)	Case report	-25 year old case in	RT-PCR & Whole Genome	Nasopharyngeal swabs -Case was positive for the 1st time in mid-April 2020, and after recovering

Preprint		Nevada, United States -April – June, 2020	Sequencing	returned ill at the end of May, 2020. -Nucleic acid sequence analysis showed that the viruses associated with each instance of infection were found to possess a degree of genetic discordance. -The case may have been re-exposed to the virus by an infected parent.

Methods:

A daily scan of the literature (published and pre-published) is conducted by the Emerging Science Group, PHAC. The scan has compiled COVID-19 literature since the beginning of the outbreak and is updated daily. Searches to retrieve relevant COVID-19 literature searches are conducted in Pubmed, Scopus, BioRxiv, MedRxiv, ArXiv, SSRN, Research Square and cross-referenced with the literature on the WHO COVID literature list, and COVID-19 information centers run by Lancet, BMJ, Elsevier and Wiley. The cumulative scan results are maintained in a Refworks database and an excel list that can be searched. The full text of every study that was tagged as Epidemiology, Clinical Data, or Modeling foci by the emerging sciences group were scanned for information relating to the infectious period of COVID-19. Article titles and summaries were scanned for mention of the following key words: "Shedding", "Viral dynamics", "Viral clearance", "Viable", "Culture", "Infectivity", "SARS-CoV-2 detection", "Infectious Period", "Communicability period", "Recurrence", and "Re-positive". This review contains key research articles published up to August 31, 2020. Each potentially relevant reference was examined to confirm it had relevant data and key relevant data was extracted into the review.

Nouveaux éléments de preuve sur la COVID-19

Revue rapide de la période infectieuse

Introduction

Quelle est la durée de la période infectieuse du SRAS-CoV-2?

La période infectieuse (également appelée période de transmissibilité) est définie comme la période pendant laquelle une personne infectée peut transmettre un agent infectieux à une autre personne. La période infectieuse et sa relation avec la manifestation des symptômes est un paramètre clinique et épidémiologique important à comprendre pour le contrôle de toute maladie infectieuse.

Les estimations de la période infectieuse ont été déterminées à partir d'une combinaison d'investigations épidémiologiques et cliniques qui, ensemble, permettent de savoir quand une personne infectée peut ou est susceptible de transmettre le virus. Pour établir qu'une personne est infectée, la plupart des études font état de l'utilisation de la RT-PCR pour diagnostiquer les cas de COVID-19 et pour surveiller l'excrétion virale au cours du temps. Cependant, la détection de l'ARN viral par test RT-PCR ne fournit pas de preuve d'infectivité et les particules virales sont susceptibles d'être excrétées des tissus infectés pendant un certain temps après que l'infection a été éliminée par le système immunitaire de l'hôte (Jefferson et coll., 2020). Pour déterminer si un virus viable a été isolé dans un échantillon, la réplication virale est établie le plus souvent en culture cellulaire et indique si le virus infectieux est présent. Dans cette revue, peu d'études ont utilisé des méthodes de culture (ou d'inoculation à l'animal), car elles sont lentes, coûteuses et moins sensibles que la RT-PCR. Les résultats des études épidémiologiques, de la RT-PCR, de la qRT-PCR et des cultures fournissent ensemble des éléments de preuve sur le moment où un cas est susceptible d'être infectieux et capable de transmettre le virus.

Cette revue rapide couvre les éléments de preuve de la période infectieuse des cas présymptomatiques, asymptomatiques et symptomatiques de COVID-19 telles qu'elles sont déduites par l'excrétion du virus en culture, la détection de l'ARN viral, les données épidémiologiques et les modèles prédictifs. Les échantillons analysés sont le plus souvent des écouvillons nasopharyngés, mais des écouvillons fécaux/rectaux et des écouvillons oculaires ont également été étudiés pour détecter la présence du SRAS-CoV-2. La transmission respiratoire est considérée comme la plus courante, et il faut davantage d'éléments de preuve pour déterminer l'importance des autres modes de transmission, y compris fécale-orale, fécale-fomite ou fécale-respiratoire, étant donné que des virus SRAS-CoV-2 viables ont été découverts dans les matières fécales.

Il s'agit d'une revue rapide évolutive de la période infectieuse qui contient des études clés saisies par l'analyse quotidienne de la littérature sur la COVID-19 effectuée par le groupe des sciences émergentes de l'ASPC jusqu'au 31 août 2020.

Points clés

Dans l'ensemble, d'après les meilleures données disponibles, on considère que la période infectieuse pour la plupart des cas symptomatiques commence en moyenne 2,5 jours avant l'apparition des symptômes, culmine vers le quatrième jour des symptômes et diminue à de faibles niveaux dans les 8 à 10 jours suivant le début des symptômes, pour un total de 10 à 13 jours. La période infectieuse asymptomatique s'est avérée similaire. Des périodes infectieuses plus longues ont été documentées dans des cas plus graves ou immunodéprimés (de 18 à 32 jours après l'apparition des symptômes).

Période infectieuse présymptomatique, N=25 études

- Le virus viable a été mis en culture' à partir d'échantillons respiratoires de cas présymptomatiques de 1 à 6 jours avant l'apparition des symptômes, comme déterminé par l'observation médicale (tableau 1). Des virus viables ont également été mis en culture'à partir d'échantillons gastro-intestinaux; par exemple, un échantillon rectal a montré des signes de réplication virale active du SRAS-CoV-2 trois jours avant l'apparition des symptômes (Qian et coll., 2020).
- Des études utilisant la RT-PCR pour détecter l'ARN viral à partir d'échantillons respiratoires suggèrent également que l'excrétion se produit en moyenne 2,5 jours (plage de 1 à 7) avant l'apparition des symptômes.

Période infectieuse asymptomatique, N=25 études

- Le virus viable et l'ARN viral détectés dans une cohorte de cas asymptomatiques étaient plus élevés pendant la première semaine de l'infection et ont diminué dans les semaines suivantes (Quicke et coll., 2020). Le virus infectieux n'a pas été détecté avec la technique par plages de lyse dans les écouvillons nasopharyngés des individus ayant moins de 100 000 copies d'ARN/écouvillons.
- Il n'y a que peu de consensus sur la question de savoir si les infections asymptomatiques et légèrement symptomatiques diffèrent en termes de temps d'excrétion du virus (tableau 2). D'après les données actuelles, la période infectieuse totale des cas asymptomatiques semble être similaire ou plus courte que celle des cas légèrement symptomatiques. Dans toutes les études, des charges virales similaires ont été rapportées pour les cas asymptomatiques, présymptomatiques et symptomatiques.

Période infectieuse symptomatique, N=107 études

- Virus viables, résultats des cultures, N=18 études de recherche primaire et 2 revues systématiques :
  - Pour les cas légers, la meilleure estimation de la période infectieuse, mesurée à partir de l'apparition des symptômes autodéclarés à l'aide d'une culture de virus à partir d'échantillons respiratoires, est de 8 à 10 jours avec un pic de charge virale pendant la première semaine de la maladie (tableau 3).
  - Des cas d'excrétion virale viable prolongée (de 18 à 32 jours) ont été répertoriés à l'aide de mis enculture du virus dans le cadre de quelques études. Nombre de ces études sont encore en phase de prépublication et comprennent des cas isolés ou des échantillons de petite taille (tableau 3). Ces

cas sont généralement des personnes atteintes d'une infection grave, qui sont soit immunodéprimées, soit atteintes de plusieurs maladies chroniques sous-jacentes.

- Quelques études ont permis de cultiver le SRAS-CoV-2 à partir d'échantillons fécaux/rectaux d'un cas confirmé (tableau 3). Une étude récente sur des furets inoculés a confirmé la présence du SRAS-CoV-2 infectieux dans des échantillons de fèces et d'urine dès jours 11, 13 et 15 de la maladie (Jeong et coll., 2020).

- Détection de l'ARN viral, résultats de RT-PCR, N=88 études de recherche primaire et 6 revues systématiques :
  - La plupart des études indiquent le temps écoulé entre l'apparition des symptômes ou le diagnostic positif et l'élimination de l'infection virale, déterminée par test RT-PCR. Les résultats positifs de RT-PCR ne constituent pas une preuve d'infectiosité.
  - La présence d'ARN viral varie considérablement selon le type d'échantillon. Les écouvillons respiratoires deviennent généralement négatifs dans les 14 à 20 jours suivant l'apparition des symptômes autodéclarés, tandis que les échantillons de selles restent positifs quelques jours à quatre semaines de plus que les échantillons respiratoires. Des éléments de preuve de la présence de l'ARN du SRAS-CoV-2 ont également été identifiés dans des écouvillons oculaires effectués jusqu'à 22 jours après l'apparition des symptômes signalés.
  - Des périodes prolongées d'excrétion d'ARN viral ont été signalées (jusqu'à 83 jours) dans des échantillons respiratoires, l'excrétion dépassant souvent la durée des symptômes. Cependant, il a été démontré que les concentrations d'ARN viral mesurées dans les échantillons des voies respiratoires supérieures diminuaient après l'apparition des symptômes et il n'y a pas eu de preuve de transmission chez les personnes cliniquement rétablies chez lesquelles l'ARN viral a été détecté de manière persistante, ni de virus viable isolé dans ces cas.
  - Il a été démontré que l'excrétion prolongée d'ARN viral est positivement associée à la gravité de la COVID-19 et à l'âge avancé dans de nombreuses études (tableau 3). Cependant, une récente méta-régression a permis d'identifier que la durée moyenne rapportée d'excrétion de l'ARN viral de quatre jours de plus dans les cas graves n'était pas statistiquement significative (Byrne et coll., 2020). La durée de l'excrétion de l'ARN viral ne diffère pas de manière significative entre le mâle et la femelle.

<u>Récurrence de l'excrétion virale en période de convalescence, N=55 études</u>

- La récurrence de l'excrétion d'ARN viral en période de convalescence après avoir satisfait aux critères de sortie (définis à l'époque comme deux tests RT-PCR consécutifs négatifs) a été signalée dans de multiples rapports de cas et études d'observation (tableau 4). Ces cas ne sont pas considérés comme une réinfection par une nouvelle souche du virus, mais plutôt comme n'ayant pas complètement éliminé l'infection initiale par le SRAS-CoV-2.
  - La récurrence se produit généralement dans les sept jours suivant la sortie.

- Après la récurrence, les patients sont restés positifs à l'ARN viral pendant environ 1 à 8 jours et sont restés généralement asymptomatiques.
- Bien qu'il s'agisse d'un domaine d'étude actif et que de nombreuses nouvelles études aient été publiées, à ce jour, une seule étude a fourni la preuve de la présence d'un virus viable dans un cas de récurrence (Quicke et coll., 2020). Aucune preuve de transmission lors de la récurrence de la détection de l'ARN viral n'a été rapportée.

- Des recherches supplémentaires sont nécessaires pour améliorer notre compréhension des résultats de la RT-PCR et la manière d'interpréter ces résultats en ce qui concerne la période infectieuse et le risque de transmission. En particulier dans les cas où les résultats des tests RT-PCR sont positifs pendant une longue période. En conséquence, le CDC a cessé de recommander deux tests RT-PCR consécutifs négatifs pour déterminer quand mettre fin à l'isolement et aux précautions à prendre pour les cas de COVID.

Réinfection, N=2 études

- Depuis le 25 août 2020, de bonnes preuves qu'une réinfection peut se produire ont été rapportées (tableau 5) :
  - Un patient de Hong Kong a été réinfecté 142 jours après l'infection initiale et cela a été documenté par des preuves épidémiologiques, cliniques et sérologiques convaincantes ainsi que par des analyses génomiques. (Qian et coll., 2020)
  - Il existe également des éléments de preuve solides d'un cas de réinfection aux États-Unis (Tillet et coll., 2020).
- À l'heure actuelle, il existe des lacunes dans les connaissances sur la question de savoir si l'évolution clinique et les caractéristiques épidémiologiques, y compris la période infectieuse des cas de réinfection, sont différentes de l'infection initiale.
- Des recherches supplémentaires sont nécessaires pour comprendre le rôle de l'immunité dans la protection contre le SRAS-CoV-2 après l'infection.

Vue d'ensemble des éléments de preuves

À ce jour, il y a eu de nombreuses publications relatives à la période infectieuse de la COVID-19. La majorité de ces publications sont des rapports de cas et des études d'observation fondées sur la recherche de contacts; ces modèles d'étude présentent un risque élevé de biais et sont donc considérés comme de faible qualité. Nombre d'entre eux sont des prépublications et n'ont pas été soumis à un processus d'examen par les pairs. Les cohortes prospectives présentent un risque de biais plus faible et sont considérées comme des recherches de meilleure qualité, mais peu de ces études contribuent à cette question. Dans l'ensemble, les résultats doivent être interprétés avec prudence, les estimations changent au fur et à mesure que de nouvelles recherches deviennent disponibles et il y a de nombreuses lacunes dans les connaissances; de

nouvelles recherches visant à combler ces lacunes pourraient modifier considérablement notre compréhension de l'infection par le SRAS-CoV-2 chez l'homme.

Les résultats des principales études sont résumés dans les tableaux de données : 1) présymptomatique, 2) asymptomatique, 3) symptomatique, et 4) récurrence de l'excrétion virale. Parmi celles-ci, les informations clés, y compris le type d'étude et les méthodes spécifiques utilisées (par exemple, culture, résultats de RT-PCR en série, données épidémiologiques ou modélisation), sont spécifiées, ainsi que les estimations de la période infectieuse et les facteurs de risque.

L'approche méthodologique utilisée et la façon dont la période infectieuse a été définie varient considérablement d'une étude à l'autre. Les recherches seulement fondées sur les séries de cas et les investigations de recherche de contacts sont considérées comme de très faible qualité. Ces conceptions d'étude souffrent d'une faible taille d'échantillon, d'un biais de sélection et d'un biais de rappel (par exemple, apparition de symptômes autodéclarés). Leurs résultats doivent être interprétés avec prudence, car ils sont susceptibles de changer avec des recherches supplémentaires.

Il existe plusieurs lacunes dans les connaissances sur la période infectieuse. La détection ou la confirmation d'un virus viable plutôt que de l'ARN est étayée par peu d'observations. La relation entre le potentiel de transmission et les résultats des tests RT-PCR n'est pas bien définie. Des recherches supplémentaires sur l'immunité post-infection, la récurrence des tests ARN positifs et la probabilité et les caractéristiques épidémiologiques de la réinfection sont nécessaires pour comprendre si et/ou quand une personne est potentiellement infectieuse après l'infection aiguë initiale. Cette recherche est fondamentale pour comprendre la dynamique de transmission du SRAS-CoV-2.

TABLE DES MATIÈRES

CONTEXTE SUR LA PÉRIODE INFECTIEUSE

La période infectieuse (également appelée période de communicabilité) est définie comme la période pendant laquelle une personne infectée peut transmettre un agent infectieux à une autre personne. La période infectieuse et sa relation avec la manifestation des symptômes sont des paramètres épidémiologiques importants à comprendre pour le contrôle de toute maladie infectieuse. Pour la COVID-19, il existe des éléments de preuve que le SRAS-CoV-2 peut être excrété par une personne infectée avant qu'elle ne présente des symptômes (présymptomatiques) (par exemple, Arons et coll., 2020; Hoehl et coll., 2020; Pan, Zhang, Yang, Poon et Wang., 2020) et par des personnes infectées qui ne développent jamais de symptômes visibles (asymptomatiques) (par exemple, Alshami et coll., 2020; Y. Lu et coll., 2020; Z. Zhang et coll., 2020). Il existe également des études qui suggèrent que l'excrétion virale peut persister pendant la phase de convalescence ou peut réapparaître après que le virus ait été indétectable pendant un certain temps (par exemple, Hoang, Daoet Gautret, 2020; Q. Hu et coll., 2020). Le présent rapport couvre les éléments de preuve pour ces différentes périodes et les études qui tentent d'estimer la période infectieuse complète de la COVID-19. Les études seront divisées en deux parties : les méthodes de détermination de l'excrétion virale et la question de savoir comment la détection de l'ARN viral par test RT-PCR en comparaison à celle de la culture et quelles déductions peuvent être faites pour ces différents résultats.

Les estimations de la période infectieuse ont été déterminées à partir d'une combinaison d'investigations épidémiologiques et cliniques qui, ensemble, permettent de savoir quand une personne infectée peut ou est susceptible de transmettre le virus. Pour déterminer si une personne est infectée, la plupart des études font état de l'utilisation de test RT-PCR pour diagnostiquer les cas de COVID-19 et pour surveiller l'excrétion de l'ARN viral au fil du temps. Cependant, la détection de l'ARN viral par test RT-PCR ne fournit pas de preuve d'infectivité et les particules virales sont susceptibles d'être excrétées des tissus infectés pendant un certain temps après que l'infection a été éliminée par le système immunitaire de l'hôte (Jefferson et coll., 2020). Pour établir si un virus viable a été isolé, la réplication du virus de l'échantillon est établie le plus souvent en culture cellulaire et indique que le virus infectieux est présent. Dans cette revue, peu d'études ont utilisé des méthodes de culture (ou d'inoculation animale), car elles sont lentes, coûteuses et moins sensibles que la RT-PCR. Les résultats des études épidémiologiques, de la RT-PCR, de la qRT-PCR et des cultures fournissent ensemble des éléments de preuve sur le moment où un cas est susceptible d'être infectieux et capable de transmettre le virus.

La variabilité dans la mesure de la période infectieuse est également présente dans les différentes études. La majorité des études mesurent le temps écoulé entre le diagnostic ou l'apparition des symptômes jusqu'à l'élimination de l'ARN viral. Ainsi, il n'y a pas de mesures préalables au diagnostic. La recherche épidémiologique, principalement sous la forme d'investigations sur les grappes de cas et de tests sur les contacts étroits des cas, quel que soit leur statut clinique, a fourni la preuve que l'excrétion du virus peut se produire avant l'apparition des symptômes (Z. Du et coll., 2020; X. He et coll., 2020). L'hétérogénéité des définitions et la manière dont la période infectieuse est déterminée dans chaque étude sont résumées dans les tableaux détaillés des éléments de preuve.

PÉRIODE INFECTIEUSE PRÉSYMPTOMATIQUE

Le tableau 1 énumère vingt-cinq études qui fournissent des estimations de la période infectieuse présymptomatique, identifiée par des séries de cas, des investigations de recherche de contacts et des modélisations. Nombre de ces rapports de cas et études de recherche de contacts proviennent de Chine et montrent des éléments de preuve de la transmission de la COVID-19 par des personnes qui sont en période d'incubation. Le SRAS-CoV-2 a été isolé avec succès des cas présymptomatiques, ce qui prouve une fois de plus qu'une transmission présymptomatique se produit. Cependant, la grande majorité des éléments de preuve est basée sur des rapports de cas et des investigations en grappes qui sont sujets à un biais de rappel, car les cas et leurs contacts sont chargés de fournir des informations sur l'exposition et le moment d'apparition des symptômes. De plus, avec la transmission généralisée de la COVID-19 dans une zone épidémique, il est possible que les infections décrites dans ces études aient été causées par d'autres sources non reconnues.

La période infectieuse présymptomatique dans l'ensemble des études suggère qu'une personne est susceptible d'excréter le SRAS-CoV-2 en moyenne 2,5 jours (fourchette de 1 à 7) avant l'apparition des symptômes d'après les échantillons respiratoires (Hoehl et coll., 2020; Z. Liu et coll., 2020; Nissen et coll., 2020; Pan et coll., 2020; Sakurai et coll., 2020). Les estimations des études de recherche des contacts suggèrent également une période infectieuse présymptomatique moyenne de 2 à 3 jours (fourchette de 1 à 12,3) (X. He et coll., 2020; S. Hu et coll., 2020; R. Huang, Xia, Chen, Shan et Wu, 2020; Kong et coll., 2020; J. Li et coll., 2020; Rothe et coll., 2020; W. E. Wei et coll., 2020). Des éléments de preuve de la réplication active du virus du SRAS-CoV-2 à partir d'un échantillon de rectum trois jours avant l'apparition des symptômes ont également été présentés (Qian et coll., 2020). Une étude menée auprès de résidents d'établissement de soins de longue durée a révélé que le virus viable pouvait être mis en culture jusqu'à six jours avant l'apparition des symptômes et a fait état de valeurs seuils de cycle similaires (c'est-à-dire de la charge virale) pour les cas asymptomatiques, présymptomatiques et symptomatiques (Arons et coll., 2020).

Il existe peu d'études qui prennent des mesures avant le diagnostic/l'apparition des symptômes. D'autres éléments de preuve sont nécessaires pour améliorer la certitude des estimations de la période infectieuse présymptomatique de la COVID-19.

Tableau 1 : Études évaluant la période infectieuse présymptomatique de la COVID-19 (N=25)

Référence	Type d'étude	-Population et environnement -Période de temps	Période infectieuse (PI) déterminée par : Culture, résultats de tests RT-PCR en série, données épidémiologiques ou modèle	Résultats pertinents
Études sur la culture et la RT-PCR				
(Arons et coll., 2020)	Investigation sur l'éclosion	-Résidents d'un établissement de soins infirmiers spécialisés à Washington, États-Unis -3 avril 2020 (date de fin)	Culture et RT-PCR	Écouvillons nasopharyngés et oropharyngés -48 (63 %) des résidents ayant participé aux enquêtes de prévalence ponctuelle ont été testés positifs. -24 étaient présymptomatiques et 2 étaient asymptomatiques selon les évaluations standardisées des symptômes effectuées par les infirmières. -Le virus viable a été isolé à partir de prélèvements collectés six jours avant et neuf jours après l'apparition des symptômes.
(Hoehl et coll., 2020)	Série de cas	-Voyageurs de Wuhan vers l'Allemagne -1er février 2020	Culture et RT-PCR	Écouvillon pharyngé -2 patients étaient asymptomatiques et le test RT-PCR était positif. Un jour plus tard, un des cas présentait une légère éruption cutanée et une pharyngite minime. -Le SRAS-CoV-2 a été isolé avec succès à partir des 2 cas, indiquant une infectiosité potentielle alors qu'ils étaient présymptomatique. -Ces résultats suggèrent que l'infectiosité peut se produire au moins un jour avant l'apparition des symptômes.
(Nissen et coll., 2020) *Prépublication*	Rapport de cas	-Un travailleur de la santé de 36 ans en Suède -Du 2 au 17 avril 2020	Culture et RT-PCR	Écouvillons nasopharyngés et oropharyngés - L'effet cytopathique observé par culture cellulaire, immunofluorescence pour l'ARNdb et la rRT-PCR ont permis de déterminer que le virus SRAS-CoV-2 de deux échantillons (prélevés les 3e et 1er jours avant l'apparition des symptômes) était infectieux dans deux expériences indépendantes.

(Qian et coll., 2020)	Rapport de cas	-Un patient se fait opérer d'un cancer du rectum en Chine -À partir du 16 janvier 2020	Culture et RT-PCR	Écouvillons pour les tissus rectaux et pharyngés -Le 16 janvier 2020, le patient a subi une intervention chirurgicale rectale. Le troisième jour postopératoire, le patient s'est présenté avec de la fièvre et de la toux et on lui a ensuite diagnostiqué la COVID-19 par RT-PCR. En mars, une étude rétrospective a été menée sur les tissus chirurgicalement enlevés du patient. Des sections ultrafines de tissus rectaux ont été préparées et des particules de virus ont été trouvées dans le cytoplasme des cellules épithéliales intestinales. Pour confirmer davantage l'infection spécifique du SRAS-CoV-2 et sa réplication dans le rectum, on a utilisé l'immunohistochimie et l'immunofluorescence à l'aide de l'anticorps NP anti-SRAS-CoV-2 du lapin. -Il s'agit du premier rapport faisant état d'éléments de preuve directs de la réplication active du SRAS-CoV-2 dans le rectum d'un patient pendant la période d'incubation.
(Z. Liu et coll., 2020)	Cohorte prospective	-Transporteurs présymptomatiques en Chine (n=16) -Chronologie non communiquée	RT-PCR	Expectorations et écouvillons pharyngés -La période médiane entre la détection d'ARN positif du SRAS-CoV-2 et l'apparition des symptômes a été calculée comme étant de 2 jours (fourchette de 1 à 5).
(Sakurai et coll., 2020)	Cohorte rétrospective	-Cas asymptomatiques (n=90) et présymptomatiques (n=11) hospitalisés au Japon à bord du navire de croisière Diamond Princess -Du 19 au 26 février 2020	RT-PCR	Type de prélèvements non rapporté -11 patients étaient présymptomatiques et ont développé des symptômes avec une médiane de quatre jours (fourchette de 3 à 7) après le premier test RT-PCR positif. -Les cas asymptomatiques présentent une durée médiane d'excrétion de l'ARN viral du SRAS-CoV-2 de 9 jours (fourchette de 3 à 21) entre le premier test PCR positif et le premier de 2 tests PCR négatifs en série.
Études de données épidémiologiques				
(Pan et coll.,	Étude sur la	-Deux personnes	Données RT-	Écouvillon respiratoire

2020)	recherche des contacts	contacts trouvées en raison de leur exposition à un patient infecté en Chine -Chronologie non communiquée	PCR et données épid.	-Les cas ont été testés en série avant l'apparition des symptômes. -Les cas ont montré des résultats positifs par RT-PCR un jour avant l'apparition des symptômes, ce qui suggère que l'infectiosité peut se produire avant l'apparition des symptômes.
(J. Li et coll., 2020)	Étude sur la recherche des contacts	-Trois grappes de famille en Chine -Du 21 janvier au 9 février 2020	Données épid.	- Les trois cas index ont transmis l'infection à 28 membres de la famille de 2 à 10 jours avant le début de la maladie.
(Kong et coll., 2020)	Étude sur la recherche des contacts	-Dix cas en Chine -Du 8 au 27 janvier 2020	Données épid.	-Les deux dernières générations ont été infectées dans des lieux publics, 3 et 4 jours avant l'apparition de la maladie chez leurs infecteurs.
(R. Huang et coll., 2020)	Étude sur la recherche des contacts	-Grappe familiale d'infection confirmée en Chine -Janvier 2020	Données épid.	-La recherche des cas contacts dans une grappe familiale (n=11) et les dates d'exposition ont montré une période infectieuse présymptomatique médiane de quatre jours (fourchette de 3 à 5).
(Rothe et coll., 2020)	Étude sur la recherche des contacts	-Grappe de cas issus de contacts présymptomatiques en Allemagne -Du 19 au 29 janvier 2020	Données épid.	-La transmission s'est faite d'un cas présymptomatique à 4 contacts. -Les résultats du traçage montrent une période infectieuse présymptomatique médiane de deux jours (fourchette de 1 à 3).
(W. E. Wei et coll., 2020)	Étude sur la recherche des contacts	-Sept grappes à Singapour -Du 23 janvier au 16 mars 2020	Données épid.	-La transmission présymptomatique était évidente dans 4 grappes avec une période infectieuse médiane de deux jours (fourchette de 1 à 3). -L'exposition à la transmission n'a pas été vérifiée pour les trois autres grappes.
(S. Hu et coll., 2020) *Prépublication*	Étude sur la recherche des contacts	-1178 personnes infectées par le SRAS-CoV-2 et leurs 15 648 contacts en Chine -Du 13 janvier au 2 avril	Données épid.	-Quarante-trois événements de transmission présymptomatique ont été enregistrés dans 23 grappes. -On estime que l'infectiosité atteint son maximum 1,8 jour avant l'apparition des symptômes, 95 % des cas de transmission se produisant entre 7,6 jours avant et 7,3 jours

		2020		après la date d'apparition des symptômes. -La proportion de transmission présymptomatique a été estimée à 62,5 %.
(X. He et coll., 2020)	Étude sur la recherche des contacts	-77 paires infecteur-infecté de transmission provenant du Vietnam, de la Malaisie, du Japon, de la Chine, de Taïwan, des États-Unis et de Singapour -Du 18 décembre 2019 au 5 mars 2020	Données épid.	-Les auteurs ont supposé une distribution de la période d'incubation de 5,2 jours en moyenne pour déduire que l'infectiosité commençait à 12,3 jours (de 5,9 à 17, IC de 95 %) avant l'apparition des symptômes et atteignait son maximum à l'apparition des symptômes (de -0,9 à 0,9, IC de 95 %). -Ils ont observé que seulement < 0,1 % de la transmission se produisait avant 7 jours, 1 % de la transmission se produisait avant 5 jours et 9% de la transmission se produisait avant 3 jours avant l'apparition des symptômes. -Une analyse de sensibilité a montré que l'infectiosité atteignait son maximum deux jours avant et un jour après l'apparition des symptômes. -Ils ont estimé que 44 % (de 30 à 57 %, IC de 95 %) des cas secondaires ont été infectés au cours de la phase présymptomatique des cas index.
(Chun, Baek et Kim, 2020) *Prépublication*	Revue documentaire	-72 paires infecteur-infecté de transmission en Corée du Sud -Du 23 janvier au 31 mars 2020	Données épid.	-Les estimations moyennes et médianes étaient respectivement de 1,31 jour (de 0,38 à 2,55, IC de 95 %) et 0,68 jour (de -0,09 à 1,73, IC de 95 %) après l'apparition des symptômes, avec un pic à 0,72 jour avant l'apparition des symptômes. -La proportion de transmission présymptomatique était de 37 % (de 16 à 52 %, IC de 95 %).
(Z. Du et coll., 2020) *Prépublication*	Revue documentaire	-468 paires infecteur-infecté identifiées grâce à la recherche des contacts en Chine -Du 21 janvier au 8 février 2020	Données épid.	-59 des 468 paires infecteur-infecté ont indiqué que la personne infectée avait des symptômes plus tôt que l'infecteur. -Ces intervalles sériels négatifs suggèrent qu'une transmission présymptomatique a pu se produire.
(Casey et coll., 2020)	Revue documentaire	-17 études faisant état de l'intervalle sériel ou du	Données épid.	-Soustraction de la période d'incubation de l'intervalle sériel ou du temps de génération pour déduire la période infectieuse

Prépublication		temps de génération de Hong Kong, Tianjin, données regroupées de Hong Kong et Shenzhen, Singapour, Chine continentale à l'exclusion du Hubei, sources mixtes, Shenzhen, Italie du Nord et Wuhan -Du 1er décembre 2019 au 15 avril 2020		présymptomatique et pour estimer la proportion de transmission présymptomatique. -Le regroupement des estimations de l'intervalle sériel du temps de transmission par rapport à l'apparition des symptômes a donné une période infectieuse présymptomatique moyenne de 0,67 jour (médiane de 0,63 jour). -Le regroupement des estimations basées sur le temps de 5 générations a donné une période infectieuse présymptomatique moyenne de 1,62 jour (médiane de 1,32 jour). -La transmission présymptomatique a été estimée à 56,1 % sur la base des estimations de l'intervalle sériel et à 65,5 % sur la base des estimations du temps de génération.
(Prakash, 2020) *Prépublication*	Revue documentaire	-Personnes signalées dans la littérature (n=1251) -Pas de limite par pays -Aucune chronologie n'a été communiquée	Données épid.	-Le pic d'infectiosité a été atteint deux jours après l'infection. -On estime que 68,4 % (de 67,0 à 69,7 %, IC de 95 %) des infections sont causées par des infecteurs présymptomatiques.
Études de modélisation				
(Nishiura, Linton et Akhmetzhanov, 2020)	Modèle prédictif bayésien	-28 paires infecteur-infecté -Pas de limite par pays -Date de fin : 12 février 2020	Modélisé	-En tenant compte de la troncature à droite et en analysant toutes les paires, les auteurs ont estimé un intervalle sériel de 4,0 jours (de 3,1 à 4,9, IC de 95 %). -Cet intervalle est plus court que les estimations préliminaires de la période d'incubation d'environ 5,0 jours. -Cela suggère que la transmission présymptomatique peut constituer une proportion substantielle de la transmission secondaire.
(Tindale et coll., 2020) *Prépublication*	Modèle statistique	-Cas d'éclosions à Tianjin, en Chine et à Singapour -Du 19 janvier au 27	Modélisé	-La période de transmission présymptomatique a été déduite des estimations de l'intervalle sériel et des périodes d'incubation pour les populations de Tianjin et de Singapour.

		février 2020		-Les périodes infectieuses présymptomatiques moyennes étaient de 2,55 jours (fourchette de 1,2 à 3,3) à Singapour et de 2,89 jours (fourchette de 2,79 à 8,2) à Tianjin.
(Zhu, 2020) *Prépublication*	Modèle SEIR	-Éclosion de Wuhan en Chine -Date de fin : 15 avril 2020	Modélisé	-Les auteurs proposent un nouveau modèle d'épidémie appelé SEIR-HC, avec 2 cercles sociaux différents. En utilisant le modèle avec un algorithme d'optimisation, le processus de propagation de l'éclosion dans la ville de Wuhan est reproduit et les caractéristiques de propagation et les données inconnues sont estimées. -Une période infectieuse présymptomatique de 1,01 jour a été estimée en prenant la différence entre la période de latence et la période d'incubation.
(Siwiak, Szczesny et Siwiak, 2020) *Prépublication*	Modèle de métapopulation SIR	-Pandémie totale (mondiale) -Du 22 janvier au 26 mars 2020	Modélisé	-Construire un mode de transmission modifié SIR de la métapopulation, paramétré analytiquement selon la littérature, et ajuster les paramètres manquants à la dynamique observée de la propagation du virus. -La période infectieuse présymptomatique est estimée à 4,6 jours.
(Peak et coll., 2020) *Prépublication*	Modèle SEIR	-Cas confirmés dans le Massachusetts, États-Unis -Chronologie non précisée	Modélisé	-La période infectieuse présymptomatique a été modélisée en supposant un intervalle sériel de 4,8 -Le délai moyen d'apparition de l'infectiosité était de 0,77 jour avant l'apparition des symptômes (1,98 jour avant, 0,29 jour après, IC de 95 %)
(H. Yuan et coll., 2020) *Prépublication*	Modèle SEIQR à deux niveaux	-Cas locaux importés et confirmés à Hong Kong -Du 18 janvier au 29 février 2020	Modélisé	-Les paramètres épidémiologiques de COVID-19 ont été estimés. -La période de transmission présymptomatique avant l'apparition des symptômes était de 3,49 jours (de 0,48 à 5,80, IC de 95 %).
(S. Zhao, 2020)	Nouveau cadre fondé sur la probabilité	-Cas confirmés -Pays et chronologie non précisés	Modélisé	-Estime que la période de transmission moyenne présymptomatique est de 2,2 jours (IC de 95 % : de 1,3 à 4,7). -Approxime que 32,2 % (de 10,3 à 73,7, IC de 95 %) des

				infections secondaires peuvent être dues à une transmission présymptomatique.

PÉRIODE INFECTIEUSE ASYMPTOMATIQUE

Le tableau 2 énumère vingt-cinq études qui fournissent des estimations de la période infectieuse asymptomatique, identifiée par des séries de cas et des investigations de recherche de contacts. Les cas asymptomatiques peuvent transmettre la COVID-19, mais peu d'études ont été menées sur la période infectieuse des cas asymptomatiques, car ils sont rarement soumis à des tests. En outre, peu d'études de mise en culture ont été menées sur l'excrétion de virus vivants à partir de porteurs asymptomatiques. La majorité des études identifient les cas asymptomatiques grâce à la recherche des contacts et déterminent la durée de l'excrétion de l'ARN viral par RT-PCR du premier jour d'un test RT-PCR positif au premier jour de résultats négatifs consécutifs. La prudence est de mise dans l'interprétation de ces résultats, car la positivité de la RT-PCR n'est pas indicative de l'infectiosité et la durée de détectabilité virale surestime probablement la période infectieuse.

Les meilleurs éléments de preuve disponibles proviennent d'une cohorte de cas asymptomatiques qui a permis de détecter un virus viable et de l'ARN viral par le biais d'une infection. La charge virale était la plus élevée pendant la première semaine d'infection et diminuait les semaines suivantes (Quicke et coll., 2020). De plus, le virus infectieux n'a pas été détecté dans les écouvillons nasopharyngés des individus ayant moins de 100 000 copies d'ARN/écouvillon, ce qui indique que de faibles niveaux d'ARN viral correspondent à de faibles niveaux de virus infectieux.

Certaines études comparant les cas asymptomatiques et symptomatiques montrent que les cas symptomatiques présentent des périodes d'excrétion d'ARN viral plus longues (Alshami et coll., 2020; Y. H. Lee et coll., 2020; S. Lee et coll., 2020; W. Li et coll., 2020; Y. Li et coll., 2020a; Y. Lu et al, 2020; Noh et coll., 2020; Saurabh et coll., 2020; Valente et coll., 2020; X. Wei et coll., 2020; Z. Zhang et coll., 2020), tandis que d'autres études ne montrent aucune différence entre les groupes (Lombardi et coll., 2020; Xiong et coll., 2020) ou font l'association inverse (Long et coll., 2020). Des charges virales similaires ont été rapportées pour des cas asymptomatiques, présymptomatiques et symptomatiques. Ainsi, la période infectieuse totale des cas asymptomatiques est probablement similaire ou plus courte que celle des cas symptomatiques. La durée de l'excrétion de l'ARN viral dans les cas asymptomatiques n'est pas significativement associée à l'âge ou au sexe.

Tableau 2 : Études évaluant la période infectieuse asymptomatique de la COVID-19 (N=25)

Référence	Type d'étude	-Population et environnement -Période de temps	Période infectieuse (PI) déterminée	Résultats pertinents

			par : Culture, Tests RT-PCR en série, données épidémiologique ou modèle	
Études sur la culture et la RT-PCR				
(Quicke et coll., 2020) *Prépublication*	Étude de surveillance longitudinale	-Personnel asymptomatique (n=454) dans 5 établissements de soins infirmiers qualifiés (la prévalence varie considérablement d'un établissement à l'autre) dans le Colorado, aux États-Unis -Chronologie non communiquée	Culture (technique par plages) et RT-PCR	<u>Écouvillons nasopharyngés</u> -Le niveau d'ARN viral N1 a été positivement corrélé avec la quantité de virus infectieux détectée par les techniques par plages. -La durée de l'infection a varié de 1 à 4 semaines, selon la détection de l'ARN viral par qRT-PCR pour le gène du SRAS-CoV-2 N1. -Les niveaux d'ARN viral et de virus infectieux étaient les plus élevés pendant la première semaine de l'infection et ont diminué au cours des semaines suivantes. -Le virus infectieux n'a pas été détecté chez les personnes ayant moins de 100 000 copies/écouvillon d'ARN N1. -Un membre du personnel a eu un résultat faiblement positif détecté par la technique par plages à passage unique trois semaines après le diagnostic initial.
(Lavezzo et coll., 2020)	Cohorte prospective	-Enquête 1 = 2812 résidents et Enquête 2 = 2343 résidents en Italie -Du 21 février au 7 mars 2020	RT-PCR	<u>Écouvillons nasopharyngés</u> -Aucune différence statistiquement significative n'a été constatée dans la charge virale des infections symptomatiques et asymptomatiques. -Il a été constaté que la charge virale a tendance à atteindre son maximum le jour de l'apparition des symptômes et que, pour la plupart des sujets, elle tend à diminuer après l'apparition des symptômes.
(W. Li et coll., 2020)	Cohorte prospective	-Cas asymptomatiques (n=3), présymptomatiques (n=6) et symptomatiques (n=9) en Chine -Du 29 janvier au 5	RT-PCR	<u>Écouvillons respiratoires et anaux</u> - La durée médiane de l'excrétion virale était plus courte chez les patients présymptomatiques (11,5 jours) que chez les cas asymptomatiques (28 jours) et les cas symptomatiques légers (31 jours).

		février 2020		
(Y. H. Lee et coll., 2020)	Cohorte prospective	-Cas asymptomatiques et légers (n=632) en Corée du Sud -Du 2 mars au 12 avril 2020	RT-PCR	Écouvillons buccaux et nasaux -Les patients symptomatiques ont eu une période plus longue entre le diagnostic et les résultats négatifs de la RT-PCR que les patients asymptomatiques : 21,8 jours (ET 7,6) contre 19,1 jours (ET 7,5), p < 0,0001. -Les symptômes respiratoires avaient une corrélation statistiquement significative avec la période d'excrétion de l'ARN (p < 0,0001). Cependant, il n'y avait pas de différences statistiquement significatives liées aux symptômes gastro-intestinaux, aux maux de tête, à la fièvre et à d'autres symptômes. Il n'y avait pas non plus de différences statistiquement significatives en fonction du sexe, de l'âge ou des conditions sous-jacentes.
(Saurabh et coll., 2020)	Cohorte prospective	-Cas asymptomatiques (n=44) et symptomatiques (n=7) en Inde -Du 19 mars au 21 mai 2020	RT-PCR	Écouvillons oropharyngés et nasopharyngés -Les personnes asymptomatiques avaient une durée médiane de persistance du virus de 8,87 jours (IC de 95 % : de 7,65 à 10,27) et une durée de 20,70 jours au 95^{e} centile (IC de 95 % : de 16,08 à 28,20). -Environ un quart des personnes asymptomatiques (10 sur 44) ont démontré une persistance du SRAS-CoV-2 au-delà de 2 semaines. -La durée de persistance du virus chez les personnes symptomatiques était de 10,98 jours (de 8,38 à 14,44, IC de 95 %). Il n'a pas été constaté que cette période était sensiblement plus longue que celle des personnes asymptomatiques (P = 0,222). -L'âge (< 60 ans) ans) et la transmission locale ont été associée de manière significative à une persistance plus longue du virus chez les individus asymptomatiques lors de la régression univariée, mais pas lors de l'analyse multivariée.
(Long et coll., 2020)	Cohorte prospective	-Cas asymptomatiques (n=37) et cas symptomatiques correspondants (n=37) en Chine -Date de fin : 10	RT-PCR	Écouvillons nasopharyngés -La durée médiane de l'excrétion de l'ARN viral dans le groupe asymptomatique était de 19 jours (IQR de 15 à 26). -Le groupe asymptomatique présentait une durée d'excrétion de l'ARN viral nettement plus longue que le groupe symptomatique (log-rang, P = 0,028). -Les données suggèrent que les personnes asymptomatiques ont eu une

		avril 2020		réponse immunitaire plus faible à l'infection par le SRAS-CoV-2.
(Y. Lu et coll., 2020)	Cohorte rétrospective	-Enfants hospitalisés avec des symptômes de COVID-19 légers et ordinaires (n=110) en Chine -Du 30 janvier au 10 mars 2020	RT-PCR	Écouvillon respiratoire -La durée médiane de l'excrétion de l'ARN viral était de 15 jours (de 11 à 20, IQR de 5 à 37). -La durée de l'excrétion virale chez les patients symptomatiques était statistiquement plus longue (p < 0,001) : 17 jours (IQR de 12 à 23) contre 11 jours (IQR de 9 à 13).
(Alshami et coll., 2020) *Prépublication*	Cohorte rétrospective	-Les sujets de COVID-19 confirmés en laboratoire qui ont été mis en quarantaine dans un établissement désigné par le gouvernement suite à un voyage hors du royaume (n=128) en Arabie Saoudite -Du 16 mars au 18 avril 2020	RT-PCR	Écouvillons nasopharyngés et oropharyngés -69 patients (54 %) ne présentaient aucun symptôme. -Pour les patients qui présentaient des symptômes, la durée médiane de résolution était de 5 jours. -La durée médiane avant la clairance virale était significativement plus longue (p=0,011) chez les patients symptomatiques que chez les patients asymptomatiques : 17 jours (de 12,4 à 21,6, IC de 95 %) contre 11 jours (de 8,7 à 13,3, IC de 95 %).
(Noh et coll., 2020)	Cohorte rétrospective	-Patients hospitalisés (n=199) en Corée du Sud, 26,6 % étaient asymptomatiques -Chronologie non communiquée	RT-PCR	Type de prélèvements non rapporté -La durée de l'excrétion virale a été définie comme le temps écoulé entre le diagnostic et le jour précédant la première conversion négative de deux résultats négatifs consécutifs de la RT-PCR. -La durée moyenne de l'excrétion virale était de 24,5 jours (ET ±4,8). -La durée de l'excrétion virale était plus longue chez les patients symptomatiques que chez les patients asymptomatiques : 25,2 jours (ET ±4,9) contre 22,6 jours (ET ±4,0), p < 0,01.

				-Les patients symptomatiques souffrant de douleurs thoraciques ont libéré le virus beaucoup plus longtemps que les autres : 30,0 (ET ±4,7) jours contre 25,0 jours (ET ±4,8), p = 0,01). -Les patients qui se sont plaints d'expectorations ont également connu une excrétion prolongée d'ARN viral : 26,8 jours (ET ±4,8) contre 24,6 jours (ET ±4,8), p = 0,03.
(S. Lee et coll., 2020)	Cohorte rétrospective	-Patients symptomatiques et asymptomatiques (n=303) en Corée -Du 6 au 26 mars 2020	RT-PCR	Nasopharynx, oropharynx, et écouvillon d'expectoration -La durée médiane entre le diagnostic et la première conversion négative de l'ARN viral a été de 17 (erreur type=1,07) jours pour les patients asymptomatiques et de 19,5 (erreur type=0,63) jours pour les patients symptomatiques (y compris présymptomatiques) (p=0,07).
(Xiong et coll., 2020)	Cohorte rétrospective	-Cas pédiatriques hospitalisés (n=244) -Du 21 janvier au 20 mars 2020	RT-PCR	Aspiration nasopharyngée -La durée entre l'aspiration nasopharyngée positive et négative était similaire chez les patients atteints de la COVID-19, qu'ils soient asymptomatiques ou symptomatiques (moyenne de 8,2 jours contre 8,9 jours; P = 0,434), ce qui suggère une durée similaire de l'excrétion virale.
(Lombardi et coll., 2020) *Prépublication*	Cohorte rétrospective	-Travailleurs de la santé en Italie -Du 24 février au 31 mars 2020	RT-PCR	Écouvillon nasopharyngé -Sur les 138 sujets dont le test d'ARN viral était positif, 41 sur 138 (29,7 %) étaient asymptomatiques. -La durée médiane entre le premier test positif et le test négatif ne diffère pas entre les sujets symptomatiques et les cas asymptomatiques, 23 jours (de 18 à 26, IC de 95 %) contre 23 jours (de 19 à 29, IC de 95 %). -La durée médiane de l'excrétion virale n'a pas été statistiquement associée au sexe ou à l'âge.
(Kim et coll., 2020)	Cohorte rétrospective	-Patients affectés par la COVID-19 hospitalisés en Corée du Sud, confirmés par un laboratoire -Du 4 février au 7	RT-PCR	Écouvillon nasopharyngé -10 sur 71 cas confirmés en laboratoire, déterminés par test RT-PCR, étaient asymptomatiques. -La durée médiane avant le premier test RT-PCR négatif après le diagnostic était de 4,5 jours (fourchette de 2,5 à 9). -Les auteurs suggèrent qu'une quarantaine de 14 jours à domicile après le diagnostic peut être suffisante pour les porteurs asymptomatiques.

		avril 2020		
(Y. J. Liu et coll., 2020)	Cohorte rétrospective	-Cas pédiatriques asymptomatiques (n=35) et subcliniques (n=18) en Chine -Chronologie non communiquée	RT-PCR	Écouvillons nasopharyngés -Le temps moyen d'élimination de l'acide nucléique du SRAS-CoV-2 dans les écouvillons nasopharyngés était de 9 ±4 jours.
(M.S. Han et coll., 2020)	Cohorte rétrospective	-Enfants légèrement symptomatiques (n=9) et asymptomatiques (n=3) en Corée du Sud -Du 8 mars au 28 avril 2020	RT-PCR	Écouvillons nasopharyngés, fécaux et de salive -La charge virale d'ARN dans les écouvillons nasopharyngés a atteint un pic au début, à la médiane de 7,56 $\log^{10}$ copies/mL, et a diminué avec le temps (p<0,001 comme tendance). La positivité des échantillons était de 75 % pendant la deuxième semaine et de 55 % pendant la troisième semaine. -En comparaison, la charge fécale initiale médiane d'ARN était de 7,68 $\log^{10}$ copies/mL et est restée constamment élevée (p = 0,148 comme tendance) pendant plus de trois semaines. La positivité fécale est restée supérieure à 80 %. -La charge médiane d'ARN dans les échantillons de selles était significativement plus élevée que celle des échantillons prélevés par écouvillonnage nasopharyngien pendant la deuxième semaine (p = 0,006) et la troisième semaine (p = 0,006). -La charge d'ARN dans la salive a diminué rapidement avec le temps (p = 0,003 comme tendance). La positivité des échantillons de salive était de 80 % la première semaine, mais elle a chuté brusquement à 33 % la deuxième semaine et à 11 % la troisième semaine. -Les enfants symptomatiques avaient une charge initiale d'ARN plus élevée dans les échantillons prélevés par écouvillonnage nasopharyngien que les enfants asymptomatiques (p = 0,048). Il n'y avait pas de différences significatives dans les selles ou la salive et aucune corrélation entre la charge d'ARN et l'âge.
(Shen et coll., 2020)	Cohorte rétrospective	-Patients pédiatriques (sept	RT-PCR	Type de prélèvements non rapporté -6 enfants ont eu une exposition familiale et ont pu fournir les dates

		légers et deux asymptomatiques) en Chine -Du 8 janvier au 26 février 2020		exactes de leur contrat avec une personne dont il a été confirmé qu'elle avait la COVID-19. -Le délai entre l'exposition et des résultats négatifs de test RT-PCR dans les cas asymptomatiques (n=2) était de 10 jours et de 14 jours.
(Z. Zhang et coll., 2020) *Prépublication*	Série de cas	-56 patients atteints de la COVID-19 sans symptômes à l'admission (33 ont présenté des symptômes par la suite) et 19 patients symptomatiques appariés par âge provenant de Chine -Du 23 janvier au 1er avril 2020	RT-PCR	<u>Écouvillons respiratoires et anaux</u> -Parmi les 56 patients ne présentant pas de symptômes à l'admission, 23 sont restés asymptomatiques pendant toute la période de suivi. -Dans cette étude, la période infectieuse a été définie comme la période allant du premier jour de test d'acide nucléique positif au premier jour de test négatif continu pendant l'hospitalisation. -Les auteurs fournissent également des estimations de jours moyens entre l'apparition des symptômes et la conversion négative de l'ARN. -La période infectieuse des patients asymptomatiques (n=19) était statistiquement plus courte que celle des patients présymptomatiques (n=30) : 9,6 jours (ET ±5,3) contre 13,6 (ET ±6,6), p=0,03. -Les patients symptomatiques ont également eu une période infectieuse plus courte, 9,71 jours (ET ±4,3), par rapport aux cas présymptomatiques (p=0,05), mais une durée similaire entre le début de la maladie et la conversion négative, 16,6 (ET ±5,6) et 16,6 (ET ±7,5).
(Mesoraca et coll., 2020)	Série de cas	-Patients asymptomatiques et légers (n=15) en Italie -Du 4 mars au 20 avril 2020	RT-PCR	<u>Écouvillons respiratoires et fécaux</u> -Sur les 10 patients dont l'échantillon fécal était négatif au cours des 10 premiers jours, 6 échantillons sont devenus positifs 2 semaines après leur premier test positif des voies respiratoires. -Dans quatre cas, les échantillons de matières fécales ont montré un ARN viral positif 25 jours de plus que les échantillons de leurs voies respiratoires.
(W. Du et coll., 2020)	Série de cas	-Cas pédiatriques asymptomatiques (n=5) et légers (n=5) en Chine -Du 23 janvier au 9 mars 2020	RT-PCR	<u>Échantillons respiratoires et fécaux</u> -La durée médiane entre l'apparition des résultats négatifs de test RT-PCR dans les échantillons des voies respiratoires et des matières fécales était de 9 jours et 34,43 jours, respectivement.

(Shin et coll., 2020)	Rapport de cas	-Fille asymptomatique de 11 ans originaire de Corée du Sud -Du 12 mars au 13 mai 2020	RT-PCR	Écouvillons nasopharyngés -L'enfant a eu un dépistage positif de l'ARN du SRAS-CoV-2 pendant plus de 62 jours sans aucun symptôme pendant toute la période.
(Mao, Wan, He, Hu et Chen, 2020)	Série de cas	-Cas asymptomatiques (n=2) en Chine -Du 27 janvier au 21 février 2020	RT-PCR	Écouvillon pharyngé -On a découvert qu'après 14 jours d'isolement, 2 cas asymptomatiques étaient toujours porteurs de la COVID-19. -Un cas a produit des résultats positifs aux tests RT-PCR jusqu'à 19 jours après le début de l'isolement.
(Y. Li et coll., 2020a) *Prépublication*	Série de cas	-Cas asymptomatiques (n=38) en Chine -Février et mars 2020	RT-PCR	Écouvillons pharyngés -La durée médiane d'excrétion virale était de 6 jours, avec un minimum de 2 jours et un maximum de 17 jours entre le premier test nucléique positif et le dernier test nucléique positif. - Les auteurs notent que cette période d'excrétion est plus courte que celle constatée dans d'autres études de cas symptomatiques, ce qui suggère une infectiosité plus courte pour les cas asymptomatiques.
(Valente et coll., 2020)	Série de cas	-Patients pédiatriques hospitalisés (n=27) en Italie, 4 étaient asymptomatiques, 15 présentaient des symptômes respiratoires et 8 des symptômes gastro-intestinaux -Du 16 mars au 15 avril 2020	RT-PCR	Écouvillons nasopharyngés et conjonctivaux -Deux cas asymptomatiques sont devenus négatifs trois jours après l'apparition des symptômes, tandis qu'un cas symptomatique s'est révélé négatif au bout de six jours, tout en restant positif sur les écouvillons nasopharyngés. -En outre, l'écouvillon nasopharyngé était négatif en moyenne 8 jours (fourchette de 2 à 17 jours) après l'apparition des symptômes, alors que l'écouvillon conjonctival est devenu négatif chez tous les patients en moyenne en 4 jours (fourchette de 3 à 6 jours).
Études épidémiologiques				
(Z. Hu et coll.,	Tests en série	-Cas d'infection	Données RT-	Écouvillon pharyngé

2020)	et étude de recherche de contacts pour des grappes	asymptomatique (n=24) en Chine -Du 28 janvier au 9 février 2020	PCR et données épid.	-Observation d'une transmission asymptomatique entre membres d'une famille cohabitant, qui a même causé une pneumonie grave due à la COVID-19. -La période médiane de contagion asymptomatique, définie comme l'intervalle entre le premier jour de tests d'acide nucléique positifs et le premier jour de tests négatifs continus, était de 6 jours (IQR de 2 à 12) dans les cas qui ne développaient pas de symptômes, mais présentaient des signes de COVID-19 à la tomodensitométrie (n=19), et de 4 jours (IQR de 2 à 15) dans les cas qui ne développaient pas de symptômes et avaient des résultats de tomodensitométrie normaux.
(Ma et coll., 2020) *Prépublication*	Revue documentaire	-Les cas dont les données permettaient d'estimer au moins un paramètre en Chine, au Japon, à Singapour, en Corée du Sud, au Vietnam, en Allemagne et en Malaisie -Date de fin : 20 février 2020	Données épid.	-Sur 49 cas asymptomatiques, la période infectieuse médiane était de 11,66 jours (fourchette de 9,9 à 13,3) -La période infectieuse a été calculée approximativement comme l'intervalle sériel moins la limite supérieure de la période de latence. Dans ces analyses, la date du diagnostic a été utilisée comme le jour d'apparition de symptômes pour les cas asymptomatiques.

PÉRIODE INFECTIEUSE SYMPTOMATIQUE

Le tableau 3 énumère cent sept études qui évaluent la période infectieuse symptomatique de la COVID-19, identifiée par des revues systématiques/méta-analyses, des séries de cas, des études d'observation et des modélisations. Les études clés font état de preuves solides de l'infectiosité par culture, de l'évaluation des facteurs de risque d'excrétion virale prolongée (par exemple, sexe, âge, gravité), de preuves de différences d'excrétion d'ARN viral entre différents types d'échantillons (fécaux ou respiratoires) et de modèles qui estiment la période infectieuse entière.

Les études qui font état de la culture du virus ne fournissent des mesures qu'à partir de l'apparition des symptômes et risquent de sous-estimer la période infectieuse totale, car elles ne tiennent pas compte de l'infectiosité présymptomatique. Elles sont également fondées sur des échantillons de taille limitée. Pour les cas bénins, les meilleures estimations disponibles pour la période infectieuse mesurée à partir de l'apparition des symptômes sont de 8 à 10 jours déterminées à l'aide d'une culture virale (Arons et coll., 2020; Bullard et coll., 2020; Folgueira et coll., 2020; La Scola et coll., 2020; Perera et coll., 2020; Singanayagam et coll., 2020; van Kampen, Jeroen J. A. et coll., 2020; Wölfel et coll., 2020), avec des charges virales élevées observées dans les cinq premiers jours et un pic viral quatre jours après l'apparition des symptômes (Wölfel et coll., 2020).

Des excrétions virales viables prolongées ont été signalées dans quelques études, principalement encore en prépublication et utilisant des échantillons de petite taille. Les rapports de cas, dont certains détaillent les cas immunodéprimés, démontrent la viabilité du virus jusqu'à 18 à 22 jours après l'apparition des symptômes (Decker et coll., 2020; Gniazdowski et coll., 2020; W. D. Liu et coll., 2020; van Kampen, Jeroen J. A. et coll., 2020). Des durées encore plus longues (jusqu'à 32 jours) ont été signalées dans un petit échantillon de cas graves (Folgueira et coll., 2020). Une étude a confirmé la présence du SRAS-CoV-2 infectieux dans des échantillons d'urine et de fèces dès jours 11, 13 et 15 de maladie grave/critique en démontrant l'infection chez des furets inoculés (Jeong et coll., 2020).

Quelques études ont mis en culture le SRAS-CoV-2 à partir d'échantillons fécaux/rectaux de cas confirmés (Qian et coll., 2020; F. Xiao et coll., 2020; Y. Zhang et coll., 2020). Cependant, il faut davantage d'éléments de preuve pour déterminer la fréquence et la durée probables de l'excrétion d'un virus viable par voie fécale et pour savoir s'il y a transmission fécale-orale, fécale-fomite ou fécale-respiratoire.

La majorité des études sur les tests en série mesurent la période infectieuse par RT-PCR à partir de la date d'apparition des symptômes auto déclarés ou du premier résultat positif par RT-PCR jusqu'au premier de deux résultats négatifs consécutifs par RT-PCR. La prudence est de mise dans l'interprétation de ces résultats, car la positivité de la RT-PCR n'est pas indicative de l'infectiosité et la durée de détectabilité virale surestime probablement la période infectieuse.

Les estimations de la RT-PCR montrent une excrétion prolongée de l'ARN viral, qui dépasse souvent la durée des symptômes. Une récente méta-analyse a estimé que la durée moyenne de la positivité des tests RT-PCR utilisant des échantillons respiratoires, depuis l'apparition des symptômes jusqu'à la guérison ou au décès, était de 13,4 jours (IC de 95 %) : de 10,9 à 15,8) (Byrne et coll., 2020). Les concentrations d'ARN viral mesurées dans les échantillons des voies respiratoires supérieures diminuent après l'apparition des symptômes (Kujawsk et coll., 2020; Lavezzo et coll., 2020; Quicke et coll., 2020; Wölfel et coll., 2020; van Kampen et coll., 2020; B. E. Young et coll., 2020b; L. Zou et coll., 2020). Des auteurs ont également rapporté des périodes prolongées d'excrétion d'ARN viral (jusqu'à 83 jours) dans des échantillons respiratoires (par exemple J. Li, Zhang, Liu et Song, 2020; N. Li, Wang et Lv, 2020; Park et coll., 2020; Shin et coll., 2020).

La présence d'ARN viral a beaucoup varié selon le type d'échantillon. Les échantillons de selles sont initialement positifs par RT-PCR plusieurs jours après l'apparition des symptômes en moyenne et restent positifs plus longtemps que les échantillons respiratoires (Cai et coll., 2020; Z. Chen et coll., 2020; Du et coll., 2020; Hua et coll., 2020; Ling et coll., 2020; Lyu et coll., 2020; Mesoraca et coll., 2020; Santos et coll., 2020; F. Xiao et coll., 2020; Y. Xing et coll., 2020; C. L. H. Xu et coll., 2020; N. Zhang et coll., 2020). Des éléments de preuve de l'excrétion de l'ARN viral du SRAS-CoV-2 ont également été identifiés dans des écouvillons oculaires (Hu et coll., 2020; Valente et coll., 2020; Xia et coll., 2020). Dans une étude, les écouvillons oculaires ont été continuellement positifs pendant deux semaines après que les écouvillons nasopharyngés soient devenus négatifs le 22^{e} jour (Y. Hu et coll., 2020). Alors que dans une autre étude, les écouvillons conjonctifs sont devenus négatifs chez les enfants plus tôt que les écouvillons nasopharyngés (4 jours 'par rapport à 8 jours) (Valente et coll., 2020). Dans une étude portant sur 17 patients atteints de la COVID-19, aucun signe d'excrétion d'ARN viral n'a été trouvé dans les larmes au cours de la maladie (Seah et coll., 2020).

Les caractéristiques des individus ou des maladies qui déterminent la durée de l'excrétion de l'ARN viral ont été étudiées, notamment le cancer, la gravité, l'âge, la symptomatologie. De plus, il a été démontré que la durée de l'excrétion d'ARN viral était inversement corrélée aux niveaux plasmatiques des cytokines IL-1β et IL-17A des cellules T à la phase initiale de l'infection (P. H. Lee et coll., 2020). Il existe également des preuves variables de l'existence d'anticorps neutralisants et de l'association avec la gravité de la COVID-19 et la clairance virale (Jeewandara, et coll., 2020; Ru et coll., 2020).

Trois études portent sur l'excrétion du SRAS-CoV-2 par les animaux. Un essai expérimental de provocation chez le macaque rhésus a permis d'isoler le virus viable jusqu'à trois jours après l'infection, tandis que l'excrétion d'ARN viral s'est poursuivie jusqu'à 17 jours après l'infection (Munster et coll., 2020). Une série de cas de grands félins du zoo du Bronx a rapporté l'isolement d'un virus viable chez deux animaux, cinq jours après que les signes cliniques aient cessé (Bartlett et coll., 2020). Un essai expérimental de provocation sur des chats a montré que les test d'ARN viral dans les écouvillons nasaux étaient positifs du 1er au 10^{e} jour après la provocation, avec des quantités maximales observées du 1er au 5^{e} jour après la provocation (Gaudreault et coll., 2020).

En raison de l'abondance des rapports de cas, tous les rapports de cas faisant état de tests en série n'ont pas été inclus dans ce tableau.

Tableau 3 : Études évaluant la période infectieuse symptomatique de la COVID-19 chez l'homme et l'animal. (N=107)

Référence	Type d'étude	-Population et environnement -Période de temps	Période infectieuse (PI) déterminée par : Culture, Tests RT-PCR en série, données épidémiologique ou modèle	Résultats pertinents
Études sur la culture et la RT-PCR				
(Jeong et coll., 2020)	Cohorte prospective	-Cinq patients atteints de la COVID-19 de Corée et des groupes de furets -Du 25 février au 5 mars 2020	Culture et RT-PCR	Écouvillons respiratoires et fécaux -Le virus SARS-CoV-2 viable a été isolé à partir de trois échantillons respiratoires prélevés sur des patients atteints de la COVID-19 après 11 et 15 jours de maladie. -Les charges virales dans les échantillons d'urine, de salive et de selles étaient presque égales ou supérieures à celles des écouvillons naso-oropharyngés. -Pour confirmer la présence du SRAS-CoV-2 infectieux dans les échantillons d'urine et de matières fécales, deux échantillons d'urine (du 11^{e} et 13^{e} jour de maladie) et un échantillon de matières fécales (15^{e} jour de maladie) ont été sélectionnés pour des expériences d'infection de furets. Tous les furets traités avec des échantillons d'urine et de selles présentaient des signes d'infection.
(B. E. Young et coll., 2020a) *Prépublication*	Cohorte prospective	-Patients hospitalisés (n=100) à Singapour -Du 22 janvier au 6 mars 2020	Culture et RT-PCR	Écouvillons respiratoires -La culture virale à partir d'échantillons respiratoires a été positive pour 14 des 73 patients. -Valeur seuil du cycle PCR ≤ 30 x durée d'isolement viral prévue par culture -La durée moyenne d'excrétion de l'ARN viral était de 16,7 jours (IC de 95 %, de 15,2 à 18,3) et ne différait pas de manière significative en fonction de la gravité de la maladie ou de

				l'utilisation du lopinavir-ritonavir.
(Wölfel et coll., 2020)	Série de cas prospectifs	-Neuf patients confirmés hospitalisés présentant des symptômes légers en Allemagne -Cas découverts le 27 janvier 2020	Culture et RT-PCR	<u>Écouvillon respiratoire</u> -Le virus vivant a été isolé à partir d'écouvillons des voies respiratoires supérieures par culture virale pendant les sept premiers jours suivant l'apparition des symptômes. Aucun isolat n'a été obtenu à partir des échantillons après le huitième jour malgré la présence continue d'ARN viral. -L'excrétion d'ARN viral a été démontrée dans des échantillons d'expectorations et des voies respiratoires supérieures jusqu'à 22^{e} et 20^{e} jours, respectivement. -La charge virale a atteint un pic le quatrième jour après l'apparition du virus, avec $7,11\times10^{8}$ copies d'ARN par écouvillon pharyngé. La charge virale moyenne d'ARN était de $6,76\times10^{5}$ copies par écouvillon entier jusqu'au cinquième jour. Les échantillons prélevés après le cinquième jour avaient une charge virale moyenne de $3,44\times10^{5}$ copies par écouvillon et un taux de détection de 39,93 %. <u>Écouvillon de selles</u> -Le virus vivant n'a pas été isolé dans les échantillons de selles malgré la présence d'ARN viral continu (détecté jusqu'à 21 jours après l'apparition des symptômes).
(van Kampen, Jeroen J. A. et coll., 2020) *Prépublication*	Cohorte rétrospective	-Patients atteints de la COVID-19 hospitalisés (n=129, 89 en soins intensifs, 40 en soins moyens) aux Pays-Bas -Du 8 mars au 8 avril 2020	Culture et RT-PCR	<u>Écouvillons respiratoires supérieurs et inférieurs</u> -L'excrétion du virus infectieux a été détectée dans 62 échantillons respiratoires de 23 sur 129 patients (17,8 %). -La durée médiane de l'excrétion virale infectieuse était de 8 jours (de 0 à 20, IQR de 5 à 11) et la probabilité de détecter le virus infectieux est tombée en dessous de 5 % après 15,2 jours (de 13,4 à 17,2, IC de 95 %) après l'apparition des symptômes. -L'excrétion du virus infectieux est tombée à des niveaux indétectables lorsque le seuil de le seuil de la charge d'ARN viral était inférieur à 7 log^{10} copies d'ARN/ml et lorsque des anticorps neutralisants sériques étaient présents. Ces associations étaient significatives dans l'analyse uni- et

				multivariée.
(Folgueira et coll., 2020) *Prépublication*	Cohorte rétrospective	-Échantillons (n=106) provenant de 105 patients en Espagne -Chronologie non communiquée	Culture	<u>Échantillons respiratoires</u> -Dans 49 sur 106 échantillons (46,2 %), un effet cytopathique a été détecté en culture. -Dans les cas bénins, la viabilité virale a été maintenue jusqu'à 10 jours après l'apparition des symptômes. -Dans les cas graves, la viabilité virale a été maintenue jusqu'à 32 jours après l'apparition des symptômes. -Par rapport aux cas bénins, les cas graves présentaient le virus infectieux dans une proportion significativement plus élevée dans les échantillons ayant une charge virale modérée ou faible ($p < 0,01$).
(La Scola et coll., 2020)	Cohorte rétrospective	-183 échantillons provenant de 155 patients en France -Du 27 février au 12 mars 2020	Culture et RT-PCR	<u>Écouvillons nasopharyngés et d'expectoration</u> -Le SRAS-CoV-2 n'a pas pu être isolé à partir des échantillons prélevés après le huitième jour de l'apparition des symptômes. - Suggère que les patients présentant des valeurs Ct ≥ 34 ne sont plus infectieux et qu'ils peuvent sortir de l'hôpital.
(Singanayagam et coll., 2020)	Cohorte rétrospective	-324 échantillons, 81 cultures positives au Royaume-Uni De janvier à mai 2020	Culture et RT-PCR	<u>Écouvillons respiratoires</u> -La détection du virus cultivable a atteint son maximum au moment de l'apparition des symptômes. La durée médiane de l'excrétion du virus, mesurée par culture, était de 4 jours (IQR de 1 à 8) à partir de l'apparition des symptômes. -Dix jours après l'apparition des symptômes, la probabilité de mise en culture du virus est tombée à 6,0 % (de 0,9 à 31,2 %, IC de 95 %) -Il n'y avait pas de différence dans les valeurs seuils du cycle entre les personnes atteintes d'une maladie asymptomatique, bénine à modérée ou grave. Il n'y avait pas de différence significative entre les groupes d'âge.
(Perera et coll., 2020)	Cohorte rétrospective	-Échantillons respiratoires (n=68) de 35 patients atteints de la	Culture et RT-PCR	<u>Écouvillons respiratoires</u> -Le virus a été isolé chez 16 patients. -Le virus SRAS-CoV-2 viable était rarement détectable au-delà

		COVID-19 à Hong Kong -Chronologie non communiquée		de 8 jours après le début de la maladie dans les cas bénins. Cependant, l'ARN viral a été détectable pendant de nombreuses semaines par RT-PCR.
(Gniazdowski et coll., 2020) *Prépublication*	Cohorte rétrospective	-Échantillons de patients (n=161) positifs au test moléculaire aux États-Unis -Du 11 mars au 11 mai 2020	Culture et RT-PCR	<u>Écouvillons oropharyngés</u> -Pour évaluer la récupération du virus infectieux, un sous-ensemble de 29 patients sélectionnés au hasard a été évalué, dont beaucoup présentaient des affections sous-jacentes chroniques (n=27). - Chez quatre patients, des virus viables ont été récupérés à partir d'échantillons respiratoires prélevés jusqu'à 22 jours après le premier résultat positif. -L'excrétion de virus infectieux n'a pas été associée à un résultat spécifique, car un patient n'a jamais été admis, un autre a été hospitalisé, mais sans gravité, et deux ont été gravement malades. - La récupération du virus infectieux a été associée à la persistance des symptômes chez tous les patients sauf un. -Le séquençage complet du génome viral a montré que ces patients étaient porteurs du même virus au fil du temps (pas de réinfection).
(Bullard et coll., 2020)	Étude transversale rétrospective des échantillons soumis au laboratoire	-Test RT-PCR des échantillons positifs pour le SRAS-CoV-2 (N=90) au Canada -Chronologie non communiquée. Échantillons prélevés à partir du jour de l'apparition des symptômes (jour 0) jusqu'à 21 jours après l'apparition des symptômes	Culture et RT-PCR	<u>Écouvillons nasopharyngés et endotrachéaux</u> -Sur les 90 échantillons de SRAS-CoV-2 positifs au test RT-PCR analysés, 26 (28,9 %) ont été cultivés avec succès. -Des cultures positives n'ont été observées que jusqu'au huitième jour suivant l'apparition des symptômes. -La probabilité d'obtenir une culture virale positive a atteint son maximum le troisième jour suivant l'apparition des symptômes. -L'infectivité était significativement réduite lorsque les valeurs seuils du cycle RT-PCR étaient supérieures à 24.

(Kujawski et coll., 2020)	Série de cas	-Les 12 premiers patients confirmés aux États-Unis -Du 20 janvier au 5 février 2020	Culture et RT-PCR	<u>Écouvillon respiratoire</u> -La culture virale a été effectuée avec succès pour les 9 patients testés, avec des résultats positifs des échantillons respiratoires 9 jours après l'apparition des symptômes. Aucun essai d'isolement viral n'a pas été effectué sur les prélèvements ultérieurs. -L'ARN du SRAS-CoV-2 a été détecté dans les échantillons respiratoires des 12 patients, généralement 2 à 3 semaines après l'apparition des symptômes. -L'ARN du SRAS-CoV-2 a été détecté pendant un maximum de 36 jours après l'apparition des symptômes, bien après que ceux-ci aient complètement disparu. -Les échantillons de sérum et de selles ont également montré une excrétion virale positive pendant un maximum de huit et 25 jours, respectivement.
(Decker et coll., 2020)	Rapport de cas	-Homme de 62 ans, patient léger atteint de la COVID-19 avec une récente transplantation cardiaque en Allemagne -À partir du 13 mars 2020	Culture et RT-PCR	<u>Écouvillons pharyngés</u> -Le patient ne présentait aucun symptôme clinique 20 jours après les premiers symptômes, mais la culture du virus sur des écouvillons pharyngés aux jours 18 et 21 a confirmé une réplication active du virus du SRAS-CoV-2. -Sous immunosuppression continue, l'ARN viral du SRAS-CoV-2 est resté détectable jusqu'au 35^{e} jour avec un nombre de copies similaire à celui du début de l'infection.
(W. D. Liu et coll., 2020)	Rapport de cas	-Femme de 50 ans à Taïwan -Chronologie non communiquée	Culture et RT-PCR	<u>Écouvillons pharyngés et échantillons d'expectorations</u> -Le SRAS-CoV-2 a pu être isolé à partir de cultures dans des écouvillons pharyngés prélevés lors de l'admission, et tous les échantillons d'expectorations collectés dans les 18 jours suivant l'apparition des symptômes. -L'ARN viral était détectable par RT-PCR jusqu'à 63 jours après l'apparition des symptômes.
(Y. Zhang et coll., 2020)	Rapport de cas	-Un cas de COVID-19 grave	Culture	<u>Écouvillon de selles</u> -Le SRAS-CoV-2 a été isolé à partir d'un échantillon de selles

		confirmé par laboratoire, en Chine -Du 16 janvier au 1er février 2020		d'un cas dont les symptômes sont apparus le 16 janvier 2020 et a été prélevé le 1er février 2020. -L'intervalle entre le prélèvement et l'apparition des symptômes était de 15 jours.
(F. Xiao et coll., 2020)	Série de cas	-Cas mortel de COVID-19 et 28 autres échantillons de matières fécales en Chine -Janvier 2020	Culture et RT-PCR	<u>Écouvillons nasopharyngés, oropharyngés et fécaux</u> -La charge virale était plus élevée dans les matières fécales que dans les échantillons respiratoires prélevés à plusieurs moments (de 17 à 28 jours après l'apparition des symptômes). -L'isolement du virus à partir d'échantillons d'excréments prélevés à des moments ultérieurs n'a pas n'a pas été un succès, malgré l'excrétion continue d'ARN viral. -Les auteurs ont également recueilli des échantillons d'excréments de 28 patients. 12, y compris le cas mentionné ci-dessus, étaient positifs quant à la détection d'ARN viral. L'isolement du virus du SRAS-CoV-2 a été un succès pour deux patients.
(Sun et coll., 2020)	Rapport de cas	-Un homme de 72 ans en Chine -Du 25 janvier au 6 mars 2020	Culture et RT-PCR	<u>Urine</u> -La charge virale dans les urines était faible, mais détectable au 12e jour et au 42e jour après l'infection, mais pas au 30e jour. -Afin de prouver que le virus isolé était infectieux pour les cellules sensibles, des échantillons d'urine positifs au test RT-PCR du 12e jour après l'infection ont été dilués en série dans des milieux d'infection et inoculés sur des cellules Vero E6. -Des effets cytopathiques ont été clairement observés au bout de 3 jours, ce qui soulève la possibilité d'une transmission fécale/urine-respiratoire.
(Mancuso et coll., 2020) *Prépublication*	Cohorte prospective basée sur la population	-Cas de COVID-19 (n=1162) en Italie -Du 26 février au 22 avril 2020	RT-PCR	<u>Écouvillons nasopharyngés</u> -La durée médiane de clairance de l'ARN viral déterminée par test RT-PCR était de 36 jours (IRQ de 28 à 45) à partir de l'apparition des symptômes. -Le temps nécessaire à la clairance du virus augmente avec l'âge et l'hospitalisation, bien que cela ne soit pas

				statistiquement significatif.
(K. Wang et coll., 2020)	Cohorte prospective	-Patients hospitalisés (n=68) en Chine -Du 10 février au 20 mars 2020	RT-PCR	Écouvillons nasopharyngés et d'expectoration -La durée médiane de l'excrétion de l'ARN viral à partir des échantillons d'expectorations a été significativement plus longue que celle des écouvillons nasopharyngés : 34 jours (IQR de 24 à 40) contre 19 jours (IQR de 14 à 25), p < 0,001. -L'âge avancé était un facteur indépendant associé à la durée prolongée de l'excrétion du virus du SRAS-CoV-2 (HR 1,71, de 1,01 à 2,93). - Chez neuf patients, l'ARN viral a été détecté dans les expectorations après que les écouvillons nasopharyngés soient devenus négatifs.
(Yu et coll., 2020)	Cohorte prospective	-Cas rétablis (n=75) en Chine -Du 9 au 14 mars 2020	RT-PCR	Échantillons respiratoires -Sur les 75 cas, 12 ont pris moins de 30 jours pour obtenir 2 tests de détection de l'ARN du SRAS-CoV-2 négatifs consécutifs, 57 ont pris de 31 à 60 jours; et 1 a pris plus de 60 jours pour remplir ce critère. -La moyenne est de 27,15 jours (de 24,72 à 29,58, IC de 95 %).
(Shrestha et coll., 2020)	Cohorte prospective	-Travailleurs de la santé (n=230) à Cleveland, aux États-Unis -Du 16 mars au 20 avril 2020	RT-PCR	Écouvillon nasopharyngé -Chez les patients atteints de COVID-19 non sévère, les charges virales dans les échantillons des voies respiratoires supérieures ont atteint un pic deux ou trois jours après l'apparition des symptômes et diminuent rapidement par la suite. - Chez les personnes atteintes d'une maladie non grave, le potentiel de transmission de la COVID-19 est fortement diminué de 7 à 10 jours après l'apparition des symptômes.
(Y. Xing et coll., 2020) *Prépublication*	Cohorte prospective	-Cas pédiatriques (n=3) en Chine -Du 17 janvier au 23 février 2020	RT-PCR	Écouvillon pharyngé -La période infectieuse médiane entre l'apparition des symptômes et la clairance du virus était de 13,5 jours (fourchette de 11 à 16 jours). Écouvillon fécal -La période infectieuse médiane entre l'apparition des

				symptômes et la clairance du virus était de 29 jours (fourchette de 24 à 34 jours).
(Yu, Zhang et coll., 2020)	Étude rétrospective de cohorte par paires appariées	-Patients hospitalisés atteints de pneumonie due à la COVID-19, 64 cas souffrant aussi de grippe A/B et 64 cas souffrant aussi de grippe négative en Chine -Du 28 janvier au 17 mars 2020	RT-PCR	Écouvillons pharyngés -La durée médiane de l'excrétion virale à partir de l'admission était plus longue pour les patients présentant une co-infection grippale (17,0 jours) que pour ceux qui n'en présentaient pas (12,0 jours) (P< 0,001).
(Spagnuolo et coll., 2020) *Prépublication*	Cohorte rétrospective	-Patients hospitalisés (n=280) en Italie -Du 25 février au 19 mai 2020	RT-PCR	Écouvillons nasopharyngés - Une étude montre qu'un retard dans la clairance du COVID-19 modéré/grave est associé à un âge plus avancé et à une maladie plus grave, mais pas à l'utilisation précoce de corticostéroïdes.
(X. Zheng et coll., 2020)	Cohorte rétrospective	-Patients hospitalisés (n=80) en Chine, 28 de type grave, 52 de type courant -Du 17 janvier au 9 mars 2020	RT-PCR	Écouvillons de gorge et de matières fécales -La plus longue durée observée d'excrétion virale pour les écouvillons de gorge et des matières fécales chez les patients atteints de COVID-19 était respectivement de 43 et 46 jours après l'apparition des symptômes. -Il n'y avait aucune corrélation entre la durée de l'excrétion virale et la gravité de la COVID-19.
(F. Hu et coll., 2020)	Cohorte rétrospective	-Patients hospitalisés (n=190) en Chine -Du 8 janvier au 9 février 2020	RT-PCR	Écouvillons pharyngés -La durée de l'apparition des symptômes à l'admission (P <0,001) et l'administration de corticostéroïdes (P = 0,002), d'arbidol (P = 0,008) et d'oseltamivir (P <0,001) ont été indépendamment associées à la durée de l'excrétion virale.
(Bahar et coll., 2020)	Cohorte rétrospective	-Cas pédiatriques (n=6369) ayant subi des	RT-PCR	Écouvillons nasopharyngés - La durée médiane de l'excrétion virale (test RT-PCR positif)

Prépublication		tests aux États-Unis -Du 13 mars au 21 juin 2020		était de 19,5 jours et du passage de tests RT-PCR positifs à négatifs était de 25 jours. -Les patients âgés de 6 à 15 ans ont présenté une excrétion virale plus longue que les patients âgés de 16 à 22 ans (médiane = 32 contre 18 jours, p = 0,015).
(X. Chen et coll., 2020)	Cohorte rétrospective	-Patients hospitalisés (n=284) en Chine -Du 20 janvier au 15 mars 2020	RT-PCR	Écouvillons pharyngés -La durée médiane de l'excrétion de l'ARN viral était de 12 jours (IQR de 8 à 16) après l'apparition du symptôme. -L'âge avancé, le délai entre le début de la maladie et l'admission à l'hôpital, la diarrhée, le traitement par corticostéroïdes et le lopinavir/ritonavir ont été associés de manière significative et indépendante à une excrétion prolongée d'ARN viral.
(Y. Shen et coll., 2020)	Cohorte rétrospective	-Cas confirmés (n=325) en Chine -Du 20 janvier au 29 février 2020	RT-PCR	Prélèvements nasopharyngés, urinaires, fécaux et sanguins -La durée médiane entre le début et la détection négative de l'acide nucléique par écouvillonnage nasopharyngé était de 8 jours. -Une plus longue durée d'excrétion virale dans le sang et les selles a été détectée chez les patients atteints d'une maladie légère et utilisant des glucocorticoïdes. -La durée médiane entre le début de la maladie et la détection virale négative était plus longue chez les patients graves et critiques que chez les patients légers. -Parmi 22 patients légers sans traitement antiviral, les délais médians entre le début de la maladie et la détection virale négative dans les écouvillons nasopharyngés, les urines, les fèces et les échantillons de sang étaient respectivement de 9, 7, 10 et 9,5 jours.
(N. Li et coll., 2020)	Cohorte rétrospective	-Cas confirmés avec excrétion virale prolongée >30 jours (n=36) en Chine	RT-PCR	-L'excrétion prolongée de l'ARN viral, même après le soulagement des symptômes, était courante, et la durée médiane de l'excrétion de l'ARN viral était de 53,5 jours (IQR de 47,75 à 60,5).

		-Du 11 février au 11 avril 2020		-La plus longue durée d'excrétion de l'ARN viral pourrait être de 83 jours. -Par rapport aux groupes de patients dont les symptômes sont apparus plus tardivement, les patients présentant ses symptômes précoces avaient des durées d'excrétion virale plus longues et souffraient de maladies plus graves.
(Korkmaz et coll., 2020)	Cohorte rétrospective	-Enfants hospitalisés (n=81) en Turquie -Du 5 mars au 5 mai 2020	RT-PCR	Écouvillons naso-oropharyngés -La durée médiane pour que l'ARN du SRAS-CoV-2 devienne négatif au test RT-PCR était de 5 jours (de 3 à 10). -Le délai avant d'avoir un test négatif était significativement plus long pour les patients âgés de cinq ans ou moins que pour les autres (P=0,037).
(T. Z. Li et coll., 2020)	Cohorte rétrospective	-Patients hospitalisés (n=101) en Chine -Du 21 janvier au 15 mars 2020	RT-PCR	Écouvillon pharyngé -La durée médiane de l'excrétion de l'ARN viral à partir de l'apparition des symptômes était de 11 jours (IQR de 8 à 14,3). -Dans l'analyse univariée, la gravité de la maladie, l'utilisation de corticostéroïdes, la fièvre et le temps écoulé entre le début de la maladie et l'hospitalisation ont été associés à une excrétion prolongée d'ARN viral. -Dans l'analyse multivariée, la gravité de la maladie n'a pas montré d'association significative.
(X. Du et coll., 2020)	Cohorte rétrospective	-Cas ventilés par âge, sexe et gravité (n=161) en Chine -Du 20 janvier au 1er mars 2020	RT-PCR	Type de prélèvements non rapporté -La durée médiane du portage viral de tous les cas (n=161) était de 20 jours (fourchette de 6 à 30). -La durée médiane du transport viral chez les hommes était de 21 jours (IQR de 16,5 à 29) chez les hommes (n=89) contre 20 jours (IQR de 16 à 26,8) chez les femmes (n=72). Il n'y avait pas de différence significative entre les sexes (p>0,05). -La durée médiane du portage viral pour les cas âgés de plus de 60 ans était statistiquement plus longue (p<0,01) que les cas âgés de 0 à 59 ans : 28 jours (IQR de 19 à 33) contre 20 jours (IQR de 16 à 26).

				-La durée médiane du portage viral pour les cas considérés comme graves (n=37) était statistiquement plus longue (p<0,01) que pour les cas non graves (n=124) : 27 jours (IQR de 19 à 33) contre 20 jours (IQR de 16 à 26).
(Tang Xiao et coll., 2020) *Prépublication*	Cohorte rétrospective	-Cas ventilés par âge et sexe (n=301) en Chine -Du 21 janvier au 11 février 2020	RT-PCR	<u>Écouvillons des voies respiratoires supérieures (écouvillons pharingés et/ou nasaux)</u> -La période médiane entre l'apparition des symptômes et le résultat négatif du test RT-PCR était de 20 jours (IQR de 17 à 24, de 7 à 44, N=216). -Les femmes (n=147) ont eu une période médiane plus courte entre le résultat positif et négatif du test RT-PCR du SRAS-CoV-2 que les hommes (n=154) : 19 jours (IQR de 17 à 24) contre 21 jours (IQR de 17 à 25). Ce résultat n'est pas statistiquement significatif (p=0,189). -La période médiane entre l'apparition des symptômes et les résultats négatifs au test RT-PCR était significativement plus longue chez les patients plus âgés (≥ 65 ans, n=110) que chez les plus jeunes (< 65 ans, n=191) : 22 jours (IQR de 19 à 26) contre 19 jours (IQR de 17 à 23), p=0,015.
(Voinsky et coll., 2020)	Cohorte rétrospective	-Patients (n=5769, 3370 hommes et 2399 femmes) en Israël -Date de fin : 28 avril 2020	RT-PCR	<u>Écouvillon pharyngé</u> -Le délai entre le premier résultat positif et le premier résultat négatif du test PCR était significativement plus long (p < 0,05) pour les patients de plus de 30 ans. Les périodes de rétablissement étaient : Homme < 30 ans : 13,84 (ET ±5,67) Homme >30 ans : 14,69 (ET ±6,0) Femme < 30 ans : 13,66 (ET ±5,87) Femme > 30 ans : 14,24 (ET ±6,16)
(Sharma et coll., 2020) *Prépublication*	Cohorte rétrospective	-Cas hospitalisés (n=234) en Inde -Du 20 mars au 30 avril 2020	RT-PCR	<u>Écouvillons nasopharyngés</u> -La durée moyenne de détectabilité de l'ARN viral était de 10,2 jours (ET 6,4). -La durée était significativement plus faible dans les cas de

				moins de 40 ans comparés à ceux de 40 à 59 ans et à ceux de plus de 60 ans : 9,1 jours (ET 5,2) contre 11,3 jours (ET 6,1) contre 16,4 jours (ET 13,3), p=0,001.
(G. Wu et coll., 2020) *Prépublication*	Cohorte rétrospective	-Patients confirmés hospitalisés en Chine -Du 23 janvier au 8 mars 2020	RT-PCR	Écouvillon des voies respiratoires supérieures -Le temps moyen d'excrétion de l'ARN viral entre l'apparition des symptômes et le premier résultat négatif chez les patients courants (n=93) était de 15,1 jours (ET ±7,23). -Les patients sévères (n=41) ont eu une période d'excrétion statistiquement plus longue (p=0,00) de 20,56 jours (ET ±6,59). Écouvillon des voies respiratoires inférieures -La durée moyenne de l'excrétion virale était de 27,45 jours (ET ±10,06) pour les patients ordinaires et de 29,78 jours (ET ±10,11) pour les patients graves. Il n'y avait pas de différence statistique entre les groupes (p=0,328). Écouvillon fécal -Dans le tube digestif, la durée moyenne de l'excrétion virale était de 22,6 jours (ET ±7,69) pour les patients ordinaires et de 27,24 jours (ET ±7,86) pour les patients graves, ce qui était statistiquement plus long (P = 0,01).
(F. Xing et coll., 2020) *Prépublication*	Cohorte rétrospective	-Patients hospitalisés (n=229) en Chine -De janvier à mars 2020	RT-PCR	Écouvillon nasopharyngé -Le délai entre le diagnostic et le premier test négatif chez les patients ordinaires était de 25,5 jours (ET ±11,3) et de 37,1 (ET ±14,4) chez les patients graves. Cela était statistiquement significatif (p < 0,001).
(Zeng et coll., 2020)	Cohorte rétrospective	-Patients hospitalisés pour la COVID-19 (n=149) en Chine -Du 20 janvier au 26 mars 2020	RT-PCR	Écouvillons pharyngés -La durée médiane entre le début de la maladie et le deuxième test négatif d'ARN du SRAS-Cov-2 était de 20 jours (IQR de 16 à 24). -Les patients admis à l'unité de soins intensifs avaient une période d'excrétion virale plus longue à partir du début de la maladie que les patients non hospitalisés : 30 jours (IQR de 22 à 33) contre 19 jours (IQR de 15,8 à 22), p < 0,0001.

(Fu et coll., 2020) *Prépublication*	Cohorte rétrospective	-Patients adultes hospitalisés pour la COVID-19 (n=3129) en Chine -Du 18 janvier au 31 mars 2020	RT-PCR	Écouvillon pharyngé ou écouvillon nasopharyngé -La durée d'excrétion de l'ARN viral chez les patients gravement malades était nettement plus longue que chez les patients non gravement malades : 24,0 jours (de 18,9 à 29,1, IC de 95 %) contre 18,0 jours (de 16,8 à 19,1, IC de 95 %). -Les patients non gravement malades (n=330) ont eu une excrétion virale persistante au-delà de 30 jours après l'apparition du virus. -Un titre d'anticorps IgM/IgG plus faible dans les 4 semaines suivant le début de la maladie peut être un facteur de risque d'infection persistante.
(P. H. Lee et coll., 2020)	Cohorte rétrospective	-Patients hospitalisés (n=201) à Singapour -Du 22 janvier au 5 avril 2020	RT-PCR	Écouvillons respiratoires -La durée de l'excrétion virale n'a pas été associée de manière significative au sexe, à l'âge, à la présence de comorbidités, aux investigations de base, à une fièvre prolongée, à une pneumonie, au besoin d'oxygène supplémentaire ou à l'utilisation d'agents antiviraux expérimentaux. -La durée médiane de l'excrétion de l'ARN viral était nettement plus longue chez les patients nécessitant une ventilation mécanique invasive. -La durée de l'excrétion de l'ARN viral était inversement corrélée aux niveaux plasmatiques des cytokines IL-1 β et l'IL-17A des cellules T à la phase initiale de l'infection.
(Talmy et coll., 2020)	Cohorte rétrospective	-Soldats des Forces de défense israéliennes souffrant légèrement du COVID-19 (n=219) en Israël -Du 20 mars au 5 mai 2020	RT-PCR	Écouvillons oropharyngés et nasopharyngés -La durée médiane de l'ARN viral à partir de l'apparition des symptômes dans ce groupe d'adultes jeunes et en bonne santé était de 21 jours (fourchette de 4 à 45, IQR de 15 à 27).
(Corsini Campioli et	Cohorte rétrospective	-Cas hospitalisés (n=251) aux États-Unis	RT-PCR	Écouvillons nasopharyngés -La durée médiane entre l'apparition des symptômes et le

coll., 2020)		-Du 1er février au 15 mai 2020		résultat négatif au test RT-PCR était de 23 jours, et ne différait pas selon les symptômes.
(T. Y. Yang et coll., 2020)	Cohorte rétrospective	-Cas hospitalisés (n=50) en Chine -Du 2 au 13 février 2020	RT-PCR	Écouvillons nasopharyngés -La durée de l'excrétion virale était significativement plus longue dans les cas présentant des symptômes gastro-intestinaux que dans les cas présentant des symptômes pulmonaires (10,22 jours ±1,93 contre 8,15 jours ±1,87, P < 0,01).
(Jeewandara et coll., 2020) *Prépublication*	Cohorte rétrospective	-Patients graves (n=6), modérés (n=5) et légers/asymptomatiques (n=13) ainsi que ceux qui étaient légèrement malades, mais avait une excrétion prolongée du virus (n=21), au Sri Lanka -Avril 2020	RT-PCR	Écouvillons respiratoires -La durée médiane de l'excrétion du virus dans l'ensemble de cette cohorte était de 25 jours (IQR de 15 à 38) -Dix personnes ont eu des excrétions du virus pendant plus de 50 jours. -Ceux qui avaient une excrétion prolongée du virus avaient des anticorps neutralisants apparaissant plus rapidement et à des niveaux plus élevés que ceux qui avaient éliminé le virus plus tôt.
(Jiang et coll., 2020)	Cohorte rétrospective	-Patients hospitalisés avec lésions hépatiques (n=76) et sans lésions hépatiques (n=55) en Chine -Du 19 janvier au 20 février 2020	RT-PCR	Type de prélèvements non rapporté -Les lésions hépatiques ont été liées à l'augmentation de la durée de l'excrétion virale (différence moyenne : 3,0, IC de 95 % : de 1,0 à 4,9).
(Carmo et coll., 2020)	Cohorte rétrospective	-Patients (n=210) au Portugal -Du 1er mars au 30 avril 2020	RT-PCR	Écouvillons nasopharyngés et oropharyngés -Dans le groupe de patients ayant subi deux tests négatifs consécutifs, le premier test RT-PCR négatif a été réalisé en moyenne 24,8 jours (fourchette de 7 à 46) après le premier test positif. -Chez les hommes, le premier test négatif a pris 24 jours (fourchette de 7 à 46) et chez les femmes, 25 jours (fourchette

				de 9 à 44), p>0,05. -69 patients ont été renvoyés chez eux et ont été légèrement malades. Les patients légèrement malades ont conservé l'ARN viral pendant une période plus longue. 47 étaient des patients hospitalisés modérément à gravement malades. Chez les patients renvoyés chez eux, le nombre de jours avant le premier test négatif était de 26,3 jours (ET ±8,5) et dans le groupe de patients hospitalisés, il était de 22,5 jours (ET ±9,3), p=0,027. -Les patients hospitalisés âgés de plus de 65 ans ont mis plus de temps (23,9 jours (±9,7)) que ceux de moins de 65 ans (18,3 (ET ±9,7)), pour obtenir le premier test négatif, p=0,026.
(D. Shi et coll., 2020) *Prépublication*	Cohorte rétrospective	-Patients hospitalisés dont la COVID-19 (n=246) a été confirmée en laboratoire en Chine -Du 27 janvier au 24 mars 2020	RT-PCR	Écouvillon nasopharyngé ou pharyngé -La durée de l'excrétion virale a été définie comme la durée entre le début de la maladie et la date du premier résultat négatif de l'excrétion virale. -La durée médiane de l'excrétion virale était de 24 jours (fourchette de 6 à 63). -Le récepteur soluble interleukine-2 (>710 U/mL), la lactate déshydrogénase (>250 U/L) et la COVID-19 grave ont été liés à la prolongation de l'excrétion virale, p < 0,05.
(Qingxian et coll., 2020) *Prépublication*	Cohorte rétrospective	-Cas ventilés par indice de masse corporelle en Chine -Du 11 janvier au 16 février 2020	RT-PCR	Écouvillon nasal -La durée médiane entre l'apparition des symptômes et la clairance du virus n'était pas significativement différente (p=0,14) entre les différents indices de masse corporelle : Normal : 14 jours (IQR de 9 à 18), poids insuffisant : 14,5 (IQR de 10 à 21), poids excessif : 15 (IQR de 10 à 22), obèse : 14 (IQR de 9 à 20).
(Moriconi et coll., 2020)	Cohorte rétrospective	-Cas hospitalisés (n=100) en Italie -Du 16 mars au 15 avril 2020	RT-PCR	Écouvillons pharyngés et nasaux -Les patients obèses ont pris plus de temps pour obtenir un écouvillon oropharyngé ou nasal négatif (19 ±8 contre 13 ±7, jours, p = 0,002).

(Xiao, Fu et Yang, 2020) *Prépublication*	Cohorte rétrospective	-Patients avec hypertension (n=24) et sans hypertension (n=24) atteints d'une COVID-19 non grave en Chine -Du 23 janvier au 15 février 2020	RT-PCR	Écouvillons nasopharyngés -La période moyenne entre l'apparition des symptômes et la conversion négative était de 17 jours (ET 5,5) et 15 jours (ET 3,6) pour les patients avec et sans hypertension (p=0,021).
(C. Cao et coll., 2020)	Cohorte rétrospective	-Patients (n=157), 63 (40,1 %) présentant des symptômes gastro-intestinaux en Chine -Chronologie non communiquée	RT-PCR	Écouvillons nasopharyngés -Il n'y a pas eu de différence significative dans la durée moyenne d'excrétion virale entre les patients avec et sans symptômes gastro-intestinaux (GI). -Total : 12,4 jours (ET 6,4) contre avec symptômes GI : 13,0 jours (ET 6,1) contre sans symptômes GI : 12,0 jours (ET 6,7), p=0,3509.
(H. Wang et coll., 2020)	Cohorte rétrospective	-Patients hospitalisés (n=95) en Chine -Du 15 janvier au 2 mars 2020	RT-PCR	Écouvillons pharyngés -Cette étude suggère que la NCD4LR est un biomarqueur potentiel et utile pour prédire le temps de conversion négative du virus chez les patients atteints de la COVID-19. -Le temps de conversion négative médian (intervalle entre l'apparition des symptômes et le premier de deux tests viraux négatifs consécutifs) chez tous les patients était de 19 jours (IQR de 11 à 27). -Les patients présentant un ratio neutrophiles/lymphocytes CD4+ élevé ont montré un temps de conversion négative relativement plus long que les patients présentant un ratio neutrophiles/lymphocytes CD4+ plus faible : 24 jours (IQR de 18 à 33) contre 13 jours (IQR de 9 à 21) (p < 0,001).
(J. Han et coll., 2020)	Cohorte rétrospective	-Cas hospitalisés (n=185) en Chine -Du 21 janvier au 8 mai 2020	RT-PCR	Écouvillons respiratoires -La durée médiane d'excrétion de l'ARN viral était de 17 jours à partir du début de la maladie; la durée la plus longue était de 51 jours, et la plus courte de 4 jours.

(G. Zheng et coll., 2020)	Cohorte rétrospective	-Cas pédiatriques (n=52) en Chine -Chronologie non communiquée	RT-PCR	Écouvillons oropharyngés -Le délai entre l'admission et le premier test RT-PCR négatif était de 12 jours (IQR de 8,0 à 16,8).
(Woodruff et coll., 2020)	Cohorte rétrospective	-Les 100 premiers patients du registre de cas COVID positifs de la clinique Mayo, en Floride, aux États-Unis -Date de fin : 15 mai 2020	RT-PCR	Écouvillons nasopharyngés -Le délai moyen d'apparition des symptômes pour un ARN viral indétectable était de 21,5 jours. -Sur la base de ces données, les auteurs suggèrent d'être plus prudent dans les lignes directives pour l'isolement.
(J. Xu et coll., 2020)	Cohorte rétrospective	-Patients adultes gravement malades (n=239) en Chine -Du 12 janvier au 3 février 2020	RT-PCR	Échantillons respiratoires et de sérum -La durée médiane de la conversion négative de l'ARN du SRAS-CoV-2 était de 30 (fourchette de 6 à 81) jours chez les 49 survivants gravement malades qui ont été identifiés.
(Nakamura et coll., 2020) *Prépublication*	Cohorte rétrospective	-Patients ayant des antécédents de cancer (n=32) au Japon -Du 31 janvier au 25 mai 2020	RT-PCR	Écouvillon nasopharyngé - La période médiane entre le début de la maladie et le premier résultat négatif de la PCR de l'ARN du SRAS-CoV-2 était de 22 jours (IQR de 18 à 25) chez les survivants. -L'excrétion virale a été détectée dans un cas jusqu'à 56 jours après le début de l'infection.
(Infante et coll., 2020)	Cohorte rétrospective	-Patients atteints de malignités hématologiques (n=26) en Espagne -Du 8 mars au 8 avril 2020	RT-PCR	Écouvillon nasal -La durée médiane de l'excrétion virale était de 32,7 jours (fourchette de 10 à 70).
(Berghoff et coll., 2020)	Cohorte rétrospective	-Patients atteints d'un cancer (n=4) en Autriche -Du 21 mars au 4 mai 2020	RT-PCR	Écouvillon nasal -La clairance virale a été obtenue chez trois des quatre patients de 14 à 56 jours après le test positif.

(J. Shi et coll., 2020)	Cohorte rétrospective	-Cas hospitalisés (n=99) en Chine -Du 19 janvier au 17 février 2020	RT-PCR	Échantillons respiratoires et de selles -Un patient a été testé négatif pour le SRAS-CoV-2 dans les 5 jours, 9 patients ont été testés négatifs dans les 10 jours, et 49 ont été testés négatifs dans les 20 jours après l'apparition des symptômes. Un sous-ensemble de 12 patients présentait des niveaux détectables du virus jusqu'à 30 jours après l'apparition des symptômes. -Le temps d'excrétion était significativement augmenté si les résultats du test ARN fécal du SRAS-CoV-2 étaient positifs. Le sexe masculin, l'utilisation d'immunoglobulines, le score APACHE II et le nombre de lymphocytes étaient des facteurs indépendants associés à une durée prolongée de l'excrétion du SRAS-CoV-2.
(Ling et coll., 2020)	Cohorte rétrospective	-66 patients rétablis après un traitement (patients convalescents) en Chine -Du 20 janvier au 10 février 2020	RT-PCR	Écouvillon oropharyngé -La durée médiane entre l'apparition des symptômes et les premiers résultats négatifs de la RT-PCR était de 9,5 jours (IQR de 6,0 à 11,0). Écouvillon fécal -Les échantillons de selles avaient des tests d'ARN du SRAS-CoV-2 négatifs après une durée médiane de 11,0 jours (IQR de 9,0 à 16,0) après l'apparition des symptômes. -43 (65 %) patients ont eu une durée d'ARN viral plus longue dans les écouvillons de selles que dans les écouvillons pharingés, avec un délai médian de 2,0 jours (IQR de 1,0 à 4,0). Écouvillon d'urine -Les résultats de seulement 4 (6,9 %) échantillons d'urine testés à l'acide nucléique viral étaient positifs sur 58 cas. -L'ARN viral était toujours présent dans les échantillons d'urine de 3 patients après des tests négatifs des écouvillons pharingés. Les patients sous traitement glucocorticoïde ont eu une clairance virale retardée par rapport à ceux qui n'en avaient pas.
(Hua et coll.,	Cohorte	-Enfants hospitalisés	RT-PCR	Écouvillon fécal

2020)	rétrospective	(n=35) en Chine -Jusqu'au 20 avril 2020		-La détection fécale de l'ARN du SRAS-CoV-2était positive dans 91,4 % (32 sur 35) des cas et certains enfants avaient une durée d'excrétion virale supérieure à 70 jours. -Le temps de clairance virale n'était pas différent entre les groupes traités avec différents régiments d'antiviraux.
(J. Huang et coll., 2020) *Prépublication*	Cohorte rétrospective	-Patients hospitalisés (n=33) en Chine -Du 27 janvier au 10 avril 2020	RT-PCR	Écouvillons pharyngés, d'expectorations et de selles -La durée médiane entre l'apparition des symptômes et l'ARN viral indétectable dans les écouvillons pharyngés, les expectorations et les prélèvements de selles était respectivement de 18,5 jours (IQR de 13,25 à 22), 22 jours (IQR de 18,5 à 27,5) et 17 jours (IQR de 11,5 à 32). -Par rapport aux écouvillons pharyngés, les charges virales dans les expectorations et les selles ont diminué beaucoup plus lentement ($p < 0,05$). -3 patients ont montré une récurrence détectable de l'ARN viral dans les expectorations lors d'un test effectué 2 semaines après leur sortie de l'hôpital.
(P. Liu et coll., 2020)	Cohorte rétrospective	-Cas de COVID-19 pédiatriques hospitalisés (n=9) en Chine -Du 19 janvier au 10 avril 2020	RT-PCR	Écouvillons nasopharyngés -La durée médiane de l'excrétion de l'ARN viral entre le jour de l'apparition de la maladie et le dernier résultat positif était de 13 jours (fourchette de 6 à 24). Écouvillons oropharyngés -3 des 9 patients ont eu des écouvillons oropharyngés qui ont eu des tests positifs à l'ARN du SRAS-CoV2 pendant une durée médiane de 4 jours (fourchette de 3 à 10). Écouvillons de selles -8 patients ont présenté une excrétion de SRAS-CoV-2 dans leurs selles pendant une durée médiane de 43 jours (fourchette de 28 à 66). Tous ont eu une excrétion virale persistante dans leurs selles après leur sortie de l'hôpital, avec une durée médiane entre le jour de la sortie et le jour de la dernière selle positive collectée au suivi de 22,5 jours (fourchette de 4 à 46). -L'ARN du SRAS-CoV-2 n'a pas été détecté dans les

				échantillons de sérum ou d'urine.
(N. Zhang et coll., 2020)	Cohorte rétrospective	-Patients hospitalisés (n=23) en Chine -Du 20 janvier au 23 février 2020	RT-PCR	Écouvillons des voies respiratoires supérieures et des selles -Une période d'excrétion du virus plus longue a été constatée dans les échantillons fécaux par rapport aux échantillons des voies respiratoires supérieures (22 jours contre 10 jours), bien que les ARN viraux des échantillons des voies respiratoires supérieures aient été généralement détectables plus tôt. -Les titres viraux des écouvillons respiratoires ont atteint leur maximum 6 à 9 jours après l'apparition des symptômes et 14 à 18 jours pour les échantillons de selles. -Chez un patient gravement malade, tous les échantillons étaient négatifs jusqu'à 21 jours après l'apparition des symptômes, lorsque l'échantillon fécal a alors été testé positif.
(Lyu et coll., 2020)	Cohorte rétrospective	-Patients sortis de l'hôpital (n=6) en Chine -Du 23 janvier au 9 mars 2020	RT-PCR	Écouvillons de gorge, d'expectorations et de selles -Les échantillons de selles ont été testés positifs chez 6 patients sortis de l'hôpital, avec des écouvillons de gorge et d'expectorations testés négatifs. -Les échantillons de selles ont été positifs jusqu'à 52 jours après l'apparition des symptômes.
(Gombar et coll., 2020)	Cohorte rétrospective	-Patients (n=87) et personnel de santé (n=63) atteints de la COVID-19 à Stanford, Californie, États-Unis -Du 3 mars au 30 avril 2020	RT-PCR	Écouvillons respiratoires -Pour les patients, la durée médiane entre le premier test RT-PCR positif et le premier test négatif était de 25 jours. Il n'y avait pas de différence démontrable avec les travailleurs de la santé qui avaient une durée médiane de 23 jours.
(Rivera-Izquierdo et coll., 2020)	Série de cas	-Professionnels de la santé symptomatiques (n=76) en Espagne -Du 11 mars au 13 avril 2020	RT-PCR	Type de prélèvements non rapporté -La durée médiane entre le début des symptômes et la PCR négative était de 31 jours. -La durée de l'excrétion virale était plus longue chez les femmes que chez les hommes (33 contre 21 jours, p=0,025) et les cas âgés de 55 ans et plus par rapport à ceux de moins de

				55 ans (33 c. 28 jours, p = 0,207).
(Warabi et coll., 2020)	Série de cas	-Cas hospitalisés (n=2) au Japon Du 30 avril au 14 mai 2020	RT-PCR	Écouvillons nasopharyngés -Le temps moyen entre l'apparition des symptômes et le moment où le virus n'est plus détectable était de 31,6 jours (fourchette de 17 à 53, ET 11,8). - Chez deux patients souffrant de retard mental et de troubles psychiatriques, la période d'excrétion virale s'est poursuivie pendant 44 jours et 53 jours, respectivement. Ces deux patients ne se sont pas brossé les dents volontairement. -Les auteurs proposent que le brossage des dents et les gargarismes éliminent l'acide nucléique viral et améliorent la précision des tests PCR.
(B. E. Young et coll., 2020b)	Série de cas	-Les 18 premiers patients diagnostiqués comme atteints du SRAS-CoV-2 à Singapour -Du 23 janvier au 3 février 2020	RT-PCR	Écouvillons nasopharyngés -L'excrétion virale a été prolongée de 7 jours ou plus chez 15 cas (83 %). -La durée médiane de l'excrétion virale du premier au dernier écouvillon nasopharyngé positif prélevé était de 12 jours (fourchette de 1 à 24), avec des charges virales décroissantes au fil du temps. - Le virus était également détectable dans les selles (4 sur 8) et le sang (1 sur 12) par PCR, mais pas dans l'urine.
(L. Zou et coll., 2020)	Série de cas	-Patients symptomatiques (n=17) en Chine -Du 7 au 26 janvier 2020	RT-PCR	Écouvillons nasaux et pharyngés -Des charges virales plus élevées (inversement par rapport à la valeur Ct) ont été détectées peu après l'apparition des symptômes, les charges virales étant plus élevées dans le nez que dans la gorge.
(Tepasse et coll., 2020)	Série de cas	-Hommes de 65 et 66 ans en Allemagne -Chronologie non communiquée	RT-PCR	Écouvillons pharyngés -Les niveaux de virus ont eu tendance à augmenter encore au cours de l'évolution de la maladie et il n'y a eu aucune indication de clairance du virus. -La virémie a atteint un pic peu avant la mort des deux patients; en outre, il n'y avait aucun signe de clairance virale à

				22 et 30 jours après l'apparition des premiers symptômes ou plutôt 22 et 26 jours après la première détection de l'ARN du SRAS-CoV-2 dans les écouvillons pharyngés.
(Wongsawat et coll., 2020)	Série de cas	-Trois cas pédiatriques en Chine -Chronologie non communiquée	RT-PCR	Écouvillons nasopharyngés et pharyngés -Les tests RT-PCR de détection de l'ARN viral se sont révélés négatifs aux jours 15, 23 et 27 de la maladie pour chaque enfant, respectivement.
(Navaneethan et LehnerNoguera, 2020)	Rapport de cas	-Femme de 43 ans ayant des antécédents médicaux de maladie de Crohn, Floride, États-Unis -Chronologie non communiquée	RT-PCR	Écouvillon nasopharyngé -Le cas a été soumis à un nouveau test RT-PCR pour détecter le SARS-CoV-2 par écouvillonnage nasopharyngé à deux reprises et s'est finalement révélé négatif, 22 jours après la présentation initiale.
(Ru et coll., 2020) *Prépublication*	Série de cas	-Cas confirmés (n=4) en Chine -Du 17 janvier au 27 avril 2020	RT-PCR	Prélèvements nasopharyngés, sanguins et de selles -La durée moyenne d'excrétion de l'ARN était de 36,5 jours, un cas ayant une excrétion allant jusqu'à 68 jours après l'apparition des symptômes. -Une clairance virale a été observée ainsi qu'un niveau élevé d'anticorps neutralisants dans trois cas. -Dans le cas de l'excrétion virale prolongée, les auteurs suggèrent que l'anticorps neutralisant n'était pas assez élevé pour éliminer complètement le virus.
(Benotmane et coll., 2020) *Prépublication*	Série de cas	-Receveurs de greffes de rein hospitalisés avec une COVID-19 non grave (n = 21) et grave (n =19) en France -Du 4 mars au 7 avril 2020	RT-PCR	Écouvillons nasopharyngés et échantillons de plasma -Dix receveurs (25 %) ont présenté une excrétion virale persistante 30 jours après l'apparition des symptômes.
(Tajima et coll., 2020)	Rapport de cas	-Un homme de 71 ans au Japon	RT-PCR	Écouvillons nasopharyngés -Bien qu'il soit devenu asymptomatique après avoir présenté

		-Du 5 février au 20 mars 2020		quelques symptômes légers de COVID-19, l'ARN du SRAS-CoV-2 a été détecté dans des échantillons de salive pendant 37 jours après l'apparition des symptômes.
(De Vriese et Reynders, 2020)	Série de cas	-Patients sous hémodialyse (n=7) en Belgique -Du 14 mars au 7 avril 2020	RT-PCR	Écouvillon nasopharyngé - Chez quatre survivants, la durée de conversion de l'acide nucléique, défini comme l'intervalle entre l'apparition des symptômes et le premier résultat négatif de RT-PCR, était de 34, 37, 37 et 44 jours. -Les valeurs seuils du cycle (une mesure inverse de la concentration en acides nucléiques) étaient les plus faibles au cours de la première semaine d'infection et sont restées relativement stables par la suite.
(Zhou et coll., 2020)	Série de cas	-Patients hématologiques concomitants à la COVID-19 (n=9) en Chine -Du 1er février au 31 mars 2020	RT-PCR	Écouvillons pharyngés -La charge virale positive chez 4 survivants a duré plus de 45 jours.
(Dong et coll., 2020)	Série de cas	-Patients hospitalisés avec des données complètes sur les sous-ensembles de lymphocytes du sang périphérique (n=18) en Chine -Du 30 janvier au 21 février 2020	RT-PCR	Échantillons respiratoires et de selles -Les cas d'excrétion d'ARN viral ≥ 15 jours ont connu une diminution significative des lymphocytes, des cellules T et de leurs sous-ensembles par rapport à ceux qui sont restés positifs pendant moins de 15 jours.
(Cai et coll., 2020)	Série de cas	-Cas pédiatriques (n=10) en Chine -Du 19 janvier au 3 février 2020	RT-PCR	Écouvillons nasopharyngés/pharyngés -Les résultats des dix patients étaient disponibles. La période infectieuse médiane entre l'apparition des symptômes et la clairance du virus était de 12 jours (fourchette de 6 à 22, IQR de

				8 à 15). Écouvillon fécal -Les écouvillons fécaux de 10 patients ont montré une période infectieuse médiane de 24 jours (de 18 à 30) entre l'apparition des symptômes et la clairance virale.
(Z. Chen et coll., 2020)	Série de cas	-Enfants hospitalisés (n=32) en Chine -Du 15 janvier au 15 mars 2020	RT-PCR	Échantillons respiratoires et fécaux -Les durées moyennes de l'ARN viral dans les échantillons respiratoires et gastro-intestinaux étaient de 15,8 jours (n=25) et 28,9 jours (n=16), respectivement. -La durée de l'excrétion de l'ARN viral dans les selles diminue considérablement avec l'âge : 39,8 jours, 27,5 jours et 20,4 jours chez les nourrissons et les enfants d'âge préscolaire, les écoliers et les adolescents respectivement.
(Park et coll., 2020)	Série de cas	-Patients hospitalisés (n=6) en Corée du Sud -Du 14 février au 26 mars 2020	RT-PCR	Écouvillons nasopharyngés/oropharyngés -Six patients ont été analysés. -La durée médiane de détection du virus du SRAS-CoV-2 après l'hospitalisation était de 34 jours (fourchette de 22 à 67). -Après résolution des symptômes/signaux, l'ARN du SRAS-CoV-2 a été détecté pendant une période médiane de 26 jours (fourchette de 9 à 48). -L'ARN a été détecté de manière persistante chez un patient jusqu'au 67^{e} jour d'hospitalisation, soit 30 jours après la disparition des symptômes. -Il s'agit de la plus longue durée de détection du SRAS-CoV-2 dans les voies respiratoires signalée à ce jour.
(J. Li et coll., 2020)	Rapport de cas	-Femme de 71 ans en Chine -Du 27 janvier au 22 avril 2020	RT-PCR	Écouvillon oropharyngé -Une femme de 71 ans a eu une excrétion virale de l'ARN du SRAS-CoV-2 pendant 60 jours après l'apparition des symptômes. -L'excrétion virale s'est poursuivie 24 jours après la disparition complète des symptômes.
(M. C. Yang et	Série de cas	-Une grappe familiale	RT-PCR	Écouvillons pharyngés

coll., 2020)		de trois générations avec 6 personnes infectées à Taïwan -Du 9 février au 6 avril 2020		-Dans cette grappe, le plus long temps de conversion de l'ARN du frottis de gorge pour le SRAS-CoV-2 était de 37 jours, et l'évolution estimée de la maladie, des symptômes au frottis de gorge négatif, était de 59 jours.
(Y. Hu et coll., 2020)	Rapport de cas	-Un homme de 70 ans en Chine -Chronologie non communiquée	RT-PCR	Écouvillons nasopharyngés et oculaires - Rapport d'un cas de la détection positive du SRAS-CoV-2 associé au virus herpès simplex de type 1 et à l'acide nucléique du virus herpès humain de type 6B dans les sécrétions lacrymales et conjonctivales d'un patient atteint de COVID-19 sans conjonctivite avec obstruction des canaux lacrymaux communs. -Les écouvillons nasopharyngés ont été positifs pendant 22 jours, mais les écouvillons oculaires sont restés positifs en continu pendant 2 semaines après que les écouvillons nasopharyngés soient devenus négatifs.
(Q. Shen et coll., 2020)	Série de cas	-Neuf patients pédiatriques (7 légers et 2 asymptomatiques) en Chine -Du 8 janvier au 19 février 2020	RT-PCR	Type de prélèvements non rapporté -6 enfants ont eu une exposition familiale et ont pu fournir les dates exactes de contact étroit avec une personne dont l'infection du COVID-19 a été confirmée.
Études épidémiologiques				
(X. He et coll., 2020)	Étude sur la recherche des contacts	-77 paires infecteur-infecté en Chine -Du 18 décembre 2019 au 5 mars 2020	Données épid.	-La dynamique virale rapportée par les auteurs (en supposant une période d'incubation de 5,2 jours en moyenne) suggère une période infectieuse qui commence 12,3 jours avant les symptômes et qui décline rapidement dans les 7 jours suivant l'apparition. -Les auteurs en ont déduit que l'infectiosité atteignait son maximum au moment de l'apparition des symptômes ou avant.
(You et coll., 2020)	Étude sur la recherche des	-169 cas en Chine -Date de fin : 31 mars	Données épid.	-Au total, 198 chaînes de transmission ainsi que les dates d'apparition des symptômes et 139 dates d'infection ont été

	contacts et modèle SIR	2020		identifiées parmi 14 829 cas confirmés. -Au total, 169 cas parmi les données collectées ont permis d'identifier les dates d'infection. -La période infectieuse a duré en moyenne 13,96 jours (ET 5,20).
(Cheng et coll., 2020)	Étude de recherche de contacts	-Cas de COVID-19 confirmés (n=100) et 2761 contacts étroits à Taiwan -Du 15 janvier au 2 avril 2020	Données épid.	-Le taux global d'attaque clinique secondaire était de 0,7 %, le taux d'attaque étant plus élevé chez les contacts dont l'exposition au cas index a commencé dans les 5 jours suivant l'apparition des symptômes que chez ceux qui ont été exposés plus tard.
Études de modélisation				
(Lin et coll., 2020)	Revue systématique des modèles dynamiques de transmission	-Cinquante-deux articles portant sur 75 modèles mathématiques ou statistiques de Chine -Du 1er décembre 2019 au 21 février 2020	Modélisé	-La période infectieuse médiane était de 9,94 jours (IQR de 3,93 à 13,50).
(Tang et coll., 2020) *Prépublication*	Modèle SEAIR	-Cumul des cas d'infection par la COVID-19 signalés en Ontario, Canada -Du 26 février au 21 avril 2020	Modélisé	-L'estimation du paramètre du taux de guérison des personnes infectées symptomatiques était de 0,1957 (ET 0,0111). -En prenant l'inverse de cette estimation, on peut déduire une période infectieuse de 5,11 jours (ET 0,31).
(Lourenco et coll., 2020) *Prépublication*	Modèle SIR	-Cas de décès au Royaume-Uni -Du 27 janvier au 16 mars 2020	Modélisé	-Étalonnage d'un modèle susceptible-infecté-rétabli (SIR) aux données sur les décès cumulés associés au SRAS-CoV-2 signalés au Royaume-Uni (UK). -La période infectieuse médiane est estimée à 3 à 5 jours (estimation postérieure du modèle).
(R. Li et coll., 2020) *Prépublication*	Modèle mathématique	-Cas documentés en Chine -Du 10 au 23 janvier	Modélisé	-Application du cadre d'interférence modèle à l'éclosion observée avant les restrictions de voyage imposées le 23 janvier 2020 – Un total de 801 cas documentés dans toute la

		2020		Chine. -La période infectieuse médiane est estimée à 3,47 jours (estimation postérieure du modèle pour les cas documentés).
(Zhu, 2020) *Prépublication*	Modèle SEIR	-Cas confirmés en Chine -Date de fin : 15 avril 2020	Modélisé	-La période infectieuse moyenne est estimée à 12,53 jours (ET±11,4). -Le paramètre a été estimé à l'aide d'une distribution de Weibull.
(Wan et coll., 2020)	Modèle SEIR	-Éclosion de Wuhan en Chine -Du 22 janvier au 12 février 2020	Modélisé	-A analysé la dynamique et la tendance de l'épidémie de nCoV-2019 à Wuhan à partir de données recueillies sur le site officiel du Comité de santé de la province d'Hubei. -Les données ont montré que la période infectieuse de la personne infectée (I) est de 14 jours.
(Peirlinck, Linka, Sahli Costabal et Kuhl, 2020)	Réseau mondial intégré et modèle SEIR	-Épidémie en Chine -Du 21 janvier au 4 avril 2020	Modélisé	-Une période infectieuse moyenne de 17,82 ±2,95 jours a été estimée à partir d'un modèle utilisant les données de cas de 30 provinces en Chine.
(Goyal et coll., 2020) *Prépublication*	Modèle mathématique	-Cas confirmés. Lieu non précisé -Chronologie non communiquée	Modélisé	-Les personnes atteintes du SRAS-CoV-2 sont généralement contagieuses pendant moins de deux jours en accord avec la charge virale maximale plusieurs jours après l'infection et cette transmission est peu probable en dessous d'une certaine charge virale.
Revues				
(Walsh et coll., 2020)	Revue systématique	-Aucune restriction sur le cadre -Études publiées entre le 30 décembre et le 12 mai 2020	Culture et RT-PCR	- Il a été conclu qu'il qu'il existe une trajectoire relativement cohérente de la charge virale du SRAS-CoV-2 durant la COVID-19 à partir d'échantillons des voies respiratoires, mais la durée de l'infectiosité reste incertaine.
(Byrne et coll., 2020) *Prépublication*	Revue de la portée et méta-analyse	-Aucune restriction sur le cadre -Études publiées entre le 1er décembre et le 1er avril 2020.	RT-PCR	-Une méta-analyse de 15 estimations a montré que la durée moyenne entre l'apparition des symptômes et 2 tests RT-PCR négatifs était de 13,4 jours (IC de 95 % : de 10,9 à 15,8), mais elle était plus courte lorsque les études portaient sur des enfants ou des cas moins graves (environ 5,8 jours de moins). -La durée maximale de détection est d'environ 20 à 49 jours, la

				durée la plus longue étant associée aux échantillons de matières fécales. -Une approche de méta-régression a montré que les cas graves avaient tendance à présenter une excrétion d'ARN viral de plus longue durée (estimée à 4,0 jours de plus), mais l'effet n'était pas significatif.
(Cevik et coll., 2020) *Prépublication*	Revue systématique et méta-analyse	-Aucune restriction sur le cadre -Études publiées entre le 1er janvier 2003 et le 6 juin 2020	Culture et RT-PCR	<u>Écouvillons respiratoires</u> -La durée moyenne d'excrétion de l'ARN du SRAS-CoV-2 dans les voies respiratoires supérieures (VRS), les voies respiratoires inférieures (VRI), les selles et le sérum était respectivement de 17,0, 14,6, 17,2 et 16,6 jours. -La durée maximale de l'excrétion de l'ARN du SRAS-CoV-2 signalée dans les VRS, VRI, les selles et le sérum était de 83, 59, 35, 42 et 60 jours, respectivement. -La durée moyenne combinée de l'excrétion de l'ARN du SRAS-CoV-2 a été positivement associée à l'âge (p=0,002), mais pas au sexe (p = 0,277). -La charge virale dans les VRS a atteint son maximum la première semaine de la maladie. -Aucune étude à ce jour n'avait mis en culture un virus actif/vivant au-delà du neuvième jour de la maladie malgré des charges virales toujours élevées.
(Santos et coll., 2020)	Revue systématique et méta-analyse	-Aucune restriction sur le cadre -Basé sur des données compilées à partir de 36 cas pédiatriques provenant d'études publiées entre le 1er janvier et le 19 avril 2020	RT-PCR	-Les enfants ont été plus nombreux à présenter une excrétion virale dans les selles après 14 jours d'apparition des symptômes que dans les échantillons respiratoires (rapport de risque = 3,2, intervalle de confiance de 95 % de 1,2 à 8,9, I2 = 51 %). -L'excrétion de l'ARN viral était plus longue dans les échantillons fécaux, avec une différence moyenne d'environ 9 jours par rapport aux échantillons respiratoires.
(Jefferson et	Revue	-Aucune restriction sur	RT-PCR	-Les auteurs ont identifié huit études qui rendent compte de la

coll., 2020) *Prépublication*	systématique	le cadre -Études publiées jusqu'au 18 août 2020		durée de l'excrétion virale telle qu'elle est évaluée par PCR de l'ARN du SRAS-CoV-2. -La durée minimale de l'excrétion de l'ARN détectée par PCR était de sept jours et la durée maximale de l'excrétion était de 35 jours après l'apparition des symptômes. Six des huit études ont fait état d'une excrétion d'ARN de plus de 14 jours.
(C. L. H. Xu et coll., 2020)	Revue systématique	-Aucune restriction sur le cadre -Basée sur les données compilées à partir de 69 cas pédiatriques provenant d'études publiées jusqu'au 8 mai 2020	RT-PCR	-La durée d'excrétion de l'ARN viral par les voies respiratoires a atteint 24 jours à partir de l'apparition des symptômes, avec une moyenne de 11,1 ± 5,8 jours. -La durée moyenne de l'excrétion virale par le tractus gastro-intestinal était de 23,6 ± 8,8 jours après l'apparition des symptômes. -Dans 89 % des cas, l'excrétion virale dans le tractus gastro-intestinal a persisté jusqu'à 4 semaines après que les écouvillons nasopharyngés ou pharyngés sont devenus négatifs.
Études sur les animaux				
(Bartlett et coll., 2020) *Prépublication*	Série de cas	-Deux tigres malaisiens, deux tigres de l'Amour et trois lions dans le zoo du Bronx, États-Unis -Mars 2020	Culture et RT-PCR	<u>Écouvillons fécaux</u> -Le cas index a libéré de l'ARN viral pendant 14 jours, dont 5 jours après la cessation des signes cliniques. -En revanche, le tigre asymptomatique ne perd son ARN viral que pendant 5 jours. -Le tigre ayant la plus longue durée d'excrétion virale (24 jours) était asymptomatique pendant cette période. -L'excrétion fécale a également été prolongée chez deux lions persistant plus de 30 jours. -Le virus a été isolé à partir des excréments de deux animaux : 5 jours après l'arrêt des signes cliniques et le dernier jour des signes cliniques.
(Munster et coll., 2020)	Essai expérimental de provocation	-Macaques rhésus adultes inoculés avec le SRAS-CoV-2 aux États-	Culture et RT-PCR	<u>Écouvillon broncho-alvéolaire</u> -Le virus infectieux a été isolé à partir du liquide de lavage bronchoalvéolaire recueilli un et trois jours après l'infection

		Unis -S.O.		chez des macaques rhésus adultes. <u>Écouvillon pharyngé</u> -Les charges virales étaient élevées dans les écouvillons pharyngés après l'inoculation. Dans un cas, les écouvillons pharyngés d'un animal se sont révélés positifs 1 et 10 jours après l'infection, mais aucun des écouvillons effectués entre ces deux dates n'a été positif. <u>Écouvillon rectal</u> -Un animal a présenté une excrétion prolongée d'ARN viral dans des écouvillons rectaux de 7 à 17 jours après l'infection, mais le virus infectieux n'a pas pu être isolé à partir de ces écouvillons.
(Gaudreault et coll., 2020) *Prépublication*	Essai expérimental de provocation	-Chats mâles (n=10) aux États-Unis -S.O.	RT-PCR	<u>Écouvillons nasaux</u> -L'ARN du SRAS-CoV-2 a été détecté dans des écouvillons nasaux des principaux chats infectés entre le 1er et le 10e jour suivant la provocation, les quantités maximales étant observées entre le 1er et le 5e jour suivant la provocation

RÉCURRENCE DE L'EXCRÉTION VIRALE EN PÉRIODE DE CONVALESCENCE

Le tableau 4 énumère les études qui fournissent des éléments de preuve de la récurrence intermittente de la détection de l'ARN viral pendant la période de convalescence (asymptomatique ou post-symptomatique) de l'infection par la COVID-19. Des rapports de cas et des études de suivi ont fait état de la récurrence de la détection de l'ARN viral chez les patients durant leur quarantaine de rétablissement après leur sortie de l'hôpital, leur ré-hospitalisation et leur nouvelle sortie de l'hôpital/rétablissement. À ce jour, une seule étude a fourni des éléments de preuve d'excrétion virale pouvant être mise en culture lors de la récurrence de la détection d'ARN viral (Quicke et coll., 2020). Aucune preuve de transmission n'a été rapportée.

La majorité des patients sortis de l'hôpital et présentant une récurrence de la positivité de l'ARN au test RT-PCR l'ont fait dans les sept jours suivant les résultats négatifs consécutifs des tests. Après une récurrence, les patients sont restés positifs à l'ARN viral pendant environ 1 à 8 jours et sont restés généralement asymptomatiques (Chen et coll., 2020; Lan et coll., 2020; McGrath et coll., 2020; Quicke et coll., 2020; To et coll., 2020b; Wong et coll., 2020; Wu et coll., 2020;Yuan et coll., 2020).

Les facteurs de risque de récurrence de la positivité de l'ARN viral comprenaient un taux élevé de cholestérol des lipoprotéines de basse densité (C-LDL) à l'admission, le nombre de lobes pulmonaires présentant des lésions d'infiltration à l'imagerie, des anomalies de l'imagerie par tomodensitométrie, la toux productive et la congestion thoracique avec dyspnée en phase de convalescence (Jin et coll., 2020; Yan et coll., 2020).

Il n'est pas clair si cette récurrence dans les résultats des tests RT-PCR indique une excrétion intermittente et prolongée de l'ARN viral ou si une récurrence (la réplication du virus recommence) ou une réinfection (une nouvelle infection se produit) est possible pendant la phase de convalescence. Cependant, des études récentes utilisant des méthodes de culture ont montré que les nouvelles détections de l'ARN viral sont associées à des niveaux de virus infectieux nuls ou très faibles (Chang et coll., 2020; Kang, 2020; Korea CDC, 2020; J. Lu et coll., 2020; Quicke et coll., 2020).

Tableau 4 : Études évaluant la récurrence de l'excrétion virale pendant la période de convalescence de l'infection par la COVID-19 (N=55)

Référence	Type d'étude	-Population et environnement -Période de temps	Période infectieuse (PI) déterminée par : Culture, Tests RT-PCR en série, données épidémiologique ou modèle	Résultats pertinents
Études sur la culture et la RT-PCR				
(Corée CDC, 2020)	Cohorte prospective	-Cas positifs à nouveau (n=285) en Corée du Sud -Jusqu'au 15 mai 2020	Culture et RT-PCR	Type de prélèvements non indiqué -Une investigation épidémiologique et une investigation sur les contacts ont été menées à bien pour 285 des 447 cas positifs. -Aucun cas secondaire parmi les contacts n'a été signalé pour les cas positifs. -Les tests de culture de cellules virales effectués sur 108 cas positifs ont tous donné des résultats négatifs. -Les valeurs seuils de cycle dans la RT-PCR pendant la période de nouvelle positivité se sont avérées supérieures à 30 dans 89,5 % des cas.
(Chang et	Cohorte	-Patients sortis d'hôpital	Culture et RT-	Écouvillons pharyngés

coll., 2020)	prospective	(n=64) en Chine -Du 28 janvier au 30 avril 2020	PCR	-Dans le cadre du suivi régulier, les patients qui sont sortis d'hôpital ont été suivis chaque semaine pour obtenir leur écouvillon pharyngé. -Quatre des patients ont été à nouveau testés positifs. -Les écouvillons pharyngés ont été envoyés pour tester la présence d'un agent pathogène vivant. Les écouvillons ont été ensemencées sur des cellules Vero pour mesurer la cytopathie et la réplication virale en utilisant la qPCR des lysats cellulaires après l'infection. Ils n'ont détecté aucune cytopathie ou présence de réplication virale dans les cellules infectées. -Les données ont également montré que les patients avec une présence persistante d'ARN viral (>16 jours) avaient des conséquences plus graves.
(J. Lu et coll., 2020) *Prépublication*	Cohorte prospective	-Patients atteints de la COVID-19 (n=619) sortis d'hôpital en Chine -Du 23 janvier au 25 février 2020	Culture et RT-PCR	<u>Échantillons respiratoires</u> -87 sur 619 cas sortis d'hôpital ont un nouveau test RT-PCR positif. -Les cas ont été testés à nouveau comme étant positifs à l'ARN viral du SRAS-CoV-2 en moyenne 6,7 jours (fourchette de 3 à 10) après leur sortie de l'hôpital. -77 sur 87 cas positifs étaient asymptomatiques et dix cas présentaient une toux sèche. -Aucune souche virale infectieuse n'a pu être obtenue par culture et aucun génome viral complet n'a pu être séquencé pour les cas à nouveau positifs.
(Quicke et coll., 2020) *Prépublication*	Étude de surveillance longitudinale	-454 personnes asymptomatiques dans 5 centres de soins infirmiers qualifiés du Colorado, aux États-Unis (la prévalence varie considérablement d'un centre à l'autre) -Chronologie non	Culture (technique par plages) et RT-PCR	<u>Écouvillons nasopharyngés</u> -Six personnes ont eu des résultats positifs récurrents après une à deux semaines d'ARN viral indétectable. Après la redétection, l'ARN viral était détectable pendant une semaine au maximum. -Ces redétections d'ARN viral ont été associées à des niveaux de virus infectieux nuls ou très faibles.

		communiquée		
(Kang, 2020)	Revue documentaire	-Patients sortis de quarantaine (n=8 922) en Corée du Sud -Du 1er au 29 avril 2020	Culture et RT-PCR	-292 (3,3 %) des 8922 patients sortis de quarantaine ont à nouveau été testés positifs. -La plus grande proportion de cas positifs se situe entre 20 et 29 ans (24 %). -Il a fallu en moyenne 13,5 jours (fourchette de 1 à 35 jours) pour avoir un test positif à nouveau après avoir été initialement déclaré négatif. -Les cas à nouveau positifs étaient asymptomatiques ou ne présentaient que des symptômes mineurs tels que toux, expectorations, fièvre et mal de gorge. -Les tests de culture étaient tous négatifs lorsque les chercheurs ont essayé de confirmer s'il y avait un virus viable dans les échantillons des cas à nouveau positifs.
(J. Zheng, Zhou et Chen, 2020) *Prépublication*	Cohorte prospective	-Patients hospitalisés (n=285) en Chine -Du 20 janvier au 14 mars 2020	RT-PCR	<u>Écouvillon nasopharyngé</u> -27 (9,5 %) des patients précédemment sortis d'hôpital ont eu un test de SRAS-CoV-2 utilisant leur écouvillon nasopharyngé positif. Les patients ont été réadmis après une durée médiane de sept jours (IQR de 5 à 8) après leur sortie initiale. -L'âge, le sexe, les antécédents épidémiologiques, les symptômes cliniques et les maladies sous-jacentes étaient similaires entre les patients qui ont connu une récurrence et ceux qui n'en ont pas connu (p>0,05). -La durée prolongée de l'excrétion de l'ARN viral et des valeurs C_t plus élevées lors de la première admission à l'hôpital ont été associées à la redétection.
(B. Yuan, Liu et Yang, 2020) *Prépublication*	Cohorte prospective	-Patients rétablis et isolés qui ont subi de nouveaux tests (n=182) en Chine -Chronologie non communiquée	RT-PCR	<u>Écouvillons nasopharyngés et anaux</u> -Vingt (10,99 %) des 182 patients ayant subi un nouveau test ont obtenu des résultats positifs. -Quatorze d'entre eux étaient positifs par écouvillonnage nasopharyngé et six par écouvillonnage anal; aucun n'était positif pour les deux écouvillonnages.

				-Les femmes sont plus nombreuses que les hommes à avoir eu un test positif (13 contre 7). -Aucun patient sévère n'a eu de test positif. -La plupart des cas ont eu des tests négatifs ultérieurement.
(Abdullah et coll., 2020)	Cohorte prospective	-Patients sortis d'hôpital (n=138) au Brunei -Chronologie non communiquée	RT-PCR	<u>Écouvillons nasopharyngés et pharyngés</u> -Sur les 138 patients sortis, 27 (19,6 %) ont eu un test positif après leur sortie. -Lors de leur réadmission, six (22,2 %) patients présentaient des symptômes légers qui se sont résolus sans traitement spécifique. -La recherche des contacts effectuée après un nouveau test positif n'a pas permis de détecter de nouveaux cas liés à ces 27 patients. - Le délai entre le résultat positif et le résultat négatif était de 7,0 ± 5,6 jours.
(Yan et coll., 2020)	Cohorte prospective	-Patients sortis de l'hôpital (n=337) en Chine -Du 23 février au 14 mars 2020	RT-PCR	<u>Écouvillons pharyngés</u> -21 sur 337 (6,2 %) des patients atteints de la COVID-19 ont eu à nouveau un test d'acide nucléique du SRAS-CoV-2 positif, et 4 sur 337 (1,2 %) patients étaient soupçonnés d'être positifs. -L'intervalle médian entre leur sortie de l'hôpital et la réactivité des acides nucléiques était de 7,5 jours (fourchette de 6 à 13 jours, IQR de 6 à 13). -Les facteurs de risque de la nouvelle réactivité des acides nucléiques comprenaient le nombre de lobes pulmonaires présentant des lésions d'infiltration (rapport de la cote [RC] 1,14; IC de 95 %, de 1,09 à 1,19), la distribution des lésions pulmonaires (RC, 0,16; IC de 95 %, de 0,13 à 0,19), des ombres irrégulières accompagnées d'une consolidation en imagerie par tomodensitométrie (RC, 9,36; IC de 95 %, de 7,84 à 11,17), des symptômes respiratoires de toux accompagnés d'expectorations (RC, 1,39; IC de 95 %, de 1,28 à 1,52) et une congestion thoracique accompagnée d'une dyspnée (RC, 1,42; IC de 95 %, de 1,28 à 1,57).
(X. Wei et	Cohorte	-Cas légers à modérés de	RT-PCR	<u>Écouvillon respiratoire</u>

coll., 2020) *Prépublication*	rétrospective	COVID-19 admis dans les hôpitaux de refuge (n=231) en Chine -Du 17 février au 7 mars 2020		-La durée médiane de conversion négative de l'ARN du SRAS-CoV-2 était plus courte dans le groupe asymptomatique (n=34) que dans le groupe symptomatique (n=197) : 15 jours (IQR de 11,5 à 17) contre 32 jours (IQR de 23 à 39), p < 0,05. -25 sur 221 (11,3 %) patients sortis de l'hôpital ont été testés à nouveau positifs pour les acides nucléiques du SRAS-CoV-2. Il n'y a pas eu de différence significative dans le taux de nouvelle réactivité des acides nucléiques ou durée de conversion négative entre le groupe symptomatique et le groupe asymptomatique.
(Miyamae et coll., 2020)	Cohorte rétrospective	-Cas asymptomatiques /mineurs (n=23) à bord du navire de croisière Diamond Princess -Du 18 au 25 février 2020	RT-PCR	Écouvillons oropharyngés et nasopharyngés -La durée médiane de l'excrétion de l'ARN viral du SRAS-CoV-2 était de 19 jours (fourchette de 6 à 37) à partir de la détection initiale du virus. -Huit cas (35 %) ont eu un autre résultat positif au test de l'ARN par RT-PCR après avoir été testés négatifs auparavant.
(Q. Hu et coll., 2020) *Prépublication*	Cohorte rétrospective	-Patients atteints de la COVID-19 confirmés (n=211) en Chine, dont 181 cas légers et modérés et 40 cas graves et critiques -Du 23 janvier au 3 mars 2020	RT-PCR	Écouvillon nasopharyngé -La concentration d'anticorps IgG et IgM du SRAS-CoV-2 et les tests d'acide nucléique positifs redétectables ont été étudiés avec les résultats des tests d'anticorps de 74 patients rétablis dans les sept jours suivant leur sortie d'hôpital. -Les écouvillons nasopharyngés ont révélé un test d'ARN du SRAS-CoV-2 positif chez jusqu'à 52,7 % des patients guéris après leur sortie de l'hôpital, et ceux-ci avaient un taux d'IgG significativement inférieur à celui des patients dont le test d'ARN était négatif (P = 0,009). -L'effet protecteur des IgG reste à étudier.
(J. Chen et coll., 2020) *Prépublication*	Cohorte rétrospective	-Patients sortis de l'hôpital (n=1067) en Chine -Du 24 février au 31 mars 2020	RT-PCR	Écouvillon pharyngé -Quatre-vingt-un (7,6 %) patients ont eu un test d'ARN du SRAS-CoV-2 positif répété dans les neuf jours (fourchette de 3 à 18) suivant leur sortie. -Pour les patients présentant une positivité récurrente à la RT-PCR, la durée médiane entre le début de la maladie et l'apparition

				d'un ARN négatif complet était de 33 jours (fourchette de 6 à 82,0). -Le délai entre le début de la maladie et sa réapparition était de 50 jours (fourchette de 21 à 95).
(Y. Zou et coll., 2020)	Cohorte rétrospective	-Patients hospitalisés atteints de la COVID-19 (n=257) en Chine -Du 1er janvier au 10 mars 2020	RT-PCR	<u>Écouvillons pharyngés</u> -Sur 257 patients, 53 ont eu une récurrence de résultats de détections d'ARN viral positifs après avoir eu des résultats négatifs consécutifs. -Les résultats positifs récurrents des tests RT-PCR chez les patients ayant obtenu trois résultats négatifs consécutifs (5,4 %) ont diminué de manière significative par rapport à ceux des patients ayant obtenu deux résultats négatifs consécutifs (20,6 %). -Les patients ont fait état de résultats positifs au test RT-PCR dans les 1 à 12 jours suivant la date à laquelle ils ont rempli les critères de sortie d'hôpital.
(W. Zhao et coll., 2020)	Cohorte rétrospective	Enfants ayant été hospitalisés pour la COVID-19 (n=14) en Chine -Patients sortis de l'hôpital entre le 21 janvier et le 18 avril 2020	RT-PCR	<u>Écouvillon nasopharyngé</u> -Sept (50 %) enfants ont fait l'expérience d'une réactivation de l'excrétion d'ARN, dont deux ont en fait l'expérience deux fois après leur sortie. -Parmi ceux qui ont subi une réactivation de l'excrétion de l'ARN viral du SRAS-CoV-2, la durée médiane était de 14 jours (de 7 à 17 jours) entre la sortie et la première récurrence d'un test positif de dépistage du SRAS-CoV-2.
(B. M. Liu et coll., 2020)	Cohorte rétrospective	-71 cas confirmés de COVID-19 qui sont sortis de l'hôpital en Chine. Tous étaient des employés de l'hôpital ou des membres de leur famille. -Du 6 février au 26 mars 2020	RT-PCR	<u>Écouvillons oropharyngés</u> -Pendant la convalescence, les résultats de la détection de l'ARN chez 35,2 % des patients (25 sur 71) sont passés de négatifs à positifs. -La plus longue période de phase inversée de l'ARN était de 7 jours.

(To et coll., 2020)	Cohorte rétrospective	-1 patient d'une cohorte de 23 personnes à Hong Kong -Du 22 janvier au 12 février 2020	RT-PCR	Écouvillon oropharyngé postérieur -Un patient a eu des tests d'ARN viral négatifs les jours 21 et 22 après l'apparition des symptômes, avec un rebond de la positivité virale les jours 23 et 24, suivi de 5 jours de charge virale indétectable.
(J. Wu et coll., 2020) *Prépublication*	Cohorte rétrospective	-Patients atteints de la COVID 19, rétablis et ayant quitté l'hôpital (n=14) en Chine -Du 23 janvier au 30 mars 2020	RT-PCR	Écouvillon nasopharyngé -Sur les 14 patients, six (42,86 %) ont eu un test d'ARN du SRAS-CoV-2 positif après leur sortie. -Les cas présentaient une légère toux, de la diarrhée, un écoulement nasal, mais pas de fièvre à la réadmission. -Le délai de conversion positive du test RT-PCR était de 3 à 15 jours après la première sortie d'hôpital. -Le délai de conversion négative du test RT-PCR était de 1 à 16 jours (7,5 jours en moyenne) après la réadmission. -Aucune aggravation des résultats ni aucune transmission active à des contacts proches n'ont été constatées pour les contacts réadmis.
(Wong et coll., 2020) *Prépublication*	Cohorte rétrospective	-Patients sortis d'hôpital (n=106) au Brunei -Date de fin : 12 avril 2020	RT-PCR	Nasopharyngien -Sur les 106 patients qui ont subi un écouvillon de suivi entre 11 et 18 jours après leur sortie, 21 (19,8 %) se sont révélés positifs. -Un seul cas a fait état de symptômes après la sortie de l'hôpital. -Les résultats des tests RT-PCR se sont à nouveau révélés négatifs chez 16 patients dans les 1 à 3 jours suivant la réadmission. -Ces résultats suggèrent que la réinfection n'est pas plausible, mais qu'une excrétion intermittente et prolongée de l'ARN viral est plus probable. -Le taux de nouvelle positivité le plus élevé a été observé chez les patients âgés de 53 ans et plus (38,5 %), suivis de ceux présentant des conditions modérées à critiques (33,3 %) et ayant reçu un traitement au lopinavir/ritonavir (30,3 %).
(L. Wang et coll., 2020)	Cohorte rétrospective	-Patients sortis de l'hôpital (n=399) en	RT-PCR	Écouvillons respiratoires et anaux -35 patients (8,8 %) ont présenté des résultats positifs récurrents

Prépublication		Chine -Du 19 janvier au 15 mars 2020		au test RT-PCR après leur sortie. -L'intervalle médian entre le premier test RT-PCR négatif et le test RT-PCR positif récurrent était de 10 jours (IQR de 7 à 16).
(X. Chen, Shui, Li et Zhang, 2020) *Prépublication*	Cohorte rétrospective	-Patients (n=758) sortis de 17 hôpitaux en Chine -Du 25 février au 15 mars 2020	RT-PCR	Écouvillon pharyngé -59 patients (7,78 %) ont eu des résultats positifs récurrents au test RT-PCR après leur sortie. -Le délai entre l'apparition des symptômes et le dernier test positif de RT-PCR varie de 14 à 61 jours. -Le délai entre la mise en quarantaine (sortie) et les derniers résultats positifs varie de 1 à 19 jours.
(H. Cao, Ruan, Liu et Liao, 2020)	Cohorte rétrospective	-Patients atteints de la COVID-19 (n=108) en Chine -Du 10 février au 13 avril 2020	RT-PCR	Écouvillons nasaux et pharyngés -8 cas étaient des patients réadmis parce que les résultats de leur test PCR étaient à nouveau positifs après leur sortie. -Lors de leur deuxième admission, tous les cas ne présentaient aucun symptôme et avaient un scanner thoracique normal. -Deux patients sont ensuite sortis alors que six étaient encore hospitalisés au moment de la rédaction du présent rapport, car ils avaient toujours le virus. La maladie chez les deux patients avait persisté plus de 90 jours depuis l'apparition des premiers symptômes.
(S. Chen et coll., 2020) *Prépublication*	Cohorte rétrospective	-Patients sortis de l'hôpital (n=1282) en Chine -Du 14 janvier au 10 mars 2020	RT-PCR	Écouvillons nasopharyngés et anaux -Sur les 1282 patients sortis de l'hôpital qui ont participé à cette étude, 155 (12,1 %) ont été testés positifs à l'ARN du SRAS-CoV-2 pendant les 14 jours de suivi. -La durée médiane de récurrence de l'ARN du SRAS-CoV-2 était de 7 jours (IQR de 4 à 9). -Comparés au groupe négatif, les patients du groupe positif étaient plus jeunes et présentaient une proportion plus élevée de cas modérés. -Aucun des patients à nouveau positifs n'a présenté de symptômes ou d'anomalies sanguines lors de la deuxième admission à l'hôpital.

				-La durée médiane pendant laquelle tous les patients à nouveau positifs sont redevenus négatifs à l'ARN viral était de 8,0 jours (IQR de 4 à 14). -Aucun des contacts étroits (n=202) issus de patients à nouveau positifs (n=67) n'a été infecté par la COVID-19.
(Su et coll., 2020) *Prépublication*	Cohorte rétrospective	-Patients sortis de l'hôpital (n=938) en Chine -Du 18 janvier au 11 mai 2020	RT-PCR	Écouvillons nasaux et pharyngés - Sur les 938 patients ayant obtenu leur congé, 58 (6,2 %) ont retrouvé des résultats positifs au test d'acide nucléique. -Les facteurs associés aux résultats positifs étaient la coronaropathie et l'hypertension.
(L. Chen et coll., 2020) *Prépublication*	Cohorte rétrospective	-Cas confirmés (n=15) en Chine -Du 10 février au 31 mars 2020	RT-PCR	Écouvillon nasopharyngé -A examiné les données de 15 patients positifs récurrents et de 107 patients témoins atteints d'une COVID-19 modérée et non récurrente. - Le taux de récurrence des maladies positives à l'hôpital était de 1,87 %. Les patients positifs récurrents étaient significativement plus jeunes que les patients témoins, 43 ans (de 35 à 54 ans) contre 60 ans (de 43 à 69 ans) P=0,011. -La durée du séjour à l'hôpital avant la récurrence était significativement plus longue chez les patients récurrents positifs que chez les patients témoins, 36 jours (fourchette de 34 à 45) contre 15 jours (fourchette de 7 à 20) p=0,001. -Le temps nécessaire pour la première conversion des résultats de RT-PCR de positifs à négatifs était significativement plus long chez les patients récurrents positifs que chez les patients témoins, 14 jours (fourchette de 10 à 17) contre 6 jours (fourchette de 3 à 9) p=0,011. -Les taux d'anticorps sériques contre la COVID-19 étaient significativement plus faibles chez les patients récurrents positifs que chez les patients témoins.
(Mei et coll., 2020)	Cohorte rétrospective	-Patients convalescents (n=651) en Chine	RT-PCR	Écouvillons nasopharyngés et oropharyngés -Au cours du suivi, 23 (3 %) des 651 patients ont été testés positifs

		-Du 11 janvier au 4 avril 2020		lors d'un nouveau test de dépistage du SRAS-CoV-2 par RT-qPCR. -Dans ce groupe de patients testés à nouveau positifs, 12 patients (52 %) ont eu des problèmes de santé modérés, neuf (39 %) graves et deux (9 %) critiques lors de leur précédente hospitalisation. -La durée médiane entre la sortie de l'hôpital et un nouveau test positif était de 15,0 jours (fourchette de 4 à 38, IQR de 11,0 à 16,5; annexe). -Parmi ce groupe de patients testés à nouveau positifs, 15 (65 %) étaient asymptomatiques au moment du nouveau test alors que huit (35 %) présentaient au moins un symptôme associé à une COVID-19 active.
(C. Liu et coll., 2020)	Cohorte rétrospective	-Patients sortis d'hôpital (n=51) en Chine -Du 23 janvier au 28 mars 2020	RT-PCR	<u>Écouvillons oropharyngés</u> -17,6 % des patients sont sortis de l'hôpital, et seulement 33,3 % d'entre eux se sont plaints de symptômes cliniques.
(Qiao et coll., 2020)	Cohorte rétrospective	-Cas graves/critiques confirmés (n=15) en Chine -De janvier à mars 2020	RT-PCR	<u>Échantillons respiratoires</u> -La plupart des patients ne présentaient aucun symptôme clinique et les tests d'acide nucléique étaient négatifs lors du suivi après la sortie de l'hôpital. -Une patiente avait la gorge qui démangeait, son scanner a montré une ombre de densité lumineuse dans le lobe inférieur droit du poumon, et l'acide nucléique était à nouveau positif.
(Jin et coll., 2020) *Prépublication*	Cohorte rétrospective	-Patients adultes hospitalisés pour la COVID-19 (n=133) en Chine -De février au 30 avril 2020	RT-PCR	<u>Écouvillon oropharyngé</u> -32,4 % des patients étaient positifs à l'ARN du SRAS-CoV-2 après leur sortie initiale. La durée moyenne de récurrence à partir de la première sortie d'hôpital était de 18,22 jours. Après la réadmission, la durée moyenne du séjour était de 14,2 jours. -Une régression de Cox univariable et multivariable a montré que la dyslipidémie du cholestérol des lipoprotéines de basse densité (C-LDL) à l'admission était associée à la récurrence de la COVID-19 pendant la période de suivi.

(Habibzadeh et coll., 2020)	Cohorte rétrospective	-Patients (n=35) ayant l'intention de donner du plasma en Iran -Mars 2020	RT-PCR	Écouvillon nasopharyngé -Le test de réaction en chaîne de la polymérase par transcription inverse était positif chez 9 (5 hommes, 4 femmes) des 13 patients rétablis – un taux positif de près de 70 %. -Le deuxième test RT-PCR s'est révélé positif chez ces patients après une période médiane de 29 (entre 22 et 54) jours après le début de leurs symptômes/maladie et de 18 (entre 15 et 48) jours après la disparition complète de leurs symptômes.
(Bongiovanni et coll., 2020)	Cohorte rétrospective	-Patients rétablis (n=1146) en Italie -Du 9 mars au 30 juin 2020	RT-PCR	Écouvillon nasopharyngé -125 (10,9 %) ont eu une récurrence de l'infection par la COVID-19. -Le délai moyen de guérison clinique et de deux écouvillons nasopharyngés négatifs était de 27,7 jours (IC de 95 %, de 11 à 51); après cela, le délai moyen de récurrence était de 19,9 jours (de 3 à 43, IC de 95 %). -Après une période moyenne de 14,8 jours (IC de 95 %, de 6 à 36), 102 sujets (81,6 %) ont eu deux écouvillons nasopharyngés négatifs supplémentaires et ont été considérés comme cliniquement rétablis pour la deuxième fois. -Au cours du suivi, 11 patients (8,8 %) sont décédés. Les patients décédés étaient plus âgés que les autres (âge moyen 86,4 ans, IC de 95 %, de 77 à 92) et 8 d'entre eux (72,7 %) présentaient des symptômes cliniques au moment de la récurrence (4 de fièvre et 4 d'insuffisance respiratoire).
(Y. Li et coll., 2020b) *Prépublication*	Cohorte rétrospective	-Écouvillons nasaux (n=484) de patients atteints de COVID-19 en Chine -De janvier à avril 2020	RT-PCR	Écouvillons nasaux -Les taux sériques de phospholipase A2 associée aux lipoprotéines étaient significativement plus élevés chez les cas de COVID-19 à nouveau positifs que chez les patients témoins sains et les patients atteints de la COVID-19 et hospitalisés.
(Peng et coll., 2020)	Cohorte rétrospective	-Patients hospitalisés (n=79) en Chine De janvier à mai 2020	RT-PCR	Écouvillon oropharyngé -La durée médiane des résultats positifs du test d'acide nucléique (TAN) pour le SARS-CoV-2 était de 16,5 (IQR de 12,0 à 22,0) jours.

				-Deux semaines après la sortie de l'hôpital, 5,6 % des survivants ont connu une récurrence des résultats positifs du test d'acide nucléique.
(Hao et coll., 2020)	Étude cas-témoin	-Patients atteints de la COVID-19 (n=104) confirmés, avec des durées d'excrétion virale courtes et longues (cas et patients témoins) en Chine -Du 19 janvier au 3 mars 2020	RT-PCR	Écouvillons respiratoires -La durée médiane d'excrétion virale entre le diagnostic confirmé et 2 (ou plus) résultats négatifs consécutifs de test RT-PCR était de 11 jours (fourchette de 1 à 39). -Des résultats positifs récurrents de test RT-PCR dans les échantillons respiratoires après 2 (ou plus) résultats négatifs consécutifs ont été observés chez 24 patients. Les probabilités de résultats positifs de test RT-PCR lors du test suivant après un ou deux résultats négatifs consécutifs étaient de 30,5 % et 16,4 %, respectivement. Avec une augmentation de 2 à 3 résultats négatifs consécutifs, le taux de résultats positifs récurrents d'ARN par test RT-PCR a fortement diminué pour atteindre 4,8 %. -Une série de résultats négatifs consécutifs (3 ou plus) a été jugée appropriée par les auteurs comme critère pour la fin de l'excrétion de l'ARN viral.
(S. Cao et coll., 2020) *Prépublication*	Programme de dépistage dans toute la ville	-9 899 828 personnes en Chine -Du 23 janvier au 8 avril 2020	RT-PCR	Écouvillons nasopharyngés et pharyngés -107 des 34 424 patients déjà guéris ayant des antécédents de diagnostic de COVID-19 étaient de nouveau positifs (taux de rechute, 0,31 %).
(McGrath et coll., 2020) *Prépublication*	Série de cas	-4 cas de COVID-19 chez des travailleurs de la santé en Irlande -De mars à avril 2020	RT-PCR	Écouvillons nasopharyngés et oropharyngés -Ces trois cas ont tous trois connu des périodes d'auto-isolement de 14 jours avec une résolution complète des symptômes. -Chacun d'entre eux a connu des épisodes distincts de symptômes récurrents après la résolution initiale et a obtenu des résultats positifs persistants au test PCR du SRAS-CoV-2, allant jusqu'à 60 jours après le début de la maladie.
(D. Chen et coll., 2020)	Rapport de cas	-Une femme de 46 ans en Chine -Du 17 janvier au 9	RT-PCR	Écouvillon oropharyngé -Rapport d'un cas confirmé de COVID-19 dont le test de l'écouvillon oropharyngé de l'ARN du SRAS-CoV-2 s'est révélé

		février 2020		positif en convalescence. -Le 17 janvier 2020, la patiente a développé des symptômes et le 24 janvier 2020, elle a été testée positive à l'ARN du SRAS-CoV-2. -Les tests d'ARN viral ont été négatifs le 28 janvier 2020 et le 30 janvier 2020, mais sont redevenus positifs le 2 février 2020. Elle est ensuite sortie de l'hôpital le 9 février 2020.
(H. Zheng, Tan, Ma et Meng, 2020) *Prépublication*	Rapport de cas	-Femme de 37 ans en Chine -Du 12 janvier au 10 mars 2020	RT-PCR	<u>Écouvillon oropharyngé</u> -Les résultats du test RT-PCR ont été positifs pendant la première période menstruelle avant l'admission (2 février 2020). -La patiente a été hospitalisée le 4 février 2020. -Les résultats du test RT-PCR sont devenus négatifs pendant l'hospitalisation (dix et douze jours après l'admission) puis sont redevenus positifs pendant la deuxième période menstruelle (24 et 25 février 2020), qui a eu lieu après la sortie de l'hôpital. -Le test RT-PCR du 10 mars 2020 était négatif. -Les auteurs suggèrent que les hormones sexuelles pourraient jouer un rôle important dans l'infection par le SRAS-CoV-2.
(Lan et coll., 2020)	Série de cas	-Un patient hospitalisé et 3 patients (tout le personnel médical) mis en quarantaine à domicile, atteints de COVID-19 en Chine -Du 1er janvier au 15 février 2020	RT-PCR	<u>Écouvillon pharyngé</u> -Les patients ont été évalués à l'aide de tests de réaction d'amplification en chaîne par polymérase par transcription inverse en temps réel (RT-PCR) pour détecter l'acide nucléique de la COVID-19 afin de déterminer s'ils pouvaient reprendre le travail. -Après leur sortie de l'hôpital ou l'arrêt de la quarantaine, les patients ont été invités à poursuivre le protocole de quarantaine à domicile pendant 5 jours. -Les tests RT-PCR se sont révélés positifs 5 à 13 jours plus tard. Les patients ont subi trois tests répétés au cours des 4 à 5 jours suivants et tous ont été positifs bien que tous les cas soient asymptomatiques.
(J. Yuan et coll., 2020) *Prépublication*	Série de cas	-Patients sortis d'hôpital rétablis de la COVID-19 (n=25) en Chine	RT-PCR	<u>Écouvillons respiratoires</u> -Tous les cas avaient auparavant obtenu des résultats négatifs à deux tests RT-PCR consécutifs, mais ont été réhospitalisés en

		-Du 23 janvier au 21 février 2020		raison de la récurrence de l'ARN viral. -Les patients se sont présentés avec un ARN récurrent dans les 3,0 (fourchette de 2 à 7) jours suivant leur sortie de l'hôpital. La durée médiane entre leur dernier résultat négatif et leur résultat positif était de 6,0 (fourchette de 4 à 10) jours. -Tous les patients étaient asymptomatiques au moment de la récurrence. -Les cas ont été traités avec des plantes médicinales chinoises et en quelques jours, tous étaient négatifs au test d'ARN viral.
(Z. Zhang et coll., 2020) *Prépublication*	Série de cas	-56 patients atteints de la COVID-19 et présentant des symptômes à l'admission (33 ont présenté des symptômes plus tard) et 19 patients symptomatiques appariés par âge en Chine -Du 23 janvier au 1er avril 2020	RT-PCR	<u>Écouvillons respiratoires et anaux</u> -Parmi les 56 patients ne présentant pas de symptômes à l'admission, 23 sont restés asymptomatiques pendant toute la période de suivi. -Pour les cas asymptomatiques, l'ARN viral est réapparu après leur sortie (valeur C_t > 40) dans des échantillons nasopharyngés et anaux, respectivement 54 et 42 jours après l'admission initiale. -Dans les cas présymptomatiques, l'ARN viral est réapparu 81 et 40 jours après l'admission initiale et dans les cas symptomatiques, 62 et 42 jours après l'admission initiale.
(Peng, Wang, Zhang et Lu, 2020)	Série de cas	-Sept patients sortis de l'hôpital en Chine -Du 22 janvier au 8 mars 2020	RT-PCR	<u>Écouvillons de gorge et d'anus</u> -7 cas ont été testés à nouveau positifs au SRAS-CoV-2 après leur sortie. -Les 7 patients ont tous eu des séjours hospitaliers plus courts, des frais médicaux moins élevés et des symptômes plus légers lors de leur deuxième visite à l'hôpital par rapport à leur première hospitalisation.
(Loconsole et coll., 2020)	Rapport de cas	-Une femme de 46 ans en Chine -Du 17 janvier au 17 février 2020	RT-PCR	<u>Écouvillon oropharyngé</u> -Le patient a eu des résultats négatifs consécutifs aux tests les 12e et 14e jours suivant l'apparition des symptômes. -Une récurrence de la positivité virale est survenue 17 jours après l'apparition des symptômes.

				-Les résultats des tests ont de nouveau été négatifs aux jours 20, 22 et 32. -Le patient n'était pas symptomatique au moment de la récidive.
(Pan et coll., 2020) *Prépublication*	Série de cas	-Cas confirmés (n=64) en Chine -Du 23 janvier au 31 mars 2020	RT-PCR	Écouvillon pharyngé et selles -Il y a eu 64 patients confirmés et 17 patients présentent un test positif après leur sortie. -L'intervalle entre le premier test négatif et le premier test positif était de 11,82 jours (±3,42).
(J. Huang & Zheng et coll., 2020) *Prépublication*	Série de cas	-Patients (n=414) en Chine -Du 11 janvier au 23 avril 2020	RT-PCR	Écouvillons nasopharyngés -16,7 % des patients guéris ont eu des résultats PCR positifs une à trois fois, malgré une quarantaine stricte. -Les jeunes patients atteints d'un syndrome respiratoire pulmonaire léger présentaient un risque plus élevé de récidive de la positivité de la PCR.
(Martinez Alonso, Fábio de O. et coll., 2020) *Prépublication*	Rapport de cas	-Un homme de 26 ans au Brésil Du 21 avril au 18 juin 2020	RT-PCR	Écouvillons oropharyngés et nasopharyngés -Le 21 avril 2020, l'homme a eu un mal de tête sans aucun symptôme respiratoire. Deux jours plus tard, il a eu un test RT-PCR positif. -Le 5 mai 2020, l'ARN viral n'a plus été détecté. -Un mois plus tard, les symptômes sont réapparus de façon plus aiguë et comprenaient fièvre, toux, maux de tête, myalgie, arthralgie, anosmie et fatigue, et ont duré près de deux semaines. -La détection de l'ARN du SRAS-CoV-2 est devenue positive le 8 juin 2020. -Le 22 juin 2020, des anticorps IgA/IgM et IgG ont été détectés dans le sérum et seul le gène N a été détecté par RT-qPCR.
(Tian et coll., 2020)	Série de cas	-Patients convalescents (n=20) en Chine -Date de fin : 22 mai 2020	RT-PCR	Écouvillon oropharyngé -Sur 147 patients, 20 cas de convalescence (13,6 %) ont eu des tests d'ARN viral positifs dans des échantillons respiratoires 7 à 47 jours après la sortie de l'hôpital. -Tous les cas sont restés asymptomatiques.
(Dou et coll.,	Rapport de	-Un homme de 34 ans	RT-PCR	Écouvillon oropharyngé

2020)	cas	avec des antécédents de diabète de type 2 en Chine -Du 27 janvier au 13 avril 2020		-Le patient a eu une récurrence de l'acide ribonucléique (ARN) positif du SRAS-CoV-2 après sa guérison. -Malgré cela, il ne présentait aucun symptôme clinique évident et son scanner thoracique s'est amélioré. -Les membres de sa famille et d'autres contacts proches n'ont ressenti aucun symptôme.
(F. Liu et coll., 2020)	Rapport de cas	-Un homme de 35 ans en Chine -À partir du 30 janvier 2020	RT-PCR	Écouvillons nasopharyngés -Cas testé positif à l'ARN viral même après une guérison apparente (imagerie par tomodensitométrie normale, pas de symptômes cliniques, test SRAS-CoV-2 négatif sur l'échantillon des selles et test IgM sérique négatif) de la COVID-19. -L'excrétion virale a duré 65 jours et le délai entre l'apparition des symptômes et la disparition a atteint 95 jours.
(F. He et coll., 2020)	Rapport de cas	-Une femme de 39 ans atteinte de lupus érythémateux systémique en Chine -Du 21 janvier au 11 avril 2020	RT-PCR	Écouvillon pharyngé -Le 8e jour de son isolement à domicile (5 mars), des symptômes de toux sèche, d'arthralgie et de maux de tête sans fièvre sont réapparus. -Le 7 mars, ses symptômes ont disparu. Les nouveaux tests de l'ARN viral du SRAS-CoV-2 pendant 3 jours consécutifs ont tous été négatifs du 7 au 9 mars, et plus tard jusqu'au 11 avril.
(González-Calvo, Bores-García, Barba-Martín et Gallego-Lema, 2020)	Rapport de cas	-Une femme de 64 ans en Iran -Du 16 février au 22 mars 2020	RT-PCR	Écouvillon nasopharyngé -Après quelques semaines, la femme a fait une rechute, comme l'indiquent les symptômes de la méningo-encéphalite aiguë. Les résultats du test RT-PCR pour la COVID-19 de ses échantillons de liquide céphalorachidien, d'aspiration nasopharyngée et trachéale sont redevenus positifs, mais les anticorps sériques contre la COVID-19 étaient négatifs.
(Alonso et coll., 2020)	Rapport de cas	-Un homme de 26 ans au Brésil Du 21 avril au 29 juin 2020	RT-PCR	Écouvillon respiratoire -Ayant une infection légère, le patient est resté en isolement pendant 14 jours à la maison, se rétablissant 3 jours après l'apparition des symptômes. -Le 6 juin (un mois plus tard), les symptômes sont réapparus de

				manière plus aiguë et comprenaient fièvre, toux, maux de tête, myalgie, arthralgie, anosmie et fatigue, et ont duré deux semaines. La détection de l'ARN du SRAS-CoV-2 est redevenue positive le 8 juin et est restée positive lors d'un autre test le 16 juin, bien que le test des anticorps contre le SRAS-CoV-2 soit resté négatif. -Le 22 juin, des anticorps IgA/IgM et IgG ont été détectés dans le sérum et seul le gène N a été détecté par RT-qPCR et enfin, le 29 juin, plus aucun gène viral n'a été détecté. -L'absence d'anticorps détectables lors du premier épisode peut avoir permis une nouvelle infection, plutôt qu'une récurrence. Cependant, comme les auteurs n'ont pas étudié la génétique virale à différentes époques, une telle affirmation est hypothétique.
(Duggan et coll., 2020)	Rapport de cas	-Un homme de 82 ans ayant des antécédents de maladie de Parkinson avancée, de diabète insulinodépendant, de maladie rénale chronique et d'hypertension aux États-Unis -D'avril à mai 2020	RT-PCR	Type de prélèvements non rapporté -Cas présenté au service des urgences début avril avec une semaine de fièvre et d'essoufflement. -Début mai 2020, deux tests RT-PCR ultérieurs du SRAS-CoV-2 ont été négatifs et il est sorti d'hôpital. -Dix jours après sa sortie (48 jours après sa première arrivée à l'hôpital), il s'est présenté à nouveau aux urgences avec de la fièvre et de l'hypoxie et un résultat positif au test RT-PCR. -Les tests RT-PCR du SRAS-CoV-2 les 11^{e} et 12^{e} jours d'hospitalisation ont tous deux été négatifs.
(Ye et coll., 2020)	Rapport de cas	-Femme de 72 ans en Chine -À partir du 30 janvier 2020	RT-PCR	Écouvillon nasopharyngé -Le cas a été admis en isolement à l'hôpital après avoir été infecté par la COVID-19 dans le cadre d'une grappe familiale le 30 janvier 2020. -Le patient s'est rétabli et est sorti de l'hôpital le 19 février. - En raison d'une faible réponse immunitaire humorale, le patient atteint de leucémie lymphocytaire chronique n'a pas pu éliminer efficacement l'infection par le SRAS-Cov-2 et a souffert de deux récurrences au cours du suivi de 69 jours.

(Alfano et coll., 2020)	Rapport de cas	-Un homme de 72 ans atteint d'une maladie rénale en phase terminale en Italie -Mars 2020	RT-PCR	Écouvillon nasal/oropharyngé -Après 41 ans jours depuis l'infection primaire, le patient cliniquement rétabli a connu une réactivation symptomatique du SRAS-CoV-2 avec séroconversion de l'immunoglobuline M. - Il a été renvoyé chez lui le septième jour après sa réadmission avec un résultat de test PCR négatif sur l'écouvillon oropharyngé/nasal.

RÉINFECTION

Le tableau 5 énumère les études qui fournissent des éléments de preuve de réinfection par la COVID-19.

Depuis le 25 août 2020, des éléments de preuve qu'une réinfection peut se produire ont été publiés. Les analyses épidémiologiques, cliniques, sérologiques et génomiques fournissent de bonnes preuves de la réinfection chez un patient de Hong Kong 142 jours après l'infection initiale (To, Hung, et coll., 2020). Il existe également des éléments de preuve solides d'un cas de réinfection aux États-Unis (Tillet et coll., 2020). Des recherches supplémentaires sont nécessaires pour comprendre le rôle de l'immunité dans la protection contre le SRAS-CoV-2 après l'infection aiguë initiale, les caractéristiques cliniques et épidémiologiques de la réinfection, et pour savoir si les cas récurrents peuvent être infectieux et la probabilité qu'ils soient atteints d'une maladie clinique.

Tableau 5 : Études évaluant la réinfection par la COVID-19 (N=2)

Référence	**Type d'étude**	**-Population et environnement -Période de temps**	**Période infectieuse (PI) déterminée par :** **Culture, Tests RT-PCR en série, données épidémiologique ou modèle**	**Résultats pertinents**
(To, Hung et coll., 2020)	Rapport de cas	-Un homme de 33 ans à Hong Kong -De mars à août 2020	RT-PCR et séquençage du génome entier	Échantillons respiratoires -Le cas immunocompétent a eu un test positif de l'ARN viral du SRAS-CoV-2 142 jours après le premier épisode symptomatique. -Bien qu'à nouveau positif, il y avait des éléments de preuve sérologiques de l'élévation de la protéine C-réactive et de la séroconversion des IgG du SRAS-CoV-2.

				-Les génomes viraux des premier et deuxième épisodes appartenaient à des clades/lignes différentes, ce qui confirme la réinfection. Les données épidémiologiques, dont un récent voyage en Espagne, confirment les résultats virologiques.
(Tillet et coll., 2020) *Prépublication*	Rapport de cas	-Un patient de 25 ans dans le Nevada, aux États-Unis -D'avril à juin 2020	RT-PCR et séquençage du génome entier	Écouvillons nasopharyngés -Le cas a été positif pour la première fois à la mi-avril 2020, et après s'être rétabli, il est retombé malade à la fin du mois de mai 2020. -L'analyse des séquences d'acides nucléiques a montré que les virus associés à chaque cas d'infection présentaient un certain degré de discordance génétique. -Le cas peut avoir été réexposé au virus par un parent infecté.

Méthodologies :

Une analyse quotidienne de la littérature (publiée et prépubliée) est effectuée par le groupe des sciences émergentes de l'ASPC. L'analyse a permis de compiler la littérature sur la COVID-19 depuis le début de l'épidémie et est mise à jour quotidiennement. Les recherches pour trouver la littérature sur la COVID-19 pertinente sont menées par Pubmed, Scopus, BioRxiv, MedRxiv, ArXiv, SSRN, Research Square et sont recoupées avec la littérature de la liste de littérature sur la COVID de l'OMS, et les centres d'information sur la COVID-19 gérés par Lancet, BMJ, Elsevier et Wiley. Les résultats cumulatifs de l'analyse sont conservés dans une base de données Refworks et une liste Excel consultable. Le texte intégral de chaque étude qui a été étiquetée comme étant Épidémiologie, Données cliniques ou Modélisation FOCI par le groupe des sciences émergentes a été analysé pour obtenir des informations relatives à la période infectieuse de la COVID-19. Les titres et les résumés des articles ont été scannés afin de trouver les mots clés suivants : « Excrétion », « Dynamique virale », « Clairance virale », « Viable », « Culture », « Infectivité », « Détection du SRAS-CoV-2 », « Période infectieuse », « Période de transmissibilité », « Récidive » et « À nouveau positif». Cette revue contient les articles de recherche clés publiés jusqu'au 31 août 2020. Chaque référence potentiellement pertinente a été examinée pour confirmer qu'elle comportait des données pertinentes et les données pertinentes ont été extraites pour être incluses dans la revue.

Emerging Evidence on COVID-19

Living Summary of SARS-CoV-2 Variants of Concern: The B.1.1.7 (Alpha) Variant Profile

Highlights up to July 1, 2021

Introduction

SARS-CoV-2 **variants of concern** (VOCs) are circulating variants that have been flagged by national or global public health organizations. VOCs are of concern when compared to the original SARS-CoV-2 variants, as their complement of mutations lead to increased transmissibility, increased virulence (morbidity or mortality), changes in clinical disease presentation, immune evasion, reduced effectiveness of treatments, vaccines and/or public health measures and/or diagnostic detection failures (1-3). Canada has established a national definition (2). In May 2021, the World Health Organization (WHO) released a naming system for VOCs and variants of interest (VOIs) using Greek letters to improve the ease of communication on variants and potential stigma related to places where variants were first identified, which has been adopted in this report (1).

TABLE 1: CURRENT VARIANTS OF CONCERN (VOCs)*

WHO name (05-21)	Pango lineage	Nextstrain clade	GISAID clade	Alternate name	First detected in	Earliest samples	Characteristic spike mutations
Alpha	B.1.1.7	20I/501Y.V1	GR/501Y.V1	VOC 202012/01	United Kingdom	Sep 2020	69/70del, 144del, N501Y, A570D, D614G, P681H, T716I, S982A, D1118H
Beta	B.1.351	20H/501Y.V2	GH/501Y.V2	VOC 202012/02	South Africa	May 2020	D80A, D215G, 241/243del, K417N, E484K, N501Y, D614G, A701V
Gamma	P.1, P.1.1. P.1.2	20J/501Y.V3	GR/501Y.V3	VOC 202101/02	Brazil and Japan	Nov 2020	L18F, T20N, P26S, D138Y, R190S, K417T, E484K, N501Y, D614G H655Y, T1027I, V1176F
Delta	B.1.617.2 AY.1 AY.2 AY.3	21A	G/478K.V1		India	Oct 2020	L452R, D614G, P681R, ± (E484Q, Q107H, T19R,

							del157/158, T478K, D950N)

* A VOC/VOI lexicon and other resources are available in the appendix.

The goal of this living summary on the SARS-CoV-2 VOC literature is to highlight new data on the B.1.1.7 (Alpha) variant, its epidemiology and how the attributes of the VOC may impact the management of the pandemic. This living evidence profile on Alpha is part of a larger project that summarizes the data on each VOC as well as captures data on variants of interest (VOIs). The focus will be on changes to epidemiological parameters (e.g., transmission rates, clinical outcomes of severity and mortality, shifts in age groups affected or asymptomatic proportions), impacts on diagnostic tests, immune evasion/vaccine effectiveness and impacts on other public health measures. The full dataset in Excel can be accessed here and filtered by the VOCs and VOIs of interest. The recent living evidence reviews on other VOCs (Beta, Gamma and Delta) and a high level contrasting table of VOC evidence can be requested here.

In this summary, "original variant" refers to any variant that was not designated as a VOC or VOI.

What's New

This update includes literature up to July 1, 2021. A total of 200 new studies on B.1.1.7 (Alpha) were identified since the last update on June 1, 2021 and are included in the dataset.

- In Canada, the national proportion of Alpha cases have continued to decline and was surpassed by Delta the week of June 13th, 2021 (37% vs 41%) (4). Studies in the UK, India, USA and Japan have also reported that Delta has replaced Alpha cases and become the dominant variant (5-15).

Key Points

As of July 1, 2021 there were 543 studies that reported on the Alpha variant. This summary considered 293 studies for inclusion that focused on transmission efficiency (n=57), clinical severity (n=54), immune escape (n=30), diagnostic performance (n=46), variant spread (n=153), and other epidemiological research (n=4). Studies not summarized in the evidence profiles (n=250): case reports or case series (n=21), point prevalence estimates (n=2), animal studies (n=40), zoonotic investigations (n=3), predictive models in which the time period has already passed (n=4), and cell infectivity, binding affinity, or genomic characterization studies (n=62), and *in vitro* studies looking at neutralization by convalescent and/or vaccinated sera (n=83), and therapeutic products (n=48).

However, details for all 543 studies can be found in the Excel dataset accessed here.

Transmissibility:

- Ninety-one percent of studies that assessed transmissibility, reported increased transmissibility of the Alpha variant (Table 2) compared to the original variant (34-118%) with large variation that can be attributed to stringency of restrictive public health measures, increasing vaccination coverage as well as the local epidemiology and other VOCs in circulation.

- In Canada, general population surveillance data reported 34% between December 2020 and March 2021 (16) and 63% between March and April 2021increased transmissibility for Alpha compared to the original variants (17). Canadian household transmission studies reported 31% higher secondary attack rates (SAR) for Alpha compared to non-VOCs in February 2021 (18) and higher SAR for Alpha compared to the original variant (24.3% vs 20.2%)between March and April 2021 (19).

Variant Spread:

- Surveillance data from the UK and the US reported that following an increase from December 2020 to March 2021, Alpha infections plateaued in April 2021 and dropped rapidly by June with the rise of the Delta variant (10, 14). A predictive model forecasting variants in North America, reported Alpha cases are expected to reach close to 0% by October 2021 and remain stable (20).

Clinical Severity:

- There was conflicting evidence on the odds of being admitted to hospital and ICU admissions with Alpha compared to the original variant. Risk of mechanical ventilation or higher severity score in the ICU was not associated with Alpha compared to the original variant. However, these data are based on a limited number of retrospective studies that analysed surveillance and hospital data.
- Indicators of changes in severity with the Alpha variant were not consistent, some reported age-stratified risk of hospitalization and increased odds in adult age groups between 20-59 years old compared to the original variant, while others reported no associations**.**
- Associations with mortality were conflicting across studies for Alpha infections.
- Ninety-six percent of studies that assessed viral load, reported that it was consistently 2-10 fold higher for Alpha compared to the original variant.
- A longer infectious period for Alpha compared to the original variant has been reported in three studies although the magnitude of the increase is highly variable across studies ranging from 0.86 days to 5.1 days (21-23). Further evidence is needed to improve confidence in this result. One small retrospective cohort in Japan that included Alpha cases (n=30) from March 2020 to March 2021 reported the mean incubation period of Alpha was shorter compared to the original variant (3.53 vs 5.71 days) (24). As well, surveillance in the UK estimated the median incubation period for Alpha was 4 days in March-June 2021 (25). Further evidence is needed to improve confidence in this result.

Immune Escape:

- Three reinfection studies from the UK and the US reported low reinfection rates of 0.7% for Alpha and is comparable to the original variant (26-28).
- Most vaccine effectiveness studies comparing the Alpha variant with the original variant have reported reduced protection after the first dose of mRNA (BNT162b2 (Pfizer) and mRNA-1273 (Moderna)) and ChAdOx1 (AstraZeneca) vaccines, but equivalent protection after the second dose of vaccine.

- An Alpha outbreak study at a long-term care facility in Germany 7 days post two doses of BNT162b2 (Pfizer), reported that the infectious period of those with COVID-19 was significantly shorter for fully vaccinated patients than in unvaccinated patients (7.5 vs 31 days) and viral load was lower in vaccinated patients, but not statistically significant (6.45 vs. 8.15 log10 copies/mL) (29).

Other Categories:

- Additional categories related to diagnostic performance and epidemiological research on spread and impact of public health measures are summarized in Table 2.
    - No studies evaluating diagnostic or detection tests for SARS-CoV-2 described failure or performance issues for detecting the VOCs, besides the well characterized S-gene drop out for Alpha.
    - Several predictive models studies reported on public health measures (e.g. restrictions to gatherings, closures, masking and lockdowns, and vaccinations) and conclude that higher stringency, more closures and restrictions, and higher vaccine coverage were needed to control Alpha due to higher transmissibility.
    - Studies on VOC introduction and spread in a geographic region as well as risk factors for spread were also reported.

Overview of the Evidence

Study designs included in this summary ranged from low risk of bias double blinded RCTs to a number of different observational study designs with varying levels of evidence. The observational studies offer low to moderate evidence depending on the specific study design and consistency across studies. Descriptive studies included in this report such as case series and case reports, predictive models, ecological studies, animal models and *in vitro* studies are low to very low evidence and generally can only be used to generate hypotheses that need to be further examined with a different study design. Given this very wide variation, an indication in the level of confidence of the evidence is provided for a particular outcome. Study designs are provided, but no formal risk of bias assessment has been conducted.

There are several knowledge gaps or areas where there is very little research noted in the key points table and additional research is needed to improve confidence in summary results and to fill in current knowledge gaps regarding the Alpha variant.

CONTENTS

ALPHA

The detailed evidence profile developed for the Alpha variant is reported below (Table 2). It covers data on transmission efficiency, clinical severity, immune escape, testing and diagnostics, and other epidemiological studies including VOC spread. The excel dataset includes summaries of all the individual studies on the Alpha variant and can be accessed here.

Categories of evidence in the tables below include the following if reported:

Transmissibility includes changes in transmissibility, secondary attack rates, and estimates of selective advantage.

Clinical Severity includes proportion of infections that are symptomatic, proportion of severe disease and mortality as well as risk factors for severe disease or mortality, viral load, infectious period, incubation period. Note risk factors for severe disease would include special populations e.g. persons who are pregnant if they are reported.

Immune Escape includes changes to vaccine efficacy, risk of re-infection in humans, animal models, *in vitro* or *in silico* experiments as well as impacts on therapeutics if reported.

Diagnostic / Detection Test Failure is captured in the individual sections, and will only be included in Table 2 if there is a concern about test performance.

Other Epidemiology includes all studies that document the emergence and spread of VOCs in a geographic area, ecological studies that examine VOC spread and risk factors for hot spots, and studies on effective public health interventions against VOCs, genomic epidemiology as subcategories.

Table 2: Evidence Profile of Alpha VOC (n=293)

CATEGORY	KEY SUMMARY OUTCOMES	OVERVIEW OF THE EVIDENCE
Transmission Efficiency (n=57)		
Transmissibility Compared to Original Variant	Across studies, estimates of the increased relative transmissibility of Alpha (1-$R_{voc}/R_{original\ variant}$) were 34-118% higher: • Canada: 34% (95%CI: 31-38) (16), 63% (95%CI 28%-108%) (17). • UK: 50-100% (30), 75% (95% CrI 70–80%) (31), 52% (95% CI 46 – 58%) (32), 43-90% (CrI range: 38-130%) (33), 44-55% (95%CI 38-61%) (34), 50% (35), 83-118% (71-140%) across the UK (36), 13.4-41.3% across UK regions in Dec 2020 (37), higher transmissibility 62% (95%CI 59%-65%) to 45% (95%CI 43%-48%) (6) and a 0.3 unit higher reproduction number compared to other lineages (38).	This section is informed by 46 observational studies including analysis of surveillance data, cross sectional, outbreak investigations, retrospective cohort, ecological studies, and predictive models. There is agreement that Alpha is more transmissible and there is a fair amount of overlap in

CATEGORY	KEY SUMMARY OUTCOMES	OVERVIEW OF THE EVIDENCE
	• Europe: France 41% (95%CI 38-44) (39) and 52% (95%CrI 54-66%) (40), Denmark 55% (CrI 45–66%) (33) and 58% (95%CI 56-60%) (41), Switzerland 74% (CrI 66–82%) (33) and 54% (95%CI 49-65%) (42) and 37% (95%CI: 25–63%) (23), Norway 24% (95%CI 0-52%) (43), Italy 55-57% (95%CI 45-66%) (44), Wales and the USA 65-72% (46-104%) (36). • USA: 59% (CrI 56–63%) (33), 35-46% (45). • Israel: 45% (95%CI 20-60) (46). • Japan: estimated a 60% increase in relative transmissibility of VOCs (not specified) (47) and 45% for Alpha in another study (15). Some studies did not provide enough data to calculate transmission efficiency, but indicated that it was higher (26, 48, 49). Other studies indicated transmissibility decreased over time (30, 49, 50) or remain unaffected (51), which may be associated with lockdown stringency or increasing vaccinations (23, 51, 52). Estimates from the UK were higher than other countries (36). In studies with multiple VOCs in circulation, Alpha had higher transmissibility than Beta or Gamma (49), except in one study from France that reported a transmission advantage of Beta over Alpha (53).	the estimates of magnitude. Transmissibility estimates may be impacted by the stringency of restrictive public health measures and increasing vaccination coverage as well as the local epidemiology and other VOCs in circulation. These studies are at risk of selection, information and confounding biases that have been inconsistently adjusted for across studies. Low level of evidence.
Selective Advantage Compared to Original Variant	• A model of selective advantage found Alpha was estimated to have a selective advantage of 0.337 (0.336-0.339) over original variants in the UK (54).	One predictive model. Low level of evidence.
Secondary Attack Rate Compared to Original Variant	• Canadian household transmission studies reported Alpha had a secondary attack rate (SAR) that was RR=1.31(95%CI 1.14-1.49) times higher than non VOCs and the risk of transmission was accentuated for asymptomatic index cases (RR=1.91, 95% CI 0.96-3.80) and presymptomatic cases (RR=3.41, 95%CI 1.13-10.26) (18). In a another study the SAR was 20% higher for household transmission from Alpha cases compared to the original variant (24.3% vs 20.2%) (17). • SAR in households was 60% (20%-114%) more transmissible in Norway (43), 50-70% higher transmission in Denmark (55), 37% (95%CI 28-47) in Germany and was similar for child 32% and adult 39% index cases (56), 88% (95%CI 67-108) in the UK (57).	Seven studies of household transmission including an outbreak in a kindergarten classes. The ratio of secondary attack rates was also provided as a measure of higher transmissibility for Alpha in some studies based on contact tracing studies. The results were conflicting across the studies summarized. These studies include four surveillance data analysis,

CATEGORY	KEY SUMMARY OUTCOMES	OVERVIEW OF THE EVIDENCE
	In Israel transmission in households due to Alpha was increased by 60% (95%CI 20-110) for adults and 150% (95%CI 60-300) for children compared to spring 2020 original variant SARs (58).	two outbreak investigations, and one retrospective study. Low level of evidence.
Public Health Measures Compared to Original Variant	Stringency: • UK: December 2020 had the highest values of Rt (~1.8) in areas with the least restrictions, lowest values in areas with the highest restrictions and lockdowns effectively reduced Rt by ~0.9 by March 2021 (6). • Canada: A predictive model of the Alpha variant conducted in January 2021 examined various levels of restrictions and school closures. It assumed transmission rates were 50% higher in children and 70% higher in adults compared with the original variant. Compared to restrictive lockdown, cases were estimated to be 3 times greater in Toronto with schools closed and community opened under moderate restrictions, 7 times higher if schools were closed, and 7.5 times higher if schools are open and the community was under light restrictions (59). • Portugal: A predictive model that assumed 50% increased transmission with Alpha and does not include Delta, reported that the scenario with partial lifting of measures and on-going vaccinations reduces R to less than 1 by June 2021 and does not lead to significant rise in hospitalization between April 2021 and January 2022, whereas other scenarios that involve faster lifting of PHMs resulted in higher cases and hospitalizations (60). • A Susceptible-Exposed-Infectious-Recovered (SEIR) model based on the situation in France described the inability of non-pharmaceutical interventions such as curfew and physical distancing measures to reduce the Ro of Alpha under 1, when the same interventions were successful against original variants (61). • An age-stratified regionally structured transmission model to control the transmission of Alpha estimated that adherence to short stricter lockdowns would result in decreased hospital admissions and a moderate lockdown would reduce distress and improve sustainability (62).	14 studies reported public health measures. The majority of studies were predictive models, with 1 ecological study, and 3 surveillance data analyses. Predictive models are excellent tools to compare options, but caution should be exercised when extrapolating results beyond comparing model scenarios. Low level of evidence.

CATEGORY	KEY SUMMARY OUTCOMES	OVERVIEW OF THE EVIDENCE
	Quarantine: • A model examining quarantine and test scenarios to control importations of SARS-CoV-2 in the EU reported Alpha did not change how effective quarantine and test strategies are (63). Personal Protective Measures: • US: A predictive model explores the impact of mask use for both source control and user protection using transmission data for the original variant and alpha. The model finds that the basic Ro of 2.5 could be decreased to Re<1.0 and Ro of 4 decreased to Re~1.6 for the original variant and Alpha respectively, suggesting masks are an effective PHM (64). • Germany: A predictive disease transmission model that estimated work place transmission risk found that the transmission rate of Alpha was 0.014 per proximity contact which is 3 times higher than the original variant. With mask use the risk is still 2 times larger than the original variant (65). Vaccination: • Vaccine strategies were examined considering the higher transmissibility of Alpha and predicted that even with 100% of the population fully vaccinated with ChadOx1 vaccine (AstraZeneca), R value would only reduce to 1.33 with 100% of the population vaccinated and could increase to 1.98 if 79% is vaccinated. The BNT162b2 (Pfizer) vaccine would require 81.9% of the population to be vaccinated to reduce the value of R to 1 (52). • A predictive model showed decreased transmission of Alpha with increased vaccination coverage had the greatest effect once transmission was already decreasing through public health mitigation strategies (66). • A predictive model in the US forecasted data from June 2021 to May 2022 which assumed 59% increased transmissibility of Alpha, 88.5% vaccine effectiveness with ≥1 dose, and included the impact of the Delta variant. This model reported that restoring social activity to pre-pandemic levels with increasing vaccination coverage (60% to 70%) would still result in epidemic control measured by decreased infections and deaths (67).	

CATEGORY	KEY SUMMARY OUTCOMES	OVERVIEW OF THE EVIDENCE
Infection, Prevention, and Control Measures	• One study reported Alpha was susceptible to heat, from 45°C TCID50/mL after 60 min and titres decreased from 8.5 to 1.5 and at 60 °C and after 10 minutes and titres decreased from 8.5 to 0.5 (68), and another study reported decrease in viral titres within 30 minutes of exposure to heat at 56°C (69). • Two studies assessed susceptibility of Alpha to irradiation: Alpha was highly susceptible to UV-C irradiation, decreasing from 8.5 to 0.5 log10 TCID50n/mL after 30 min of exposure (68), and another study reported infectious titer reduction rate for Alpha was 96.3% after exposure to continuous deep-ultraviolet light-emitting diode irradiation for 1 second and the rate increased to 99.9% after irradiation for 5 seconds (70). • Alpha was efficiently inactivated by treatment with at least 30 % (v/v) ethanol for 30 seconds or after exposure to soap for 1 - 5 minutes (69). • Another study reported Alpha was susceptible to heat and UV irradiation at increasing temperatures and durations (68).	Four in vitro studies of infection, prevention and control measures. Low level of evidence.
Clinical Severity (n=54)		
Virulence / Severity or Duration of Disease Compared to Original Variant	• Conflicting evidence on whether Alpha results in more asymptomatic infections: Prevalence of symptomatic disease was the same in an Italian study (71). Symptomatic proportion: Alpha cases, 72.6% (5,365/7,390) vs. original variant cases (81.4%; 547/672; p < 0.001) (72). Majority of studies reported higher hospitalizations rates with Alpha infection: • Higher hospitalizations with Alpha (11% vs. 7.5% p<0.001) (72); (5.8% vs 4.1% p=0.04) (27). Higher hospital admission 2.39% during the Alpha wave vs. 1.55% in the initial wave in Spain (73). • Higher odds of Alpha cases being admitted to hospital compared to original variant (aOR 1.7, 95%CI 1.0-2.9) (72); OR 1.64 (95%CI 1.32-2.04) (74); OR 1.25 (95%CI 1.22 - 1.28) (74); (OR 1.36 95%CI 1.16-1.60, p=0.0002) (75); OR 2.25 (95% CI 2.10-2.40) (76). The hazard ratio for hospitalization due to Alpha vs. original variant (aHR 1.34, 95%CI 1.07-1.66) and length of stay was similar in both groups p=0.07 (77).	25 studies on severity, these included surveillance data analysis, outbreak investigations, ecological studies, prospective cohorts, retrospective cohorts, and cross sectional studies, most of which have been conducted in the UK. Moderate level of evidence.

CATEGORY	KEY SUMMARY OUTCOMES	OVERVIEW OF THE EVIDENCE
	• A study in Czech Republic reported no change in hospitalizations (78). Higher ICU admissions with Alpha infection was reported in most studies: • ICU admission was 1.4% for Alpha vs original variant 0.6% p=0.002, or a higher odds of ICU admission for Alpha of aOR 2.3 (95%CI 1.4-3.5) (72). • OR 3.31 (95%CI 2.84-3.86) (76); aHR: 2.15 (95%CI 1.75 - 2.65) (79). • Among hospitalized cases there was higher odds of ICU admission (OR 2.56) (76). • One study reported no association in intensive care admission with Alpha HR 1.01 (95% CI 0.75-1.37, P=0.94), thus the risk was the same as the original variant (80). • Among hospitalized cases there was no association between severe disease and death among Alpha vs. original variants, adjusted PR 1·02 (95%CI: 0·76–1·38) (81); ICU scores or mechanical ventilation requirements (82); or mechanical ventilation support (oxygen therapy, mechanical ventilation) (p=0.265) (83). Symptoms: • Two studies reported higher rates of hypoxia (70.0% vs 62.5%, p=0.029) and respiration (p=0.001) in patients with the Alpha variant (84, 85). • One study found fever over 38°C was significantly higher among hospital patients infected with the Alpha variant vs. the original variant (46% vs 22%, p=0.015) (86). • One study found that a sore throat was more frequent: OR 1.6 (95% CI: 1.0–2.6), and anosmia or ageusia were less frequent OR 0.5 (95% CI: 0.3–0.9) (87) in those with the Alpha variant. • Another study reported longer (≥7 days) symptom duration (p=0.02) in Alpha cases compared to the original variant (87).	
Severity Risk Factors Compared to Original Variant	There was no agreement across studies on whether ethnicity or gender were risk factors for Alpha infection severity, however several studies identify higher risk in certain age groups (with a lot of variability) and that individuals infected with Alpha were less likely to have comorbidities:	14 studies on severity risk factors. These included surveillance data analysis, prospective cohorts, retrospective cohorts, and cross sectional studies,

CATEGORY	KEY SUMMARY OUTCOMES	OVERVIEW OF THE EVIDENCE
	• Two studies reported no significant difference in patient age, gender and median length of hospital stay (75, 82). • Three studies showed a small but significant age difference (37 vs. 39 years) (88), (37 vs 38 years) (76), and (58 vs 64 years) (78). • Another study found increased risk of hospitalization with age: HR of 0.93-1.21 in patients younger than 20, HR 1.29 aged 20-29 and HR 1.45-1.65 in those over 30 years (74). • In the age-stratified models, Alpha cases in the age groups 20–39 and 40–59 years had, respectively, 3.0 and 2.3 times higher odds of hospitalisation when compared with original variant cases (72). Pre-existing conditions were lower with Alpha, vs original variant, (44.8% vs. 89% p<0.001) (72). • A prospective cohort study in hospital patients identified a statistically significant difference in the age of those infected with the Alpha variant (39 years, IQR: 30.50 - 62.50) compared to those infected with the B.1.470 non-variant (31 years, IQR: 27.50 - 41.00) (P = 0.014) (86). • A hospital cohort between Dec 2020 - Jan 2021 in France describes younger patients (63% >65 years dropped to 50%) with a mean age of 59.2 down from 70.7, patients without comorbidities increased from 16% to 42% (p=0.007) (85). • A study of hospitalized COVID-19 cases reported a higher proportion of females with Alpha (48.0% vs 41.8%, p=0.01), fewer frail patients (14.5% vs 22.4% p=0.001) and higher proportions of obese cases (30.2% v 24.8%, p=0.048), but no difference by age or ethnicity (84). • For intensive care admission, there were no significant associations between Alpha and ethnic group (p = 0.09), lower risk in pregnant women HR 0.13 (95% CI 0.02 to 0.98, P=0.048), higher risk with male sex HR 1.33 (1.05-1.68; P=0.02), strongly associated with higher age, and higher with one or more comorbidities: HR: R 1.25 (0.92-1.71) for one comorbidity, 1.24 (0.89-1.74) for two and 0.79 (0.54-1.15) for ≥three vs none; P=0.03) (80). • A Canadian study on VOCs (predominately Alpha during the study period) reported hospitalized cases were	most of which have been conducted in the UK. Moderate level of evidence.

CATEGORY	KEY SUMMARY OUTCOMES	OVERVIEW OF THE EVIDENCE
	younger (59 vs 64 years) and were more likely to be male (57% vs. 52%) (76). Compared to females, male VOC cases had a larger increase in the odds of hospitalization (OR 3.11, 2.83-3.41 vs OR 1.63, 1.49-1.79) and ICU admission (OR 7.35, 5.68-9.52 vs OR 1.86, 1.51-2.30) (76).	
Mortality Compared to Original Variant	There is conflicting evidence on the association of mortality and Alpha infection: • Seven studies reported no significant difference in mortality overall: Italy (2.1 vs. 4.1%) (71), USA (27, 75), UK 1.01 (95% CI: 0.79-1.28, p=0.94) (80), and no association with 28 day mortality in UK (OR: 0.90, 95%CI 0.57-1.41, p=0.64) (77), no significant difference in 28-day mortality in UK (32.1% vs 20.7%, p=0.326) (83), or 60-day mortality in the UK (89), or case fatality (OR= 1.37; CI: 0.5808-3.215, p = 0.52) (78). • Two studies report Alpha had a lower odds of mortality compared to original variant in the multivariable analysis (aOR 0.5, 95%CI 0.3-0.9) (72), lower risk of mortality in care home residents HR 0.52 (95% CI: 0.27-1.02) (80). • Eleven studies reported higher risk of mortality: higher odds of mortality OR 1.75 (95% CI 1.47-2.09) (76), higher among hospitalized cases OR 1.62 (95% CI 1.23-2.15) (76), higher 28-day hazard of death (55%, 95% CI: 39-72%) (90), aHR 1.65 (95%CI 1.36-2.01) (79), aHR 1.67 (95%CI 1.34 – 2.09; P <0.0001) (81), aHR 1.59 (1.44 to 1.74) (74). HR 1.64 (95%CI 1.32 - 2.04, p <0.001) (91), which equates to an increase of 2.5 to 4.1 deaths per 1000 detected cases (73, 92, 93). The meta-analysis of these four studies had a pooled mortality risk of HR=1.45 (95%CI 1.18-1.78) (94). An ecological studies from the UK estimates that Alpha is 33% more lethal (95).	19 studies reported on mortality these included surveillance data analysis, ecological studies, prospective cohorts, retrospective cohorts, and cross sectional studies, most of which have been conducted in the UK. Moderate level of evidence.
Mortality Risk Factors Compared to Original Variant	There was no agreement across studies on whether any risk factors were associated with Alpha mortality risk including age, and sex, and ethnicity, but one study did report that Alpha infections with more comorbidities were at higher risk. • One study found mortality was higher in younger age groups than older age groups (59.0% in 1-34 year olds vs 55.4% in those 85 or older) and was higher among Blacks (69.6%), mixed or unknown ethnicity (64.8%), White (58.0%) and Asian (57.6%) (90).	Two studies which include surveillance data analysis, a retrospective cohort. Low level of evidence.

CATEGORY	KEY SUMMARY OUTCOMES	OVERVIEW OF THE EVIDENCE
	• No significant associations between Alpha and sex (p = 0.35), ethnic group (p = 0.75) or age group (p = 0.30) (79). • Male sex was a risk factor HR 1.46 (95% CI: 1.22-1.75, p<0.001, age was strongly associated, higher risk with one or more comorbidities: HR: 1.78 (95% CI: 1.26-2.52) for one comorbidity, HR: 2.03 (95% CI: 1.43-2.88) for two comorbidities, and HR: 2.89 (95% CI: 2.04-4.08) for three comorbidities; p < 0.001), and ethnicity was not associated (p=0.36) (80).	
Viral Load Compared to Original Variant	• Several studies measured viral load as Ct or estimated copies/mL for different target proteins (usually N and ORF1ab). They consistently indicate that Alpha samples are more likely to have lower Ct values or higher estimated viral loads. The median order of magnitude higher varies across studies and target protein from 2 to 10-fold differences (21, 23, 38, 39, 71, 75, 78, 86-88, 96-99, 99-103). • One study reported no significant difference in Ct values between Alpha and the original variant (median 20.2 vs. 20.1; OR = 0.1, 95% CI: −0.9 to 1.6) (87).	28 studies that were mainly surveillance data analyses, cohort or cross sectional studies that analysed the PCR Ct values across Alpha samples and original variant samples. This measure is indirect and all study designs are observational, however the conclusion that Alpha cases have lower Ct values (indicative of higher viral loads) was consistent across the majority of studies. Low to moderate level of evidence.
Animal Model of Viral Load Compared to Original Variant and Other VOCs/VOIs	• Studies in hamsters, ferrets, and rhesus macaques identified higher viral loads of genomic RNA in the nasal mucosa of Alpha infected animals compared to those infected with the original variant, or Beta variant (104-107). • A mouse model identified viral load was significantly lower for the Alpha virus in the lungs of infected mice compared to Beta and Gamma viruses in both C57BL/6 and BALB/c lungs, with no infectious virus detected in the BALB/c lungs (108). Studies in hamsters and rhesus	Seven animal model studies in agreement offer consistent evidence of decreased viral load in lungs and increased viral loads in nasal mucosa. Low level of evidence.

CATEGORY	KEY SUMMARY OUTCOMES	OVERVIEW OF THE EVIDENCE
	macaques identified viral antigens in lung tissues were lower compared to the original variant (105, 106)	
Infectious Period	Alpha cases had a longer infectious period compared to other variants. • A small prospective study in the USA that included Alpha cases (n=7) between November 2020 and January 2021, reported average infections last 13.3 days compared with 8.2 days for other variants (21). • A surveillance study that included data from Niger, Brazil, USA, France, and Japan between February until April 2021, reported Alpha had a longer infectious period with a median increase in the duration of the decline phase of the virus load of 0.86 days (HR 0.81, 95%CI: [0.75-0.88]) (22). • A surveillance study that included data from Switzerland and South Africa between October 2020 and March 2021, reported 51% (95% CI: 32–80%) increase of the infectious duration (23).	One small prospective cohort, one large longitudinal study, and one surveillance data analysis. This outcome needs further evaluation with a larger sample size and range of cases. Low level of evidence.
