Incubation Period	• A retrospective cohort that included Alpha cases (n=30) between March 2020 and March 2021 reported the mean (median) incubation period of Alpha was shorter compared to the original variant (3.53 (3.0) days vs 5.71 (5.0) days. The incubation period for Alpha in close-contact environments was 0.62 times shorter than other strains (95% CI: 0.47, 0.82) after adjusting for age and sex (24).	One small retrospective cohort. This outcome needs further evaluation with a larger sample size and range of cases. Very low level of evidence.
Immune Escape - Re-infection and Impact on Vaccine Efficacy (n=30)		
Re-infection from Infection Compared to Original Variant	Three studies estimate the rate of re-infection. A study in the UK identified re-infection of 0.7% (95%CI: 0.6-0.8) (26) and in the USA previous seropositivity rate for persons with Alpha was 0.7% compared to original variant infections at 0.9% (27). A prospective study in the UK HCWs reported there was no evidence that Alpha changed the extent of protection from any PCR positive infection in those who were seropositive (aIRR 0.40, 95%CI 0.10-1.64, p=0.20) (28).	Three re-infection studies have included analysis on Alpha and are in agreement that Alpha does not evade natural immunity. These include surveillance data analysis, cohort and ecological studies. Moderate level of evidence.

CATEGORY	KEY SUMMARY OUTCOMES	OVERVIEW OF THE EVIDENCE
Animal Model of Re-infection Compared to Original Variant	Hamsters infected with original SARS-CoV-2 and recovered were all protected from re-infection with Alpha (106, 109).	Two animal models reported consistent findings and support the evidence documented in human and *in vitro* studies. Low level of evidence.
***In vitro* studies Convalescent Sera** Compared to Original Variant	The majority of *in vitro* studies consistently showed minimal or small reductions in neutralization of Alpha compared to an original variant. Studies can be found in the dataset. There is consistency in the findings, the evidence is obtained from low quality studies.	There are many *in vitro* studies and this list is not complete at this time. Low level of evidence.
Breakthrough Infection After Vaccination / Vaccine Efficacy or Effectiveness (VE) Compared to Original Variant	Breakthrough: • Prospective and surveillance studies also report breakthrough infections were not more common 1.29 fold (95%CI 0.75-2.20, p=0.468) with Alpha cases in the USA after mRNA-1273 (Moderna) or BNT162b2 (Pfizer) (110), higher aOR 2.4 (95%CI 1.2-5.1) between first dose and up to 14 days after the second dose of BNT162b2 (Pfizer) in Israel (111), and fewer following the first dose of ChAdOx1 (AstraZeneca) aHR 0·32 (0·15-0·66) and of BNT162b2 (Pfizer) aHR 0·35 (0·17, 0·71) vaccines at 35-48 days in the UK (112) compared to unvaccinated individuals. Vaccination 1 dose: Vaccine effectiveness (VE) studies have reported protection against symptomatic and asymptomatic Alpha infection and reduced risk of hospitalization after the first dose of vaccines for Alpha infection compared to unvaccinated individuals • In a prospective UK HCW study, there was no evidence that Alpha changed the extent of protection afforded against symptomatic or asymptomatic infection by the first vaccine dose of ChAdOx-1 (AstraZeneca) or BNT162b2 (Pfizer) VE 64-67%, compared to the original variant (aIRR=1.84, 95%CI 0.75-4.49, p=0.18) (28). • In a prospective study in the UK after the first dose of ChAdOx-1 (AstraZeneca) or BNT162b2 (Pfizer), VE was 62% (23-81%) at 35-48 days (112).	27 studies reported on breakthrough infection after vaccination or VE. The generalizability depends on the representativeness of the evidence to the general population. Consistent findings across studies improves the certainty in the results. These studies include RCTs, prospective cohorts, retrospective cohorts, outbreak investigations, predictive models, case-control studies, longitudinal studies, and surveillance data analysis. High level of evidence for RCTs cohort studies, moderate evidence for prospective cohort studies and low level of evidence for all other study designs. Overall, moderate to high level of evidence.

CATEGORY	KEY SUMMARY OUTCOMES	OVERVIEW OF THE EVIDENCE
	• In the UK, VE after the first dose of BNT162b2 (Pfizer) in adults aged 70 +, VE was 60% at 28-34 days (113), adjusted VE was 71.4% (95%CI 46.5-90.6) in adults 80+ after 14 days (114). • In the UK, adjusted VE after the first dose of ChAdOx-1 (AstraZeneca) was 80.4% (95%CI 36.4-94.5) in adults 80+ after 14 days (114). • After the first dose of BNT162b2 (Pfizer) or ChAdOx-1 (AstraZeneca) the reduced risk of emergency hospital admission was estimated to be 43% (33% to 52%) and 37% (3% to 59%) respectively and a 51% (37% to 62%) reduced risk of death in adults aged 70 years and older in England (115). • Scotland, among Alpha cases, vaccination with ChAdOx-1 (AstraZeneca) or BNT162b2 (Pfizer) (>28 days post first dose (majority of cases) or second dose) was associated with a reduced risk of hospitalization compared to unvaccinated HR= 0.28 (95% CI 0.18–0.43) (116). • A prospective UK cohort study reported significantly lower viral load (mean Ct 31·3, p<0·001) in vaccinated individuals with first dose of BNT162b2 (Pfizer) or ChAdOx-1 (AstraZeneca) vs unvaccinated individuals (mean Ct 26.6) (112). Vaccination 2 doses: Across studies VE for Alpha >7 days after being fully vaccinated was similar to the original variant: • In Canada, two doses of the mRNA-1273 (Moderna) or BNT162b2 (Pfizer) vaccine had comparable adjusted VE (≥ 88%) against symptomatic Alpha, Beta, and Gamma variant infections, ≥7 days after receiving the second dose (117). • ChAdOx1 (AstraZeneca) vaccine efficacy in a UK RCT was 70.4% (95%CI 43.6- 84.5) against symptomatic COVID-19 caused by Alpha and 81.5% (95%CI 67.9-89.4) against symptomatic COVID-19 caused by original variants (118). For asymptomatic or unknown symptom infection, vaccine efficacy for non-Alpha infections (69.7%, 95%CI 33.0-86.3) were not statistically different then the uncertain estimate for Alpha (28.9%, 95%CI –77.1-71.4) (118). In Scotland the VE was 73% (95%CI 66-78) for Alpha (116).	

CATEGORY	KEY SUMMARY OUTCOMES	OVERVIEW OF THE EVIDENCE
	• ChAdOx1 (AstraZeneca) and BNT162b2 (Pfizer) combined VE in asymptomatic and symptomatic cases was 80% (95%CI 74–84%; P < 0.001) (119). • BNT162b2 (Pfizer) VE against symptomatic infection was >96% 14 days after the second dose in Israel (120, 121), 90% in 70+ in UK (113), 79.3% (95%CI 47.0-92.5) in 80+ in the UK (114), 92% (95%CI 90–93) in Scotland (116), 89.8% (95%CI 85.9-92.3) in Qatar and against severe disease was 100% (95% CI: 81.7-100) (122, 123). • NVX-CoV2373 (Novavax) vaccine efficacy in a UK RCT against Alpha 86.3% (95%CI 71.3-93.5) and original variant 96.4% (95%CI 73.8-99.5) was not statistically different (124). • A meta-analysis of VE for Alpha against symptomatic illness estimates across trials of BNT162b2 (Pfizer) reported VE after dose 1:51% (95%CI: 47-55%), after dose 2: 93% (95%CI: 90-96%) and ChAdOx1 (AstraZeneca) VE after dose 1: 49% (95%CI: 43-55%) after dose 2: 66% (95%CI: 54-75%) (125). • In the UK, VE against hospitalizations was 86% (95%CI 53-96) for ChAdOx1 (AstraZeneca) and 95% (95%CI 78-99) BNT162b2 (Pfizer) in the UK and was similar to Delta (126). • Germany, In an Alpha outbreak at a long-term care facility in Germany 7 days post two doses of BNT162b2 (Pfizer), those vaccinated with BNT162b2 (Pfizer), had less hospitalizations (12.5% vs 100%), fewer required oxygen therapy (6.3% vs 75%), and fewer required oxygen therapy after discharge (6.3% vs 25%) compared to unvaccinated cases (29). The infectious period was shorter for vaccinated patients 7.5 days (95%CI 7–17.3) than unvaccinated patients 31 days (95%CI 21.5–34.5; p=0.003) and viral load was lower in fully vaccinated patients, but not statistically significant (6.45 vs. 8.15 log10 copies/mL; p = 0.10) (29). • In Greece there was no difference in viral load (measured by CT value) (p=0.70) or the presence of symptoms (p=0.76) between fully vaccinated BNT162b2 (Pfizer) HCWs and unvaccinated cases during an outbreak of Alpha (127).	

CATEGORY	KEY SUMMARY OUTCOMES	OVERVIEW OF THE EVIDENCE
Animal Model of Vaccination Compared to Original Variant	• Hamsters vaccinated with ChAdOx1 (AstraZeneca) and then challenged with Alpha resulted in no weight loss, no lung pathology and no virus detected in tissue samples compared to controls who had extensive pulmonary pathology (128). Another study reported vaccinated hamsters with ChAdOx1 (AstraZeneca) vaccine and challenged with Alpha continued to gain weight while control animals had weight loss and extensive pulmonary pathology caused by Alpha in the control animals was observed, but not in the vaccinated animals (129). • Animals vaccinated with other vaccine candidates including spike RBD proteins (130-133) and SARS-CoV-2 infected human plasma, DNA vaccines (134), and circRNA vaccines (135) all had neutralization activities against Alpha.	18 studies in animals were inconsistent in weight loss but consistent with pathology findings which are in agreement with human studies and *in vitro* studies. Low level of evidence.
***In vitro* study of Vaccinated Sera** Compared to Original Variant	• There are many *in vitro* studies that are available in the dataset. The *in vitro* studies consistently showed minimal or small reductions in neutralization of Alpha compared to an original variant. They have not been summarized in the evidence profile.	There are many *in vitro* studies and this list is not complete at this time. Low level of evidence.
Animal Model of Therapeutics Compared to Original Variant	• A number of monoclonal antibodies tested protected mice and hamsters against Alpha (136, 137). • Locked nucleic acid antisense oligonucleotides (138) and 4'-fluorouridine, a ribonucleoside analog (139) efficiently suppressed viral replication in hamsters and ferrets, respectively. • Convalescent plasma treatment resulted in decreased viral copy number in the lungs of mice infected with either the wild-type or Alpha variant. Convalescent plasma treatment did not reduce viral copy number in brain tissue of mice infected with Alpha compared to wild-type (132). • LY-CoV555 monotherapy protected against the Alpha infections whereas AbbVie 2B04/47D11 showed a partial loss of activity against Alpha (140).	Five animal models. Low level of evidence.
Therapeutics	• A case-control study that included Alpha cases (n=30) found that compared to non-Alpha patients, Alpha patients more often received dexamethasone (72% vs 42%, P=0.049), remdesivir (14% vs 5%, P=0.547), and tocilizumab (4% vs 0% P=1.000) (83).	One small case-control study. This outcome needs further evaluation with a

CATEGORY	KEY SUMMARY OUTCOMES	OVERVIEW OF THE EVIDENCE
		larger sample size and range of cases. Very low level of evidence.
Testing and Diagnostics (n=46)		
Testing and Detection	• PCR is effective at detecting and distinguishing the variant (141-148). • Detection of Alpha in wastewater at proportions as low as 0.1% of SARS-CoV-2 (149) and PCR approaches are effective in detecting Alpha in wastewater (150). • Multiple studies report reliable assays for rapid detection of variants including detection in wastewater samples (143, 149, 151-153).	46 studies, 40 diagnostic test accuracy studies, 6 surveillance data analyses that also described a new test or set of primers. As these are all describing different tests the studies are considered to be individual and cannot be summarized together. Low level of evidence.
Spread Epidemiology (n=153)		
VOC Emergence Over Time	Studies were captured from many countries around the world, most describe the first detection of Alpha in mid to late December followed by a rapid increase in the variant over 3.5 to 10 weeks. It was noted to have become the dominant strain in several studies (38, 78). Alpha infections plateaued in April, have continued to decrease and was surpassed by the Delta variant in mid-June (10, 14). A predictive model forecasting variants in North America estimates Alpha will reach close to 0% by October 2021 (20). • Canadian studies conducted between December 2020 and March 2021: Two Canadian studies detail that Alpha cases were initially clustered in two regions and quickly spread (154, 155). Similarly, two studies from Ontario have documented the rapid increase in Alpha (16, 156).	147 studies report on the emergence and spread of Alpha in a country or region over time. Most of these studies are based on surveillance data, prospective cohorts often of HCWs, retrospective cohorts of hospital records, longitudinal studies, and ecological studies. Point prevalence or case reports of infected travellers were excluded from this summary. Low to moderate level of evidence.
Attribution to Alpha	In a model fit to data in the UK, an increase of 0.1 in the proportion of Alpha, considering the pre-peak period, was found to be associated with 35.8% increase in the height of the second wave peak. During the period from 1 January to	One model used to estimate the additional burden of COVID-19 due to Alpha.

CATEGORY	KEY SUMMARY OUTCOMES	OVERVIEW OF THE EVIDENCE
	25 February 2021, an increase of 0.1 in the proportion of Alpha was related with a 15.3% increase in the cumulative number of deaths during that period (157).	Low level evidence.
Risk Factors for Spread	• An ecological study conducted in Toronto and Peel regions in Ontario showed that Alpha growth rate (11.3%, 19.8%, and 30.8%), overall cases (19.0%, 32.7%, and 48.3%) and VOC cases (18.4%, 30.8% and 50.8%) were positively correlated with the proportion of essential workers (30.4%, 47.9% and 63.2%) and median income ($33k, $45k and $60k CAD) of the community, respectively (158). • Surveillance data from France found the Alpha variant infections were more common among older individuals compared to Beta or B.1.525. In hospital settings, there was an under-representation of Alpha compared to Beta. In specific regions of France, the odds of being infected by the original variant or a B.1.525 virus were either identical or lower than being infected by Alpha (53). • Three studies report a shift towards younger individuals being infected with Alpha in France, Germany and Japan, however the cause of this shift in demographics is not explained and may be due to a combination of factors such as increased contacts in younger age groups, and vaccine coverage in older groups rather than a biological explanation (24, 87, 159, 160)	Five studies assessed risk factors. These include ecological studies, prospective cohorts, predictive models, and surveillance data analysis. Moderate level of evidence for prospective cohort studies. Low level of evidence for all other study designs.
Genomic Analysis of Spread	• Results do not suggest that the canonical mutations of VOC Alpha evolved independently in different locations and points to an origin in and spread of the VOC Alpha from the UK (161-163).	Four studies of genomic surveillance data. Low level of evidence.

CFR = case fatality rate, CI = confidence interval, Ct = cycle threshold, ICU = intensive care unit, OR = odds ratio, PCR = polymerase chain reaction, VE = vaccine effectiveness, OR= odds ratio, aOR= adjusted odds ratio, aHR = adjusted Hazard Ratio, aPR= adjusted Prevalence Ratio, HCW= Healthcare worker

Methods:

A daily scan of the literature (published and pre-published) is conducted by the Emerging Science Group, PHAC. The scan has compiled COVID-19 literature since the beginning of the outbreak and is updated daily. Searches to retrieve relevant COVID-19 literature are conducted in Pubmed, Scopus, BioRxiv, MedRxiv, ArXiv, SSRN, Research Square and cross-referenced with the COVID-19 information centers run by Lancet, BMJ, Elsevier, Nature and Wiley. The daily summary and full scan results are maintained in a Refworks database and

an excel list that can be searched. One of the foci is to identify studies as variants of concern or under investigation. Studies identified under this foci are further characterized in our VOC/VOI database and VOC results are extracted into this review. A cross check for relevant articles is also conducted within the databases using targeted keyword searching (B.1.1.7 OR Alpha OR 202012/02 OR 501Y.V1).

This review contains research published up to July 1, 2021.

Each potentially relevant reference was examined to confirm it had relevant data and relevant data was extracted into the review.

Peer-review

This document underwent peer-review by a subject matter expert, and editorial and science to policy review by the Office of the Chief Science Officer.

There is a lot of overlap from these reports and research publications.
Public Health England. Investigation of novel SARS-COV-2 variant: Variant of Concern 202012/01 [Internet]. 2020 Dec	The VOC (Alpha) has grown rapidly in the UK and has been assessed as having substantially increased transmissibility
Public Health England. Analysis of transmissibility based on genomics [Internet]. 2020 Dec	Indication that Alpha grows 71% (95% CI: 67%-75%) faster per generation (6.5 days), yet consistent frequency does not indicate a constant selective advantage of Alpha
NERVTAG. NERVTAG meeting on SARS-CoV-2 variant under investigation VUI-202012/01 [Internet]. 2020 Dec	Moderate confidence that Alpha demonstrates a substantial increase in transmissibility compared to other variants.

NERVTAG. Update note on B.1.1.7 severity [Internet]. 2021 Feb	It is likely that infection with VOC Alpha is associated with an increased risk of hospitalization and death compared to infection with original variant viruses

Emerging Evidence on COVID-19

Living Summary of SARS-CoV-2 Alpha, Beta and Gamma Variants of Concern

Highlights up to June 1, 2021

Introduction

SARS-CoV-2 **variants of concern** (VOCs) are circulating variants that have been flagged by national or global public health organizations. VOCs are of concern when compared to the original SARS-CoV-2 variants, as their complement of mutations lead to increased transmissibility, increased virulence (morbidity or mortality), changes in clinical disease presentation, immune evasion, reduced effectiveness of treatments, vaccines and/or public health measures and/or diagnostic detection failures (1, 2). Canada has established a national definition (2). The goal of this living summary on the SARS-CoV-2 VOC literature is to highlight new data on the B.1.1.7 (Alpha), B.1.351 (Beta) and P.1 (Gamma) VOCs, their epidemiology and how the attributes of the VOCs may impact the management of the pandemic. The focus will be on changes to epidemiological parameters (e.g., transmission rates, clinical outcomes of severity and mortality, shifts in age groups affected or asymptomatic proportions), impacts on diagnostic tests, immune evasion/vaccine effectiveness and impacts on other public health measures. In May 2021, the World Health Organization (WHO) released naming system for VOCs and variants of interest (VOIs) using Greek letters to improve the ease of communication on variants and potential stigma related to places where variants were first identified, which has been adopted in this report (1). Literature on the Delta VOC is highlighted in a separate living summary.

TABLE 1: CURRENT VARIANTS OF CONCERN (VOCS)

WHO name (05-21)	Pango lineage	Nextstrain clade	GISAID clade	Alternate name	First detected in	Earliest samples	Characteristic spike mutations
Alpha	B.1.1.7	20I/501Y.V1	GR/501Y.V1	VOC 202012/01	United Kingdom	Sep 2020	69/70del, 144del, N501Y, A570D, D614G, P681H, T716I, S982A, D1118H
Beta	B.1.351	20H/501Y.V2	GH/501Y.V2	VOC 202012/02	South Africa	Aug 2020	D80A, D215G, 241/243del, K417N, E484K, N501Y, D614G, A701V
Gamma	P.1, B.1.1.28.1	20J/501Y.V3	GR/501Y.V3	VOC 202101/02	Brazil and Japan	Dec 2020	L18F, T20N, P26S, D138Y, R190S,

							K417T, E484K, N501Y, D614G H655Y, T1027I, V1176F
Delta	B.1.617.2[1]		G/452R.V3		India	Oct 2020	L452R, D614G, P681R, ± (E484Q, Q107H, T19R, del157/158, T478K, D950N)

[1] B.1.617.2 (Delta) was added to the VOC list May 11, 2021 and is summarized in a separate evidence profile.

Variants of interest (VOIs), also referred to as variants under investigation (VUI), is a designation used to flag a variant that has the potential to be a VOC, but requires further investigation or evidence. Indicators for a VOI designation include; phenotypic change or acquisition of mutations with established phenotypic implication AND has been the cause of community transmission/clusters or is detected in multiple countries OR is assessed to be a VOI by an authority such as WHO (1, 2). In Canada, the Canadian SARS-CoV-2 Variant Surveillance Group (CSVSG) has established the VOI definition, and are responsible for the evaluation and designation of potential VOIs (2). Data on VOIs is collected, but is not highlighted in this summary. The full dataset in excel can be accessed here and filtered by the VOIs of interest.

This living evidence review profiles the key evidence on Alpha, Beta and Gamma VOCs, including changes in epidemiology, immune evasion/vaccine effectiveness, impacts on diagnostic testing, and public health measures.

What's New

This update includes literature up to June 1, 2021. A total of 345 new studies on B.1.1.7 (Alpha, n=200 studies), B.1.351 (Beta, n=163) or P.1 (Gamma, n=91) since the last update on April 28, 2021 are included in the dataset.

Key Points

As of June 1, 2021 there were 548 studies that report on a VOC or VOI. 501 studies identified report on B.1.1.7 (Alpha), B.1.351 (Beta) and P.1 (Gamma) and were considered for the summaries below. Studies on VOIs (n=47 studies), case reports and point prevalence estimates (n=35), and cell infectivity, binding affinity, or genomic characterization studies (n=77) were not summarized in the evidence profiles. Overall summaries can be found in the key points (Table 2) with more detailed summaries of each VOC in the corresponding review sections. Individual study details can be found in the Excel dataset accessed here. Overall, the predominance of available evidence was on Alpha (n=342) compared with Beta (n=229) and Gamma (n=125).

Transmissibility:

- All studies showed increased transmissibility for Alpha (Table 5), Beta (Table 4), and Gamma (Table 3) compared to the original variant although the extent ranged greatly. For Alpha, two Canadian studies

using general population surveillance data and household transmission data reported 34% increased transmissibility and 31% higher secondary attack rates, respectively. Alpha had higher transmission efficiency than Beta and Gamma variants.

Clinical Severity:

- For Alpha there was conflicting evidence on odds of being admitted to hospital, whereas a small number of studies reported higher odds of hospitalization for both Beta and Gamma. Conflicting associations were reported for ICU admissions with Beta and Alpha and higher odds for Gamma. Risk of mechanical ventilation or higher severity score in the ICU was not associated with Alpha, Beta, compared to the original variant. However, these data are based on a limited number of studies that retrospectively analysed surveillance and hospital data
- For severity indicators,
    - A few studies on Alpha, Beta and Gamma reported age-stratified risk of hospitalization and increased odds in adult age groups between 20-59 years old, while others reported no associations**.**
    - Several studies also reported a lower proportion of pre-existing conditions among VOC cases with the exception of obesity.
- Associations with mortality were conflicting across studies for Alpha, Beta and Gamma. Increased ICU mortality for Beta was reported in one study. Risk of mortality was reported to have increased in some adult age groups for Alpha and Gamma variants.
- Compared to the original variant, viral load was consistently 2-10 fold higher for Alpha. It was also higher for Gamma and Beta than the original variant, but lower than that of Alpha.
- There were no studies assessing infectious period for Gamma and Beta. One small study, 7 people with Alpha, found that average infection, cultured virus, with Alpha lasted for 13.3 days compared with 8.2 days for other variants. Additional research is needed to improve confidence in this result.
- There were no studies on incubation period for any of the VOCs.

Immune Escape:

- There is no evidence that the reinfection rate for Alpha has changed compared to the original variant, no data for Beta. Two studies from Brazil that suggest there may be substantial reinfections from Gamma, however this is based on ecological analyses and needs further study.
- Data from vaccine effectiveness studies has reported reduced protection after the first dose of vaccines, but equivalent protection after the second dose in most studies for Alpha and Gamma, whereas the studies for Beta have had variable results.

Other Categories:

- Additional categories related to diagnostic performance and epidemiological research on spread and impact of non-pharmaceutical interventions are summarized in the in-depth VOC sections.
    - No studies evaluating diagnostic or detection tests for SARS-CoV-2 described failure or performance issues for detecting the VOCs, besides the well characterized S-gene drop out for Alpha.
    - Several predictive models studies reported on non-pharmaceutical interventions (e.g.restrictions to gatherings, closures, masking and lockdowns). Although higher stringency, more closures and restrictions, was needed to control the VOCs due to higher transmissibility, no changes to individual interventions were needed.

- Studies on VOC introduction and spread in a geographic region were not included in the table below, but summaries are available within the profiles for the individual VOCs, as were summaries of animal models and in vitro studies on re-infection, vaccine efficacy and potential impact of VOCs on therapeutics.

Categories of evidence in the tables below include the following if reported:

Transmissibility includes changes in transmissibility, secondary attack rates, and estimates of selective advantage.

Clinical severity includes proportion of infections that are symptomatic, proportion of severe disease and mortality as well as risk factors for severe disease or mortality, viral load, infectious period, incubation period. Note risk factors for severe disease would include special populations e.g. persons who are pregnant if they are reported.

Immune Escape includes changes to vaccine efficacy, risk of re-infection in humans, animal models, *in vitro* or *in silico* experiments as well as impacts on therapeutics if reported.

Diagnostic / Detection Test Failure is captured in the individual sections, and will only be included in Table 2 if there is a concern about test performance.

Other Epidemiology includes all studies that document the emergence and spread of VOCs in a geographic area, ecological studies that examine VOC spread and risk factors for hot spots, and studies on effective public health interventions against VOCs, genomic epidemiology as subcategories.

TABLE 2: SUMMARY OF KEY EVIDENCE OF P.1 (GAMMA) VOC (N=125), B.1.351 (BETA) VOC (N=229) AND B.1.1.7 (ALPHA) VOC (N=342)

Category	P.1 (Gamma)	B.1.351 (Beta)	B.1.1.7 (Alpha)
TRANSMISSION EFFICACY			
Transmissibility Compared to Original Variant or to Alpha	3 surveillance data analyses, 1 cross-sectional study, and 1 predictive model: • 27% higher in France (combined Gamma / Beta) (3) • 160% - 100% higher in Brazil (4, 5) • A model studying Gamma in Italy reported 12% - 39% higher transmissibility depending on whether Gamma exhibits any immune evasion (6).Other studies place Gamma transmissibility between the original variant and Alpha (7) Low level of evidence.	5 reports of surveillance data: • 27% higher in France (combined Gamma / Beta) (3) vs. the original variant. • 55% (8, 9) and 20-100% higher in South Africa (10) vs. the original variant. • 15.8%-17.1% transmission advantage compared to Alpha, in some regions of France from April to May 2021 (11). Low level of evidence.	34 surveillance and observational studies: • Alpha increased relative transmissibility (1-$R_{voc}/R_{original\ variant}$) estimates varied between 34-118% higher across studies, some of the variation by time (12) and country (higher in UK) (9): o Canada 34% (95% CI: 31-38) (13), USA 35-59% (14, 15). o UK: Ranged from 43-118% (9, 12, 14, 16-18), 13.4% - 41.3% across UK regions in Dec 2020 (19). o Europe: France 41 -52% (3, 20), Denmark 55%, Switzerland 54-74% (14), (21), Norway 24% (22), Italy 55-57% (23), Wales and the USA 65-72% (9). o Israel 45% (24). o Japan estimated a 60% increase in relative transmissibility of VOCs (not specified) (25). o Alpha had higher transmission efficiency than Beta and Gamma variants (7) • Similarly ratios of secondary attack rates among household transmission studies was 30-70% higher in Canada (26), Norway (22) and Denmark (27). Low to moderate level of evidence.

Category	P.1 (Gamma)	B.1.351 (Beta)	B.1.1.7 (Alpha)
		CLINICAL SEVERITY	
Virulence / Severity or Duration of Disease Compared to Original Variant or to Alpha	2 surveillance studies: • A higher proportion of cases were hospitalized (p<0.001) (28). • Higher odds of being admitted to hospital (aOR 2.6, 95%CI 1.4-4.8) (28). • Higher odds of being admitted to ICU (aOR 2.2, 95%CI 1.8-2.9) (28). • Exponential growth of hospitalized cases was reported in Rio Grande do Sul and Porto Alegre (29). Low level of evidence.	4 studies including surveillance and observational studies: • Higher odds of hospitalization due to Beta vs. the original variant (aOR 3.6, 95% CI: 2.1-6.2) (28) or Alpha (OR 1.56) in several European countries (11). Conflicting evidence on Beta related ICU admissions, with a higher odds (aOR 3.3, 95% CI: 1.9-5.7) reported in European countries (30), and a lower proportion (35% vs. 48.5%, p=0.03) reported in South Africa (31), compared to the original variant. Low level of evidence.	17 surveillance and observational studies: • Conflicting evidence on prevalence of symptomatic disease found no difference in one study and fewer symptomatic cases (p<0.001) in another (28, 32). • 7 studies found higher odds of being admitted to hospital (aOR 1.36 – 1.7 and aHR 1.34) (28, 33-38) and one report no difference (39). • Two studies found higher odds of ICU admission (aOR 2.3, aHR 1.99) (28, 40). • In one study, there was no association of Alpha and severe disease and death (aPR 1·02) among hospitalized cases (41). • There was no significant difference in ICU scores or mechanical ventilation requirement between Alpha, Beta, and the original variant (42). • Higher rates of hypoxia on admission to hospital were reported in two studies (43, 44). Moderate level of evidence.
Severity Risk Factors Compared to Original Variant or to Alpha	1 European surveillance study: • Gamma cases had a 3.0 - 13.1 times higher odds of hospitalization in the age groups 20–79 years (28).	3 studies including surveillance and observational studies: • Beta cases had higher odds of hospitalization among adults aged 40-59 and 60-79 (OR 3.5-3.6) in several European countries (28), and hospitalized cases were significantly	10 observational studies: • One study of hospitalized COVID-19 cases reported a higher proportion of females (48.0% vs 41.8%, p=0.01), fewer frail patients (14.5% vs 22.4% p=0.001) and a higher proportion of obese cases (30.2% vs 24.8%,

Category	P.1 (Gamma)	B.1.351 (Beta)	B.1.1.7 (Alpha)
	• Admission to ICU was 2.9–13.9 times higher in ≥ 40 age groups (28). • Pre-existing conditions were lower 27.8% in Gamma vs 89% original variant, p<0.001 (28). Low level of evidence. 3 other observational studies were conducted in which whole genome sequencing was not performed (very low level of evidence).	older (57 vs. 54 years, p=0.03) in South Africa (31) compared to original variant cases. • Conflicting evidence on the age of Beta ICU admissions, with a higher odds for adults aged 40-59 (aOR 8, 95% CI: 3.7-17.3) in several European countries (28) and no significant difference in age (63 vs. 67 years, p=0.15) in France (42), compared to the original variant. • Beta cases were less likely to have comorbidities compared to original variant cases in Europe and South Africa (28, 31). Low level of evidence.	p=0.048), but no difference by age or ethnicity (43). • Studies reported no significant difference in patient age, gender and median length of hospital stay (35, 42). Age difference was statistically significant in another study (37 vs. 39 years) (45). • One study reported a 3.0 higher odds ratio of hospitalization in 20–39 year olds and a 2.3 times higher odds ratio in 40–59 years and that pre-existing conditions were lower (44.8% vs. 89% p<0.001) (28). • A hospital study from France noted mean age was 59.2, down from 70.7 and patients without comorbidities increased 16% to 42% (p=0.007) (44). Low to moderate level of evidence.
Mortality Compared to Original Variant or to Alpha	2 observational studies and 1 predictive model: • Gamma had lower odds of mortality overall (aOR 0.6, 95%CI 0.3-1.0) (28). • Higher hospital mortality rates in adults aged 18-50 (46). • Predictive model estimated mean mortality 1.5 (50%CrI	3 studies including surveillance and observational studies: • Conflicting evidence from studies in different countries/contexts on Beta mortality, with South Africa reporting an increased proportion of mortality (36.4% vs. 32.6%, p=0.26) (31), and several European countries reporting no difference in the odds of death (aOR 1.1, 95% CI: 0.4-3.4) (28) compared to the original variant.	16 surveillance and observational studies: • Five studies reported no significant difference in mortality overall (2.1 vs. 4.1%) (32, 35, 38, 39), or after 28 days (OR: 0.90, 95%CI 0.57-1.41, p=0.64) (36). • One study reported lower odds of mortality (aOR 0.5, 95%CI 0.3-0.9) (28). • Eight studies reported higher risk of mortality: higher 28 day hazard of death (55%, 95% CI: 39-72%) (47), aHR 1.59 (95%CI 1.25-2.03) (40), aHR 1.67 (95%CI 1.34 – 2.09;

Category	P.1 (Gamma)	B.1.351 (Beta)	B.1.1.7 (Alpha)
	1.2–1.9) times higher after emergence of Gamma (5). Low level of evidence.	• Higher proportion of Beta ICU mortality (74.4% vs. 57.1%, p=0.002) compared to the original variant in South Africa (31), and a higher odds of ICU death (OR 5.67, 95% CI: 1.04-30.81, P=0.04) compared to Alpha in France (42). Low level of evidence.	P <0.0001) (41). HR 1.64 (95%CI 1.32 - 2.04, p <0.001) (48), which equates to an increase of 2.5 to 4.1 deaths per 1000 detected cases (37, 49, 50). An ecological study estimated that Alpha was 33% more lethal in the UK (51). • Among ICU patients in France, Beta cases had higher odds of dying within 60 days after ICU admission compared to Alpha cases (OR 5.67, 95% CI 1.04-30.81) (42). Moderate level of evidence.
Mortality Risk Factors Compared to Original Variant	1 surveillance study from Brazil: • Mortality in COVID-19 cases <60 years old increased from 18% in Nov 2020 to 28% in Feb 2021 (52). • Mortality among people with no pre-existing conditions was higher after Gamma emerged for women 20-39 years old (RR 5.65, 95%CI 2.9-11.03; p <0.0001) and 40-59 years old (RR 7.7, 95%CI 5.01-11.83; p <0.0001) (52). Low level of evidence.	No studies	2 surveillance and retrospective cohort studies: • One study found mortality was higher in younger age groups than older age groups (59.0% in 1-34 year olds vs 55.4% in those 85 or older) and was higher among Blacks (69.6%), mixed or unknown ethnicity (64.8%), White (58.0%) and Asian (57.6%) (47). • Another study found no increased mortality by sex (p = 0.90), ethnic group (p = 0.64) or age group (p = 0.15) (40). Low level of evidence.
Viral Load Compared to Original Variant	2 surveillance studies: • Viral load from Gamma cases were ~ 10-fold higher than	No studies	22 observational studies and surveillance analyses:

Category	P.1 (Gamma)	B.1.351 (Beta)	B.1.1.7 (Alpha)
	non- Gamma (original variants) cases (53). • Viral load was higher than original variant but lower than Alpha (3). Low level of evidence.		• Consistently found lower Ct values or higher estimated viral loads. The median order of magnitude higher varies across studies and target protein from 2 to 10 fold differences (3, 32, 35, 45, 54-59, 59-61). Low to moderate level of evidence.
Infectious Period Compared to Original Variant	No studies	No studies	One small study (n=7 Alpha cases) conducted in the USA calculated average infections last 13.3 days compared with 8.2 days for other variants (57). Very low level of evidence.
Incubation Period	No studies	3 studies including surveillance and observational studies: • Beta cases had higher odds of hospitalization among adults aged 40-59 and 60-79 (OR 3.5-3.6) in several European countries (28), and hospitalized cases were significantly older (57 vs. 54 years, p=0.03) in South Africa (31) compared to original variant cases. • Conflicting evidence on the age of Beta ICU admissions, with a higher odds for adults aged 40-59 (aOR 8, 95% CI: 3.7-17.3) in several European countries (28) and no significant difference in age (63 vs. 67 years, p=0.15) in France (42), compared to the original variant.	No studies.

Category	P.1 (Gamma)	B.1.351 (Beta)	B.1.1.7 (Alpha)
		• Beta cases were less likely to have comorbidities compared to original variant cases in Europe and South Africa (28, 31). Low level of evidence.	
IMMUNE ESCAPE - Potential Impact on Vaccine Efficacy/Effectiveness, Possibility of Re-infection			
Re-infection from Infection Compared to Original Variant	2 surveillance studies: • Assuming 78% of population was previously infected, 28% of the cases in Manaus from Nov 2020 to Jan 2021 estimated to be re-infections (4). • 16.9% of P.1 cases (95% CI 9.48-28.5) in Manaus from Jan 2021 to Mar 2021 estimated to be re-infections (81). Low level of evidence.	3 studies including case reports and observational studies: • Three cases of re-infection with Beta have been reported (62-64). Very low level of evidence.	3 studies found Alpha does not evade natural immunity: • One estimated re-infection rate of 0.7% (95%CI: 0.6-0.8) (65). • In a USA study, previous seropositivity rate for persons with Alpha was 0.7% compared to non- VOC infections at 0.9% (38). • A UK study found no evidence that Alpha changed the extent of protection from any-PCR positive infection in those who were seropositive (aIRR 0.40, 95%CI 0.10-1.64, p=0.20) (66). Moderate level of evidence.
Breakthrough Infection After Vaccination / Vaccine Efficacy or Effectiveness Compared to Original Variant	2 case-control studies: Vaccination 1 dose: • Vaccination with at least one CoronaVac dose was associated with a 0.50-fold reduction (adjusted VE, 49.6%; 95% CI 11.3 - 71.4) in the odds of symptomatic	7 studies including RCTs, and observational studies: Breakthroughs: • No breakthrough infections were identified >14 days post second dose (mainly Pfizer) in Israel case control study (67).	13 studies that included RCTs, cohorts and surveillance studies: Breakthroughs: • An outbreak investigation in HCWs reported two fully Pfizer-BioNTech vaccinated physicians became infected with Alpha, with the second dose given 1 month before symptom onset (73).

Category	P.1 (Gamma)	B.1.351 (Beta)	B.1.1.7 (Alpha)
	SARS-CoV-2 infection 14 days after first dose (82). Vaccination 2 doses: • Moderna or Pfizer vaccine 7 or more days after the second dose had an adjusted VE against symptomatic P.1 infection of 88% (95%CI 61-96) versus symptomatic wild-type infection (93%, 95%CI 87-96). Adjusted VE for one dose against P.1 was 43% (95%CI 22-59) versus wild-type (61%, 95% CI 53-67) (72). Low level of evidence.	• 50% (13/26) of nursing home residents and 5.2% (1/19) of staff who received the Pfizer-BioNTech vaccine experienced breakthrough Beta infections (64). Vaccinated 2 doses: • AstraZeneca (ChAdOx1-S): 10.4% efficacy for prevention of symptomatic disease (68). • Johnson and Johnson: VE was 52% and 64% for moderate and 73% and 82% for severe disease at 14 days and 28 days respectively (69). • Novavax (NVX-CoV2373: 51.0% (95% CI: -0.6 – 76.2) VE against symptomatic disease in HIV-negative individuals (70). • Pfizer-BioNTech (BNT162b2): 75.0% (95% CI: 70.5% – 78.9%) VE against Beta infection ≥ 2 weeks after the second dose in Qatar (71). A VE of 50% (95% CI: 34%-73%) among nursing home residents (median age: 87.0±8.2 years) for two doses spaced 19 days apart (64). • Moderna/Pfizer-BioNTech: Comparable VE of ≥ 88% against symptomatic Beta infection, ≥ 7 days after receiving the second dose (72).	• In the USA, breakthrough cases of Alpha were not more common than the original variant (1.29 fold, 95%CI 0.75-2.20, p=0.468) (74). Vaccination 1 dose: • Pfizer-BioNTech (BNT162b2) in Israel where 94% of cases were Alpha, vaccine effectiveness against symptomatic infection between the first dose and up to 14 days after the second dose (aOR 2.4 (95%CI: 1.2 to 5.1) (67). • Pfizer-BioNTech (BNT162b2) or AstraZeneca (ChAdOx1-S) first dose of vaccine reduced risk of emergency hospital admission in adults aged 70 years and older by 43% (33% to 52%) and 37% (3% to 59%) in England, respectively (75). • Risk of death was reduced by 51% (37% to 62%) in adults aged 70 years and older in England who had received one dose of Pfizer-BioNTech (75). • A UK study found no difference in protection for Alpha compared to other variants following a first vaccine dose (aIRR=1.84, 95%CI 0.75-4.49, p=0.18) (66). Vaccination 2 doses: • AstraZeneca/ COVISHIELD (ChAdOx1) vaccine effectiveness was 70.4% (95%CI 43.6-

Category	P.1 (Gamma)	B.1.351 (Beta)	B.1.1.7 (Alpha)
			84.5) vs 81.5% (67.9 - 89.4) in original variants in a UK RCT (76). • Novavax (NVX-CoV2373) vaccine efficacy against Alpha 86.3% (71.3 to 93.5) vs the original variant 96.4% (73.8 to 99.5) in a UK RCT (77). • Pfizer-BioNTech (BNT162b2) in Israel where 94% of cases were Alpha, vaccine effectiveness was >96% 14 days after the second dose (78) and >90% in 70+ year olds (79) • In Canada, two doses of the Moderna (mRNA-1273) or Pfizer-BioNTech vaccine had comparable adjusted vaccine effectiveness (≥ 88%) against symptomatic Alpha, Beta, and Gamma variant infections, ≥ 7 days after receiving the second dose (72). Variable levels of evidence from RCT (moderate to high) to case reports (very low).
		Low to moderate level of evidence.	

CFR = case fatality rate, CI = confidence interval, Ct = cycle threshold, ICU = intensive care unit, OR = odds ratio, PCR = polymerase chain reaction, VE = vaccine effectiveness, OR= odds ratio, aOR= adjusted odds ratio, aHR = adjusted Hazard Ratio, aPR= adjusted Prevalence Ratio

Overview of the Evidence

Study designs included in this summary ranged from low risk of bias double blinded RCTs to a number of different observational study designs with varying levels of evidence. The observational studies offer low to moderate evidence depending on the specific study design and consistency across studies. Descriptive studies included in this report such as case series and case reports, predictive models, ecological studies, animal models and *in vitro* studies are low to very low evidence and generally can only be used to generate hypotheses that need to be further examined with a different study design. Given this very wide variation, an indication in the level of confidence of the evidence is provided for a particular outcome. Study designs are provided, but no formal risk of bias assessment has been conducted.

There are several knowledge gaps or areas where there is very little research noted in the key points table and additional research is needed to improve confidence in summary results particularly for Beta and Gamma.

CONTENTS

P.1 (GAMMA)

The excel dataset includes summaries of individual studies and can be accessed here. Below is the detailed evidence profile developed for Gamma and covers data on changes in transmission efficiency, changes in clinical severity, immune escape, testing and diagnostics, and other epidemiological studies mainly on VOC spread.

Table 3: Evidence Profile of P.1 (Gamma) VOC (n=125)

CATEGORY	KEY SUMMARY OUTCOMES	OVERVIEW OF THE EVIDENCE
Transmission Efficiency		
Transmissibility Compared to Original Variant	Increased transmissibility above the original variant: • 27% higher in France for combined Gamma and Beta (3). • 2.6 (95% CI: 2.4-2.8) times higher (4) and 2.0 (50%CrI 1.7-2.4) times more transmissible with median cross immunity	Five studies provided estimates of Gamma transmissibility including: 3 surveillance data analyses from Brazil (2) / global (1), 1 cross-sectional study from France, and 1 predictive model from Italy. Across studies there is little

CATEGORY	KEY SUMMARY OUTCOMES	OVERVIEW OF THE EVIDENCE
	estimated at 68% (50%CrI 54-79) in Brazil (5). • 1.12 (95%CI 1.03-1.23) times more transmissible with complete immune evasion to 1.39 (95%CI 1.26-1.56) with complete cross protection in Italy (6). • Other studies place Gamma transmissibility between the original variant and Alpha (Alpha) and show the transmissibility of Gamma has slightly decreased over time from Jan 2021 to April 2021 worldwide (7).	consistency. Heterogeneity in increased transmissibility estimates may be due to factors such as geographic location and time points in which estimates were taken. Low level of evidence.
Non-Pharmaceutical Interventions Compared to Original Variant	• Gamma emerged in Manaus Brazil in late Nov 2020 and showed a high effective reproductive number (Re) of 2.6 (95% Highest Posterior Density [HPD]: 1.5-4.5) during Dec 2020. After increased social distancing restrictions, the Re was estimated to have decreased to 1.2 (95% HPD: 0.9-1.6) in late Dec 2020 and January 2021 (53). In comparison, a previous variant also had a Re of 2.6 (HPD 1.6-3.8) in Mar 2020 that decreased to 1.0 (HPD 0.8-1.2) in Apr 2020 after social distancing increased by more than 50% in Manaus (due to implementation of NPIs).	1 surveillance data analyses from Brazil. Low level of evidence.
Clinical Severity		
Virulence / Severity or Duration of Disease Compared to Original Variant	• A higher proportion of hospitalized Gamma cases were reported compared to the original variant (20% vs. 7.5% p<0.001) (28). • One study reported a higher adjusted odds ratio (aOR 2.6, 95%CI 1.4-4.8) of Gamma cases being admitted to hospital or to ICU (aOR 2.2, 95%CI 1.8-2.9) compared to original variant (28). • Hospitalized cases exhibited exponential growth in Rio Grande do Sul, with an average doubling time of 13.4 days and a daily growth rate of 5.3% from Feb 2021-Mar 2021 (29). • Similar exponential growth (doubling time 13.3 days, daily growth rate 5.4%) for	2 surveillance data analyses from Europe and Brazil. Low level of evidence.

CATEGORY	KEY SUMMARY OUTCOMES	OVERVIEW OF THE EVIDENCE
	hospitalizations was reported in the city of Porto Alegre (29).	
Severity Risk Factors Compared to Original Variant	• In age-stratified analysis Gamma cases had 3.0-13.1 times higher odds of hospitalization in the age groups 20–39, 40–59 and 60–79 (28). • Odds of admission to ICU were 2.9–13.9 times higher in 40–59, 60–79 and ≥ 80 age groups (28). • Pre-existing conditions were lower in Gamma cases (27.8%) vs original variant (89%), p<0.001 (28). In three studies, cases were not whole genome sequenced so the lineage was not determined (very low level of evidence): • Among severe cases, people under 60 years of age increased from 39% in the first wave (Nov-Dec 2020) to 47% in the second wave (Feb 2021) when Gamma was predominant (52). • There was no increase in the proportion hospitalized in any age group before (Feb-Oct 2020) and after (Oct 2020-Feb 2021) when Gamma emerged in Brazil (46). • There was no significant difference in the mean age of infected hospitalized patients before and after Mar 2021 when Gamma became dominant in Sao Paulo, Brazil (80).	2 surveillance data analyses from European countries and Brazil, 1 ecological study in Brazil, and 1 retrospective cohort study in Brazil. Low level of evidence.
Mortality Compared to Original Variant	• Lower odds of mortality due to Gamma compared to original variant in multivariable analysis (aOR 0.6, 95%CI 0.3-1.0) (28). • A differentiated increase in COVID-19 mortality among adults aged 18-50 after Gamma emerged in Brazil suggests the possibility of greater severity of Gamma in this population. Young adults had high hospital mortality rates >10% (46). • Predictive model estimated Gamma infections in Manaus are median 1.5 (50%CrI 1.2–1.9) times more likely to result in mortality in the period following the emergence of Gamma in	1 surveillance data analysis from European countries, and 1 ecological study and 1 predictive model from Brazil.

CATEGORY	KEY SUMMARY OUTCOMES	OVERVIEW OF THE EVIDENCE
	Nov 2020, compared to before (5). However, it cannot be determined whether the estimated increase in relative mortality risk is due to Gamma infection, stresses on the Manaus healthcare system, or both.	Low level of evidence.
Mortality Risk Factors Compared to Original Variant	1 study in which cases were not whole genome sequenced so the lineage was not determined (very low level of evidence): • Mortality in COVID-19 cases <60 years old increased from 18% in November 2020 to 28% in February 2021 when Gamma was predominant (52). • The case fatality ratio increased the most in 20 -59 year olds and among patients without pre-existing risk conditions. Among severe cases, the proportion of patients without pre-existing risk conditions was higher in February 2021 (33% vs. 25% in Nov 2020) (52). • Compared with Nov/Dec 2020, females 20-39 years old, with no pre-existing risk conditions, were at 5.65 (95%CI 2.9-11.03; p <0.0001) times higher risk of death in Feb 2021 and 40-59 year olds were at 7.7 (95%CI 5.01-11.83; p <0.0001) times higher (52).	1 surveillance data analysis from Brazil. Low level of evidence.
Viral Load Compared to Original Variant	• Viral load (measured by Ct values) in Gamma samples was lower than Alpha samples and higher compared to original variants (3). • The viral load (measured by Ct values) in Gamma infections was approximately 10-fold higher compared to non- Gamma infections (53). • Viral load for Gamma infections was significantly lower than non-Gamma infections in adult (18-59 years) men (P=0.0005), adult women (P<0.0001), and elderly (>59 years) women (P=0.0149), but not significantly different in elderly men (P=0.4624) (53). 1 study in which cases were not whole genome sequenced so the lineage was not determined (very low level of evidence):	2 surveillance data analyses from France and Brazil, and 1 retrospective cohort study in Brazil.

CATEGORY	KEY SUMMARY OUTCOMES	OVERVIEW OF THE EVIDENCE
	• There was no significant difference in mean Ct values among infected hospitalized patients and healthcare workers before and after March 2021 when Gamma became dominant in Brazil (80).	Low level of evidence.
Infectious Period	No studies	
Incubation Period	No studies	
Immune Escape - Potential Impact on Vaccine Efficacy, Possibility of Re-infection		
Re-infection from Infection Compared to Original Variant	• 28% of the cases in Manaus Brazil from Nov 2020 to Jan 2021 were estimated to be re-infections considering 78% of the population was previously infected (4). • 16.9% of Gamma cases (95%CI 9.48-28.5) in Manaus from Jan 2021 to Mar 2021 were estimated to be re-infections. If probable reinfections are also included, then 25.8% were reinfections (95%CI 16.7-37.4). If possible reinfections are also included, then 31.0% were reinfections (95%CI 21.4-42.5) (81).	2 surveillance data analyses from Brazil. Low level of evidence.
Breakthrough Infection After Vaccination / Vaccine Efficacy or Effectiveness Compared to Original Variant	• In Manaus Brazil where >75% of the cases were Gamma during the study period, vaccination with at least one CoronaVac dose was associated with a 0.50-fold reduction (adjusted VE, 49.6%; 95% CI, 11.3 - 71.4) in the odds of symptomatic SARS-CoV-2 infection during the period 14 days or more after receiving the first dose. Female sex (OR, 0.50; 95% CI, 0.38 - 0.81) and a positive SARS-CoV-2 RT-PCR or antigen test in the prestudy period (OR, 0.38; 95% CI, 0.17 - 0.87) were associated with a reduced odds of symptomatic SARS-CoV-2 infection (82). • Moderna or Pfizer vaccine 7 or more days after the second dose had an adjusted VE against symptomatic Gamma infection of 88% (95%CI 61-96) versus symptomatic wild-type infection (93%, 95%CI 87-96). Adjusted VE against symptomatic Gamma infection for one dose was 43% (95%CI 22-59) versus symptomatic wild-type infection (61%, 95% CI 53-67) (72).	2 case-control studies from Brazil and Canada. Low level of evidence.

CATEGORY	KEY SUMMARY OUTCOMES	OVERVIEW OF THE EVIDENCE
In Vitro Study of Therapeutics Compared to Original Variant	• Multiple therapeutics have been shown to have reduced effectiveness against Gamma compared to the original variant, including Casirivimab (83-85), Bamlanivimab (85), Etsevimab and Imdevimab (83). • The combination of Imdevimab and Casirivimab was shown to efficiently inhibit Gamma (85).	*In vitro* studies are a low level of evidence that offer preliminary insights into what we may expect in vivo.
***In vitro* Studies of Convalescent and Vaccinated Sera** Compared to Original Variant	Most studies have shown that convalescent sera and vaccinated sera (Pfizer, CoronaVac, Sinopharm, Moderna) have reduced neutralizing activity for Gamma compared to the original variant (86-89). *Note: Many in vitro studies have been identified, please see the excel dataset for details on each study.*	Very low level of evidence. The immune response is complex, and lack of or reduced neutralizing antibodies does not mean a lack of immune protection. Further research is needed (see the PHAC Emerging Science review on protective immunity).
Testing and Diagnostics		
Testing and Detection Compared to Original Variant	• No testing failures have been reported for Gamma PCR, antigen tests, or serological assays (90).	One diagnostic test accuracy study evaluated the performance of these tests. Low level of evidence.
Spread Epidemiology		
VOC Emergence Over Time	• Many studies use whole genome sequencing to report the point or period prevalence of Gamma in a specific area, which have not been summarized (11, 91). • The prevalence of Gamma grew from 0% in Nov 2020 to 73.8% in Amazonas, Brazil (53) and almost 30% in Amazonas, Columbia by Jan 2021 (92). • The prevalence of Gamma in Italy remained relatively stable from Feb 2021 (5.0%, 95%CI 3.9-6.4) to Mar 2021 (4.8%, 95%CI 3.9-5.9) compared to Alpha, which grew from 53.1% (95%CI 50.3-55.9) to 85.7% (95%CI 84.1-87.3) (23).	3 surveillance data analyses from Brazil (2) and Italy (1). Low level of evidence.
Predictions of Spread	• If a full return to pre-pandemic levels of contact is attempted after 50% of the USA population is vaccinated in July 2021, Gamma is predicted to outcompete Alpha and Beta	2 predictive models. A limitation is that these models do not take into account B.1.617 (Delta), and only compare the predicted

CATEGORY	KEY SUMMARY OUTCOMES	OVERVIEW OF THE EVIDENCE
	and become the dominant strain in 2-3 months. The model assumes Gamma has 68% vaccine or wild-type immune efficacy (93). • If Gamma and Beta become established in the New York City population simultaneously, Gamma is predicted to outcompete Alpha and become co-dominant with Beta by August 2021. However, if Gamma becomes established in the population before Beta, Gamma would suppress Beta and become dominant. The model assumes Gamma has the same VE as wild-type (94).	spread of Gamma with Alpha and Beta. Low level of evidence.

CFR = case fatality rate, CI = confidence interval, Ct = cycle threshold, ICU = intensive care unit, OR = odds ratio, PCR = polymerase chain reaction, VE = vaccine effectiveness, OR= odds ratio, aOR= adjusted odds ratio

B.1.351 (BETA)

The excel dataset includes summaries of individual studies and can be accessed here. Below is the detailed evidence profile developed for Beta and covers data on changes in transmission efficiency, changes in clinical severity, immune escape, testing and diagnostics, and other epidemiological studies mainly on VOC spread.

Table 4: Evidence Profile of B.1.351 (Beta) VOC (n=229)

CATEGORY	KEY SUMMARY OUTCOMES	OVERVIEW OF THE EVIDENCE
Transmission Efficiency		
Transmissibility Compared to Original Variant or Alpha	• Increased transmissibility above the original variant: 27% in France for combined Beta and Gamma (3), 55% (8, 9) and 20-100% (as high as 175%) in South Africa (10). • Increased transmission advantage compared to the Alpha variant in Ile-de-France (15.8%, 95% CI: 15.1%-16.1%) and Hauts-de-France (17.1%, 95% CI: 16.1% - 18.8%) between April to May 2021 (11).	These have been estimated from 5 surveillance data analyses. Across studies there is little consistency. Heterogeneity in increased transmissibility estimates may be due to many factors including the point in the pandemic estimates are taken. Low level of evidence.
Secondary Attack Rates Compared to Original Variant	• SAR=76.9% which was equivalent to (R_{eff}=4) in this investigation(95)	1 outbreak investigation. Low level of evidence.
Clinical Severity		
Virulence / Severity or Duration of Disease Compared to Original Variant or Alpha	• Symptomatic proportion: Beta cases (90.3%; 28/31) vs. original variant cases (81.4%; 547/672, p = 0.2) in multiple European countries (28). Increased hospitalization and ICU admission: • Higher odds of hospitalization with Beta (19.3%) vs. original variant (7.5%) p<0.001 in a multivariable analysis (aOR = 3.6, 95% CI: 2.1-6.2) in several European countries (28). • Increased proportion of Beta cases in the ICU (2.3%) vs. original variant (0.6%) p=0.001, and higher odds of ICU admission among Beta cases compared to original variant cases (aOR = 3.3, 95% CI: 1.9-5.7), in several European countries (28). • Beta cases were more likely to be hospitalized (OR = 1.56, p < 0.0001) compared to Alpha cases in France (11).	4 studies on severity, including 2 surveillance studies and 2 retrospective cohort studies from France and South Africa. The cohort studies are single-centered, therefore have limited external validity and are at risk of confounding bias. Low confidence in the increased/decreased severity of the Beta variant. Low level of evidence.

CATEGORY	KEY SUMMARY OUTCOMES	OVERVIEW OF THE EVIDENCE
	Decreased ICU admission: • In hospitalized cases there were lower ICU admissions (35% vs. 48.5%, p = 0.03) and mechanical ventilation (8.9% vs. 15.5%, p = 0.009) during the Beta wave compared to the original variant wave in South Africa (31). No difference: • No significant difference in ICU scores and mechanical ventilation requirements between Beta, original variant or Alpha cases in a hospital in France (42).	
Severity Risk Factors Compared to Original Variant or Alpha	Age: • In an age-stratified analysis Beta cases had 3.5–3.6 times higher odds of hospitalization for age groups 40–59 and 60–79 years compared to original variant cases of the same age, in several European countries (28). • Admission to the ICU was significantly more likely for Beta cases (aOR 8, 95% CI 3.7–17.3) aged 40–59 years (28). • Hospitalized cases during the Beta wave were significantly older (median age 57 vs. 54 years, p = 0.03) compared to cases during the original variant wave in South Africa (31). • No significant difference in the age (63 years vs. 67 years, p = 0.15) or sex of ICU admissions among Beta cases compared to original variant or Alpha cases in France (42). Comorbidities: • Pre-existing conditions were lower in all 3 VOC (79.6% Beta vs. 89% original variant, p<0.001) (28). • More cases during the Beta wave had no comorbidities (47% vs. 36.9%, p = 0.008) and less hypertension (32.2% vs. 45.2%, p < 0.001) compared to the original variant wave in South Africa (31). • No difference in diabetes mellitus, chronic respiratory disease, cerebrovascular disease, and HIV positivity (31).	3 studies on severity risk factors, including 1 surveillance study of European countries and 2 retrospective cohort studies from France and South Africa. The cohort studies are single-centered, therefore have limited external validity and are at risk of confounding bias. Low level of evidence.

CATEGORY	KEY SUMMARY OUTCOMES	OVERVIEW OF THE EVIDENCE
Mortality Compared to Original Variant or Alpha	Increased mortality: • Increased overall mortality (36.4% vs. 32.6%, p = 0.26) and significantly higher ICU mortality (74.4% vs. 57.1%, p = 0.002) during the Beta wave compared to the original variant wave in South Africa (31). • Hospital admission during the Beta wave (p=0.006) was independently associated with mortality, in a multivariate analysis (31). • Higher odds of death within 60 days of ICU admission (OR = 5.67, 95% CI: 1.04-30.81, p = 0.04) for Beta cases compared to Alpha cases in France (42). No difference: • No difference in the odds of death for Beta cases compared to original variant cases in the multivariable analysis (aOR 1.1, 95%CI 0.4-3.4) (28).	3 studies on mortality, including 1 surveillance study of European countries and 2 retrospective cohort studies from South Africa and France. The cohort studies are single-centered, therefore have limited external validity and are at risk of confounding bias. Low level of evidence.
Mortality Risk Factors Compared to Original Variant	No studies	
Viral Load Compared to Original Variant	• Viral load (measured by CT values) in Beta samples was lower than Alpha samples and higher compared to original variants (3, 54).	2 studies, secondary outcomes. Very low level of evidence.
Infectious Period	No studies	
Incubation Period	No studies	
Immune Escape - Potential Impact on Vaccine Efficacy, Possibility of Re-infection		
Re-infection from Infection Compared to Original Variant	• Three cases of re-infection with Beta have been reported (62-64).	3 studies report re-infection, including 2 case reports and 1 prospective cohort study. These studies have a very low level of evidence.
Breakthrough Infection After Vaccination / Vaccine Efficacy or Effectiveness	Vaccine Efficacy/Effectiveness: • AstraZeneca: 10.4% efficacy for prevention of symptomatic disease (68). • Johnson and Johnson: Estimates of efficacy in South Africa were lower than other countries.	7 studies on breakthrough infections and vaccine efficacy/effectiveness, including 3 RCTs, 1 prospective cohort study, and 3 case control studies. These studies have a low to moderate

CATEGORY	KEY SUMMARY OUTCOMES	OVERVIEW OF THE EVIDENCE
Compared to Original Variant	VE for Beta was 52% and 64% for moderate and 73% and 82% for severe disease at 14 days and 28 days respectively (69). • Novavax: 51.0% (95% CI: -0.6 – 76.2) VE against symptomatic disease in HIV-negative individuals (70). • Pfizer-BioNTech: 75.0% (95% CI: 70.5% – 78.9%) VE against Beta infection ≥ 2 weeks after the second dose, and 97.4% (95% CI: 92.2%-99.5%) VE against severe, critical, or fatal outcomes for any SARS-CoV-2 variant in Qatar (71). A VE of 50% (95% CI: 34%-73%) among nursing home residents (median age: 87.0±8.2 years) for two doses spaced 19 days apart (64). • Moderna/Pfizer-BioNTech: Comparable VE of ≥ 88% against symptomatic Beta infection ≥ 7 days after receiving the second dose (72). Breakthrough Infection after Vaccination: • No breakthrough infections of Beta were identified >14 days post second dose (mainly Pfizer) in an Israel case control study (67). • 50% (13/26) of nursing home residents and 5.2% (1/19) of staff who received the Pfizer-BioNTech vaccine experienced breakthrough Beta infections. Residents were infected 24 to 41 days after receiving the second dose (15.4% were asymptomatic, 69.2% had mild to moderate symptoms and 15.4% developed acute respiratory distress syndrome) (64).	level of evidence. There were single studies per vaccine from RCT's, therefore additional trials are needed to improve confidence in these estimates.
Therapeutics Compared to Original Variant	• Casirivimab and Etesevimab showed reduced neutralization (83, 85, 96), Bamlanivimab showed no neutralization (85), and there was conflicting evidence on the neutralization of Imdevimab (83, 96) against Beta.	3 in vitro studies on therapeutics. Very low level of evidence.
Animal Models of convalescent or vaccinated protection	• Animal models challenged with Beta concluded that previously infected or vaccinated hamsters have shown protection from clinical disease (97, 98).	2 animal models. Very low level of evidence.
In vitro Studies	• Most vaccine and convalescent sera have shown reduced neutralizing activity for Beta	Very low level of evidence. The immune response is complex,

CATEGORY	KEY SUMMARY OUTCOMES	OVERVIEW OF THE EVIDENCE
	compared to the original variant or Alpha. In most studies Beta has more reduced neutralization than Gamma. The neutralization experiments are not summarized, but can be found in the dataset.	and lack of or reduced neutralizing antibodies does not mean a lack of immune protection. Further research is needed (see the PHAC Emerging Science Group review on protective immunity).
Testing and Diagnostics		
Testing and Detection Compared to Original Variant or Alpha	• PCR, antigen tests, serological assays and sequencing methods are effective at detecting and/or distinguishing Beta (90, 99-108). • The TRF-ELISA S1-based antigen assay detected Beta with a 2 to 3-fold reduced sensitivity compared to the original and Alpha variant (109).	12 studies on testing and detection, including 10 diagnostic test accuracy studies and 2 in vitro studies. As these are all describing different tests, the studies are considered to be individual and cannot be summarized together. Low level of evidence.
Spread Epidemiology		
VOC Emergence Over Time	• Studies that report the point or period prevalence of Beta have not been summarized. • Two studies show the growth of Beta in different areas of South Africa and British Columbia, Canada (110, 111). • In South Africa, Beta emerged around August 2020, and was first detected in October 2020. By March 2021, it became the dominant variant representing approximately 20% (1769/8746) of genomes (112). • Studies from countries outside of South Africa, report the first detection of Beta since December 2020 (113-115).	16 studies on the emergence and spread of Beta, including 12 surveillance studies, 1 outbreak investigation, 1 predictive model, and 2 retrospective cohort studies. Low level of evidence.

CFR = case fatality rate, CI = confidence interval, Ct = cycle threshold, ICU = intensive care unit, OR = odds ratio, PCR = polymerase chain reaction, VE = vaccine effectiveness, OR= odds ratio, aOR= adjusted odds ratio, aHR = adjusted Hazard Ratio, aPR= adjusted Prevalence Ratio

B.1.1.7 (ALPHA)

The excel dataset includes summaries of individual studies and can be accessed here. Below is the detailed evidence profile developed for Alpha and covers data on changes in transmission efficiency, changes in

clinical severity, immune escape, testing and diagnostics, and other epidemiological studies on mainly on VOC spread.

Table 5: Evidence Profile of B.1.1.7 (Alpha) VOC (n=342)

CATEGORY	KEY SUMMARY OUTCOMES	OVERVIEW OF THE EVIDENCE
Transmission Efficiency		
Transmissibility Compared to Original Variant	Alpha increased relative transmissibility (1-$R_{voc}/R_{original\ variant}$) estimates varied between 34-118% higher across studies, some of the variation is due to when in the Alpha emergence the data was drawn. One study notes variation over time (12) and most of the estimates from the UK are higher than other countries (9): • Canada: 34% (95% CI: 31-38) (13). • UK: 50-100% (12), 75% (95% CrI 70–80%) (16), 52% (95% CI 46 – 58%) (17), 43-90% (CrI range: 38-130%) (14), 44-55% (95%CI 38-61%) (18), 83-118% (71-140%) across the UK (9), 13.4-41.3% across UK regions in Dec 2020 (19), higher transmissibility 62% (95%CI 59%-65%) to 45% (95%CI 43%-48%) (116), 0.3 unit higher reproduction number compared to other lineages (117). • Europe: France 41% (95%CI 38-44) (3) and 52% (95%CrI 54-66%) (20), Denmark 55% (CrI 45–66%), Switzerland 74% (CrI 66–82%) (14) and 54% (95%CI 49-65%) (21), Norway 24% (95%CI 0-52%)(22), Italy 55-57% (95%CI 45-66%) (23), Wales and the USA 65-72% (46- 104%) (9). • USA: 59% (CrI 56–63%) (14), 35-46% (15). • Israel: 45% (95%CI 20-60) (24). • Japan estimated a 60% increase in relative transmissibility of VOCs (not specified) compared to original variants (25). • Alpha has higher transmissibility than Beta or Gamma in one study that did not report estimates (7). • In some areas of France (April-May) where Beta was increasing beta was estimated to have a transmission advantage of 15.8% (95%CI 15.1-16.1) in Île de France and 17.1% (95%CI 16.1-	This section is informed by 35 observational studies including analysis of surveillance data, cross sectional, retrospective cohort, ecological studies, and predictive models. There is agreement that Alpha is more transmissible and there is a fair amount of overlap in the estimates of magnitude. Transmissibility may be impacted by restrictive public health measures and increasing vaccinations. These studies are at risk of selection, information and confounding biases that have been inconsistently adjusted for across studies. Low level of evidence.

CATEGORY	KEY SUMMARY OUTCOMES	OVERVIEW OF THE EVIDENCE
	18.8) in Hauts de France compared to Alpha (11). • A predictive model explored the impact of increased speed of transmission and transmissibility on the epidemiology of Alpha (118). Some studies do not provide enough data to calculate increased transmission efficiency, but indicated that it was higher (7, 65, 119). Other studies indicated transmissibility decreased over time (7, 120) or remain unaffected (121), which may be associated with lockdown stringency or increasing vaccinations (121, 122). A scoping review on transmissibility included studies up to Feb 21, 2021 (8).	
Selective Advantage Compared to Original Variant	• A model of selective advantage found Alpha was estimated to have a selective advantage of 0.337(0.336-0.339) over original variants in the UK (123).	One predictive model. Low level of evidence.
Secondary Attack Rate Compared to Original Variant	• In a Canadian study of household transmission Alpha had a secondary attack rate (SAR) that was RR=1.31(95%CI 1.14-1.49) times higher than non VOCs and the risk was accentuated for asymptomatic index cases (RR=1.91, 95% CI 0.96-3.80) and presymptomatic cases (RR=3.41, 95%CI 1.13-10.26) (26). • Within households in Norway alpha was 60% (20%-114%) more transmissible compared to original variants and overall the SAR was 0.13 for original variant and 0.15 for Alpha, which equates to 16% (-6% - 43%) more infectious (ratio of SARs) even when adjusting for age (22). • A study from Denmark reported 50-70% higher transmission among Alpha households compared to the original variants. Age specific transmissibility followed a U shaped pattern with the lowest transmission from primary cases in the 10 to 30 years age range, higher from younger children, and highest from elderly cases (27).	Five studies of household transmission including an outbreak in a kindergarten classes. The ratio of secondary attack rates was also provided as a measure of higher transmissibility for Alpha in some studies based on contact tracing studies. The results were conflicting across the studies summarized. These studies include three surveillance data analysis and one retrospective study. Low level of evidence.

CATEGORY	KEY SUMMARY OUTCOMES	OVERVIEW OF THE EVIDENCE
	• A German study reported household SAR in children and adults was 37% (95%CI 28-47) and was similar for child 32% vs adults 39& (124). Among daycare contacts the SAR for children 23% was similar to adults 30% (124). • In the UK, Alpha cases were almost twice as likely to lead to household clusters compared to the original variant (adjusted OR = 1.88, 95% CI 1.67 to 2.08, p<0.001) (125).	
Non-Pharmaceutical Interventions Compared to Original Variant	Stringency: • In the UK a Bayesian hierarchical model was used to show Tier 1 (light restrictions) had negligible effect on cases while Tiers 2 (moderate restrictions) and 3 (strong restrictions) reduced transmission by 6% (5%-7%) and 23% (21%-25%), respectively (120). Another analysis highlights that during December 2020 in the UK the highest values of Rt (~1.8) were recorded in areas with the least restrictions, lowest values in areas with the highest restrictions and Lockdowns effectively reduced Rt by ~0.9 by March 2021 (116). • A predictive model based in Canada parameterized Alpha (50% increased transmission in children and 70% in adults). Compared to restrictive lockdown, cases were estimated to be 3 times greater in Toronto with schools closed and community opened under moderate restrictions, 7 times higher if schools are closed/ 7.5 if they are open and the community is under light restrictions (126). • An SEIR model based on the situation in France describes the inability of non-pharmaceutical interventions such as curfew and physical distancing measures to reduce the Ro of Alpha under 1, when the same interventions were successful against original variants (127). • An age-stratified regionally structured transmission model to control the transmission of Alpha estimate that adherence to short stricter lockdowns would result in decreased	Seven predictive models and 1 ecological study, 1 surveillance data analysis. Predictive models are excellent tools to compare options, but caution should be exercised when extrapolating results beyond comparing model scenarios. Low level of evidence.

CATEGORY	KEY SUMMARY OUTCOMES	OVERVIEW OF THE EVIDENCE
	hospital admissions and a moderate lockdown would reduce distress and improve sustainability (128). Quarantine: • A model to examine quarantine and test scenarios to control importations of SARS-CoV-2 in the EU reports Alpha does not change how effective quarantine and test strategies are (129). Personal Protective Measures: • This model is based on the US data and explores the impact of mask use for both source control and user protection using transmission data for the original variant and alpha the basic Ro of 2.5 could be decreased to Re<1.0 and Ro of 4 decreased to Re~1.6 respectively, thus better and more stringent mask use would be needed (130). • This disease transmission model estimated work place transmission risk for Alpha (0.041 transmission/contact vs. 0.014 for the original variant), with mask use the risk is still 2 times larger than the the original variant (131). Vaccination: • Vaccine strategies were given the higher transmissibility of Alpha were examined and predicted that even with 100% of the population vaccinated with AstraZeneca, R value would only reduce to 1.33 with 100% of the population vaccinated and could increase to 1.98 if 79% is vaccinated. The Pfizer-BioNTech vaccine would require 81.9% of the population to be vaccinated to reduce the value of R to 1 (122). • A predictive model showed decreased transmission of Alpha with vaccination had the greatest effect once transmission was already decreasing through public health mitigation strategies (132).	
Clinical Severity		

CATEGORY	KEY SUMMARY OUTCOMES	OVERVIEW OF THE EVIDENCE
Virulence / Severity or Duration of Disease Compared to Original Variant	More Alpha cases were hospitalized in 5 studies and admitted to the ICU in 2 studies of the general population. • Conflicting evidence on whether Alpha results in more asymptomatic infections: Prevalence of symptomatic disease was the same in an Italian study (32). Symptomatic proportion: Alpha cases, 72.6% (5,365/7,390) vs. original variant cases (81.4%; 547/672; p < 0.001) (28). • Majority of studies reported higher hospitalizations with Alpha infection: • Higher hospitalizations with Alpha vs original variant (11% vs. 7.5% p<0.001) (28); (5.8% vs 4.1% p=0.04) (38). Higher hospital admission 2.39% during the alpha wave vs. 1.55% in the initial wave in Spain (37). • Higher odds of Alpha cases being admitted to hospital compared to original variant (aOR 1.7, 95%CI 1.0-2.9) (28); OR 1.64 (95%CI 1.32-2.04) (33); OR 1.58 (95%CI 1.50 - 1.67) (34); (OR 1.36 95%CI 1.16-1.60, p=0.0002) (35). The hazard ratio for hospitalization due to Alpha vs. original variant (aHR 1.34, 95%CI 1.07-1.66) and length of stay was similar in both groups p=0.07 (36). • A study in Czech Republic reported no change in hospitalizations (39). • Higher ICU admissions with Alpha infection was reported in several studies: • ICU admission was 1.4% for Alpha vs original variant 0.6% p=0.002, which was a higher odds of ICU admission for Alpha aOR 2.3(95%CI 1.4-3.5) (28). ICU admission for Alpha aHR: 1.99 95%CI 1.59 - 2.49 compared to original variant (40). • Among hospitalized cases there was no association between severe disease and death among Alpha vs. original variants, adjusted PR 1·02 (95%CI: 0·76–1·38) (41); ICU scores or mechanical ventilation requirements (42). Symptoms:	14 studies on severity, these included surveillance data analysis, prospective cohorts, retrospective cohorts, and cross sectional studies, most of which have been conducted in the UK. Moderate level of evidence.

CATEGORY	KEY SUMMARY OUTCOMES	OVERVIEW OF THE EVIDENCE
	• Hypoxia (70.0% vs 62.5%, p=0.029) and higher respiratory rates (p=0.001) were reported among Alpha admissions in two studies (43, 44). • Fever over 38°C was significantly higher among hospital patients infected with the Alpha vs. the original variant (46% vs 22, p=0.015) (133)	
Severity Risk Factors Compared to Original Variant	There was no agreement across studies on whether any risk factors were associated with Alpha severity including age, and gender, but several studies did report that Alpha infections were less likely to have comorbidities: • A study from the USA reported no significant difference in patient age, gender, median length of hospital stay (35). • In another study age difference was statistically significant (37 vs. 39 years) (45). A study from Czech Republic reported significantly younger patients were hospitalized with the Alpha (median difference 58 vs 64 years of age) compared to the original variant (39). • In the age-stratified models, Alpha cases in the age groups 20–39 and 40–59 years had, respectively, 3.0 and 2.3 times higher odds of hospitalisation when compared with original variant cases (28). • A prospective cohort study in hospital patients identified a statistically significant difference in the age of those infected with the Alpha variant (39 years, IQR: 30.50 - 62.50) compared to those infected with the B.1.470 non-variant (31 years, IQR: 27.50 - 41.00) (P = 0.014) (133). • Among ICU patients in France, no significant difference in age or sex between Alpha and the original variant or Beta was documented (42). • A hospital cohort between Dec 2020 - Jan 2021 in France describes younger patients (63% >65 years dropped to 50%) with a mean age of 59.2 down from 70.7, patients without comorbidities increased 16% to 42% (p=0.007) (44). Pre-	9 studies on severity risk factors. These included surveillance data analysis, prospective cohorts, retrospective cohorts, and cross sectional studies, most of which have been conducted in the UK. Moderate level of evidence.

CATEGORY	KEY SUMMARY OUTCOMES	OVERVIEW OF THE EVIDENCE
	existing conditions were lower with Alpha, vs original variant, (44.8% vs. 89% p<0.001) (28). • A study of hospitalized COVID-19 cases reported a higher proportion of females with Alpha (48.0% vs 41.8%, p=0.01), fewer frail patients (14.5% vs 22.4% p=0.001) and higher proportions of obese cases (30.2% v 24.8%, p=0.048), but no difference by age or ethnicity (43).	
Mortality Compared to Original Variant	There is conflicting evidence on the association of mortality and Alpha infection: • Five studies reported no significant difference in mortality overall: Italy (2.1 vs. 4.1%) (32), USA (35, 38) and no association with 28 day mortality in UK (OR: 0.90, 95%CI 0.57-1.41, p=0.64) (36) or case fatality (OR= 1.37; CI: 0.5808-3.215, p = 0.52) (39). • One study estimated Alpha had a lower odds of mortality compared to original variant in the multivariable analysis (aOR 0.5, 95%CI 0.3-0.9) (28). • Four studies reported higher risk of mortality: higher 28 day hazard of death (55%, 95% CI: 39-72%) (47), aHR 1.59 (95%CI 1.25-2.03) (40), aHR 1.67 (95%CI 1.34 – 2.09; P <0.0001) (41). HR 1.64 (95%CI 1.32 - 2.04, p <0.001) which equates to an increase of 2.5 to 4.1 deaths per 1000 detected cases (48). The meta-analysis of these four studies had a pooled mortality risk of HR=1.45 (95%CI 1.18-1.78) (134). • Ecological studies from the UK estimates that Alpha is 33% more lethal (51) and has higher mortality (49).	13 studies reported on mortality these included surveillance data analysis, ecological studies, prospective cohorts, retrospective cohorts, and cross sectional studies, most of which have been conducted in the UK. Moderate level of evidence.
Mortality Risk Factors Compared to Original Variant	• Demographics of Alpha mortalities were similar in males and females, but was more prevalent in younger age groups than older age groups (59.0% in 1-34 year olds vs 55.4% in those 85 or older) (47). There was also variation by ethnicity: Black (69.6%), mixed or unknown ethnicity (64.8%), White (58.0%) and Asian (57.6%) and	Two studies which include surveillance data analysis, a retrospective cohort. Low level of evidence.

CATEGORY	KEY SUMMARY OUTCOMES	OVERVIEW OF THE EVIDENCE
	was lowest in the most deprived quintile of the index of multiple deprivation (53.9%) (47). • No evidence of a significant associations between Alpha and sex (p = 0.90), ethnic group (p = 0.64) or age group (p = 0.15) (40).	
Viral Load Compared to Original Variant	• Several studies (n=14) measured viral load as Ct or estimated copies/mL for different target proteins (usually N and ORF1ab). They consistently indicate that Alpha samples are more likely to have lower Ct values or higher estimated viral loads. The median order of magnitude higher varies across studies and target protein from 2 to 10 fold differences (3, 32, 35, 39, 45, 54-59, 59-61, 117, 133, 135, 136).	22 studies that were mainly surveillance data analyses, cohort or cross sectional studies that analysed the PCR Ct values across Alpha samples and original variant samples. This measure is indirect and all study designs are observational, however the conclusion that Alpha cases have lower Ct values was consistent across studies Low to moderate level of evidence.
Animal Model of Viral Load Compared to Original Variant and Other VOCs/VOIs	• An animal study in rhesus macaques identified higher viral loads of genomic RNA in the nasal mucosa of Alpha infected animals compared to those infected with the wild-type and Beta variant and lower viral antigens in lung tissues compared to the wild-type (137). • Another study documented Alpha infected hamsters demonstrated high viral RNA shedding through nasal secretions during the first weeks of infection (138). • A mouse model identified viral load was significantly lower for the Alpha virus in the lungs of infected mice compared to Beta and Gamma viruses in both C57BL/6 and BALB/c lungs, with no infectious virus detected in the BALB/c lungs (139).	Three animal model studies in agreement offer consistent evidence of decreased viral load in lungs and increased viral loads in nasal mucosa. Low level of evidence.
Infectious Period	A prospective study that included Alpha cases (n=7) reported average infections last 13.3 days compared with 8.2 days for other variants (57).	One small prospective cohort. This outcome needs further evaluation

CATEGORY	KEY SUMMARY OUTCOMES	OVERVIEW OF THE EVIDENCE
		with a larger sample size and range of cases. Very low level of evidence.
Incubation Period	*No studies*	
Immune Escape - Potential Impact on Vaccine Efficacy, Possibility of Re-infection		
Re-infection from Infection Compared to Original Variant	Three studies estimate the rate of re-infection. A study in the UK identified re-infection of 0.7% (95%CI: 0.6-0.8) (65) and in the USA previous seropositivity rate for persons with Alpha was 0.7% compared to original variant infections at 0.9% (38). A prospective study in the UK HCWs reported there was no evidence that Alpha changed the extent of protection from any PCR positive infection in those who were seropositive (aIRR 0.40, 95%CI 0.10-1.64, p=0.20) (66).	Three re-infection studies have included analysis on Alpha and are in agreement that Alpha does not evade natural immunity. These include surveillance data analysis, cohort and ecological studies. Moderate level of evidence.
Animal Model of Re-infection Compared to Original Variant	Hamsters infected with original SARS-CoV-2 and recovered were all protected from re-infection with Alpha (97, 140).	Two animal models reported consistent findings and support the evidence documented in human and *in vitro* studies. Low level of evidence.
***In vitro* studies Convalescent Sera** Compared to Original Variant	The majority of *in vitro* studies consistently showed minimal or small reductions in neutralization of Alpha compared to an original variant. Studies can be found in the dataset. There is consistency in the findings, the evidence is obtained from low quality studies.	There are many *in vitro* studies and this list is not complete at this time. Low level of evidence.
Breakthrough Infection After Vaccination / Vaccine Efficacy or Effectiveness Compared to Original Variant	Breakthrough: • Case reports and case series report asymptomatic break through infections with Alpha in adults (73, 74, 141, 142) and elderly (143), HCWs in Brazil after Sinopharm (144), and HCW in India after Covishield vaccine (AZD1222) (145). • Alpha was 1.29 fold (95% CI [0.75, 2.20], p=0.468) more common in vaccine	20 studies reported on breakthrough infection after vaccination or vaccine effectiveness. The generalizability depends on the representativeness of the evidence to the general population. Consistent findings across studies improves the certainty in the results.

CATEGORY	KEY SUMMARY OUTCOMES	OVERVIEW OF THE EVIDENCE
	breakthrough cases compared to the original variant cases (74). • In New York, among SARS-CoV-2 positive fully vaccinated persons, 22% were infected with Alpha compared to 44% had non-VOC infections (38). • A disproportionate number of Pfizer-BioNTech (BNT162b2) breakthrough infections between first dose and up to 14 days after the second dose in Israel resulted in an adjusted higher odds of being PCR positive with Alpha (aOR 2.4 (95%CI: 1.2 to 5.1) (67). • Real world studies in the UK have reported no difference in vaccine effectiveness (combined data with AstraZeneca and Pfizer-BioNTech) with Alpha variant (146). • After Pfizer-BioNTech vaccination the adjusted odds of inadequate neutralisation activity against the Alpha variant in the older (>80) age group compared to adult HCWs was aOR 4.4 (1.5-12.6, p<0.007) (147). Vaccination 1 dose: • In a prospective UK HCW study, there was no evidence that Alpha changed the extent of protection afforded by the first vaccine dose compared to the original variant (aIRR=1.84, 95%CI 0.75-4.49, p=0.18) (66). • After the first dose of Pfizer-BioNTech or AstraZeneca the reduced risk of emergency hospital admission was estimated to be 43% (33% to 52%) and 37% (3% to 59%) respectively and a 51% (37% to 62%) reduced risk of death in adults aged 70 years and older in England (75). Vaccination 2 doses: • After two doses of the Moderna or Pfizer-BioNTech vaccine a comparable adjusted vaccine effectiveness (≥ 88%) against symptomatic Alpha, Beta and Gamma variant	These studies include RCTs, prospective cohorts, case-control studies, longitudinal studies, and surveillance data analysis. High level of evidence for RCTs cohort studies, moderate evidence for prospective cohort studies and low level of evidence for all other study designs. Overall, moderate to high level of evidence. Case series and reports are very low levels of evidence but can be used to inform hypotheses for future research.

CATEGORY	KEY SUMMARY OUTCOMES	OVERVIEW OF THE EVIDENCE
	infections ≥ 7 days after receiving the second dose were observed (72). • AstraZeneca (ChAdOx1-S) vaccine efficacy in a UK RCT of was 70.4% (95%CI 43.6- 84.5) against symptomatic COVID-19 caused by the Alpha and 81.5% (67.9 - 89.4) against symptomatic COVID-19 caused by original variants (76). For asymptomatic or unknown symptom infection, vaccine efficacy was higher for non-Alpha infections (69.7%, 33.0-86.3) than for Alpha (28.9%, –77.1-71.4) (76). • Novavax (NVX-CoV2373) vaccine efficacy in a UK RCT against Alpha and original variant was 86.3% (71.3 to 93.5) vs 96.4% (73.8 to 99.5), respectively (77). • Pfizer-BioNTech (BNT162b2) in Israel where 94% of cases were Alpha demonstrated vaccine effectiveness was >96% 14 days after the second dose (78, 148), this was 90% in adults 70+ in the UK (79). • A meta-analysis of vaccine efficacy trials of Pfizer-BioNTech VE after dose 1 51% (95%CI: 47-55%), after dose 2 93% (95%CI: 90-96%) and AstraZeneca VE after dose 1 49% (95%CI: 43-55%) after dose 2 66% (95%CI: 54-75%) (149).	
Animal Model of Vaccination Compared to Original Variant	• Hamsters vaccinated with AstraZeneca and then challenged with Alpha resulted in no weight loss, no lung pathology and no virus detected in tissue samples compared to controls who had extensive pulmonary pathology (98). Another study reported vaccinated hamsters with AstraZeneca vaccine and challenged with Alpha continued to gain weight while control animals had weight loss and extensive pulmonary pathology caused by Alpha in the control animals was observed, but not in the vaccinated animals (150). • Animals vaccinated with other vaccine candidates including spike RBD proteins (151-154) and SARS-CoV-2 infected human plasma,	Nine studies in animals were inconsistent in weight loss but consistent with pathology findings which are in agreement with human studies and *in vitro* studies. Low level of evidence.

CATEGORY	KEY SUMMARY OUTCOMES	OVERVIEW OF THE EVIDENCE
	DNA vaccines (155), and circRNA vaccines (156) all had neutralization activities against Alpha.	
***In vitro* study of Vaccinated Sera** Compared to Original Variant	There are many *in vitro* studies that are available in the dataset. The *in vitro* studies consistently showed minimal or small reductions in neutralization of Alpha compared to an original variant. They have not been summarized in the evidence profile.	There are many *in vitro* studies and this list is not complete at this time. Low level of evidence.
Animal Model of Therapeutics Compared to Original Variant	• A number of monoclonal antibodies tested protected mice and hamsters against Alpha (157). • Locked nucleic acid antisense oligonucleotides (158) and 4'-fluorouridine, a ribonucleoside analog (159) efficiently suppressed viral replication in hamsters and ferrets, respectively. • Convalescent plasma treatment resulted in decreased viral copy number in the lungs of mice infected with either the wild-type or Alpha variant. Convalescent plasma treatment did not reduce viral copy number in brain tissue of mice infected with Alpha compared to wild-type (153).	Four animal models. Low level of evidence
***In vitro* study of Therapeutics** Compared to Original Variant	Minimal loss of activity: several monoclonal antibodies (157, 160-162), polyclonal CP or purified hCoV-2-IG antibody preparations (163).	*In vitro* studies offer preliminary insights into what we may expect in vivo. Low level of evidence.
***In vitro* study of Infectivity** Compared to Original Variant	Pseudovirus carrying the UK-N501Y mutation to transduce its target cells compared to the original variant was significantly increased, up to 9-fold (164).	*In vitro* studies offer preliminary insights into what we may expect in vivo. Low level of evidence.
Testing and Diagnostics		
Testing and Detection	PCR is effective at detecting and distinguishing the variant (90, 165-171). Detection of Alpha in wastewater at proportions as low as 0.1% of SARS-CoV-2 (172). Multiple studies report reliable assays for rapid detection of variants including detection in wastewater samples (90, 100, 101, 172, 173).	32 studies, 28 diagnostic test accuracy studies, 3 surveillance data analyses that also described a new test or set of primers, and one *in silico* study designing primers. As

CATEGORY	KEY SUMMARY OUTCOMES	OVERVIEW OF THE EVIDENCE
		these are all describing different tests the studies are considered to be individual and cannot be summarized together. Low level of evidence.
Spread Epidemiology		
VOC Emergence Over Time	• Two Canadian studies detail that Alpha cases were initially clustered in two regions and quickly increased (111, 174). Similarly, two studies from Ontario have documented the rapid increase in Alpha (13, 175). Studies were captured from many countries around the world, most describe the first detection of Alpha in mid to late December followed by a rapid increase in the variant over 3.5 to 10 weeks. It was noted to have become the dominant strain in several studies (39, 117). • One study from Israel documented a plateau and decline in the >60 years age group as >50% of the population had been vaccinated (1 dose Pfizer-BioNTech> 14 days) (24). The USA documented several introductions of Alpha around the country (15). One study from the USA documented daily SARS-CoV-2 positive tests from Alpha increased from 0.25% to 0.5% from October to December 2020 (176). Several studies document detection of Alpha in wastewater (172, 177-179).	116 studies report on the emergence and spread of Alpha in a country or region over time. Most of these studies are based on surveillance data, prospective cohorts often of HCWs, retrospective cohorts of hospital records, longitudinal studies, and ecological studies. Point prevalence or case reports of infected travellers were excluded from this summary.Low to moderate level of evidence.
Attribution to Alpha	An increase of 0.1 in the proportion of Alpha, considering the pre-peak period, was found to be associated with 35·8% increase in the height of the second wave peak. During the period from 1 January to 25 February 2021, an increase of 0.1 in the proportion of Alpha was related with a 15.3% increase in the cumulative number of deaths during that period (180).	One model used to estimate the additional burden of COVID-19 due to Alpha. Low level evidence.
Risk factors for spread	• An ecological study conducted in Toronto and Peel regions in Ontario showed that Alpha growth rate (11.3%, 19.8%, and 30.8%), overall	Five studies assessed risk factors. These include ecological studies,

CATEGORY	KEY SUMMARY OUTCOMES	OVERVIEW OF THE EVIDENCE
	cases (19.0%, 32.7%, and 48.3%) and VOC cases (18.4%, 30.8% and 50.8%) were positively correlated with the proportion of essential workers (30.4%, 47.9% and 63.2%) and median income ($33k, $45k and $60k CAD) of the community, respectively (181). • Surveillance data from France found the Alpha variant infections were more common among older individuals compared to Beta or B.1.525. In hospital settings, there was an under-representation of Alpha compared to Beta. In specific regions of France, the odds of being infected by the original variant or a B.1.525 virus were either identical or lower than being infected by Alpha (11).	prospective cohorts, predictive models, and surveillance data analysis. Moderate level of evidence for prospective cohort studies. Low level of evidence for all other study designs.
Genomic Analysis of Spread	Results do not suggest that the canonical mutations of VOC Alpha evolved independently in different locations and points to an origin in and spread of the VOC Alpha from the UK (182).	One study of genomic surveillance data. Low level of evidence.

CFR = case fatality rate, CI = confidence interval, Ct = cycle threshold, ICU = intensive care unit, OR = odds ratio, PCR = polymerase chain reaction, VE = vaccine effectiveness, OR= odds ratio, aOR= adjusted odds ratio, aHR = adjusted Hazard Ratio, aPR= adjusted Prevalence Ratio

Methods:

A daily scan of the literature (published and pre-published) is conducted by the Emerging Science Group, PHAC. The scan has compiled COVID-19 literature since the beginning of the outbreak and is updated daily. Searches to retrieve relevant COVID-19 literature are conducted in Pubmed, Scopus, BioRxiv, MedRxiv, ArXiv, SSRN, Research Square and cross-referenced with the COVID-19 information centers run by Lancet, BMJ, Elsevier, Nature and Wiley. The daily summary and full scan results are maintained in a Refworks database and an excel list that can be searched. One of the foci is to identify studies as variants of concern or under investigation. Studies identified under this foci are further characterized in our VOC/VOI database and VOC results are extracted into this review. A cross check for relevant articles is also conducted within the databases using targeted keyword searching. This table is evolving as the evidence evolves.

Nouveaux éléments de preuve sur la COVID-19

Résumé évolutif à propos des variants préoccupants Alpha, Bêta et Gamma du SRAS-CoV-2

Faits saillants jusqu'au 1er juin 2021

Introduction

Les **variants préoccupants** (VP) du SRAS-CoV-2 sont des variants en circulation qui ont été signalés par les organisations nationales ou mondiales de santé publique. Ces variants deviennent préoccupants lorsqu'on les compare aux variants originaux du SRAS-CoV-2, puisque la complémentation de leurs mutations crée une transmissibilité et une virulence accrues (morbidité ou mortalité), des changements dans la présentation clinique de la maladie, de l'évasion immunitaire, une diminution de l'efficacité des vaccins, des thérapies ou des mesures de santé publique disponibles ou des échecs dans la détection aux fins de diagnostic (1, 2). Le Canada a créé sa propre définition nationale (2). Ce résumé évolutif axé sur la littérature sur les variants préoccupants du SRAS-CoV-2, soit B.1.1.7 (Alpha), B.1.351 (Bêta) et P.1 (Gamma), vise à présenter de nouvelles données sur les VP, leur épidémiologie et la façon dont leurs attributs peuvent influer sur la gestion de la pandémie. Ce résumé porte sur les changements dans les paramètres épidémiologiques (p. ex., taux de transmission, résultats cliniques en ce qui concerne la gravité et la mortalité, changements dans les groupes d'âge touchés ou proportions de personnes asymptomatiques), les répercussions sur les tests de diagnostic, l'évasion immunitaire ou et l'efficacité des vaccins, ainsi que les répercussions des VP sur d'autres mesures de santé publique. En mai 2021, l'Organisation mondiale de la Santé (OMS) a publié un système de nomenclature des variants préoccupants (VP) et des variants d'intérêt (VI) utilisant des lettres grecques afin de simplifier la communication à propos des variants et d'éliminer la stigmatisation potentielle découlant des endroits où les variants ont été identifiés la première fois et cette nomenclature est celle qui a été utilisée dans le présent résumé (1). La documentation sur le VP Delta est présentée dans un résumé évolutif distinct.

TABLEAU 1 : VARIANTS PRÉOCCUPANTS ACTUELS (VP)

Dénomination de l'OMS (mai 2021)	Lignée Pango	Clade Nextstrain	Clade GISAID	Autre nom	Premier cas détecté	Premiers échantillons	Mutations du spicule caractéristiques
Alpha	B.1.1.7	20I/501Y.V1	GR/501Y.V1	VOC 202012/01	Royaume-Uni	Septembre 2020	69/70del, 144del, N501Y, A570D, D614G, P681H, T716I, S982A, D1118H
Bêta	B.1.351	20H/501Y.V2	GH/501Y.V2	VOC 202012/02	Afrique du Sud	Août 2020	D80A, D215G, 241/243del, K417N, E484K, N501Y, D614G, A701V
Gamma	P.1, B.1.1.28.1	20J/501Y.V3	GR/501Y.V3	VOC 202101/02	Brésil et Japon	Décembre 2020	L18F, T20N, P26S, D138Y, R190S, K417T, E484K, N501Y, D614G H655Y, T1027I, V1176F
Delta	B.1.617.2[1]		G/452R.V3		Inde	Octobre 2020	L452R, D614G, P681R, ± (E484Q, Q107H, T19R, del157/158, T478K, D950N)

[1] B.1.617.2 (Delta) a été ajouté à la liste des variants préoccupants le 11 mai 2021 et est présenté dans un résumé évolutif distinct.

La désignation **variants d'intérêt** (VI) ou variants à suivre est utilisée pour signaler un variant qui a le potentiel d'être un VP, mais pour lequel une enquête ou des preuves plus poussées sont requises. Les indicateurs de la désignation de VI incluent des changements phénotypiques ou l'acquisition de mutations ayant des implications phénotypiques établies EN PLUS du fait que ce variant doit avoir été à l'origine de la transmission dans la communauté, de plusieurs cas ou de concentration de cas de COVID-19 ou doit avoir été détecté dans plusieurs pays OU est par ailleurs vu comme un variant d'intérêt (VI) par un organisme comme l'OMS (1, 2). Au Canada, le groupe de surveillance des variants du SRAS-CoV-2 a établi la définition des VI et est responsable de l'évaluation et de la désignation des VI potentiels (2). Les données sur les VI ont été recueillies, mais ne sont pas mises en évidence dans le présent résumé. Le jeu complet de données en Excel est accessible ici et peut être filtré par variant d'intérêt.

Cet examen évolutif des éléments de preuve présente les éléments de preuve clé sur les variants Alpha, Bêta et Gamma, y compris les changements dans l'épidémiologie, l'échappement immunitaire et l'efficacité des vaccins, les répercussions sur les tests de diagnostic et les mesures de santé publique.

Quoi de neuf

Cette mise à jour comprend la littérature disponible jusqu'au 1er juin 2021. Au total, 345 nouvelles études sur le variant B.1.1.7 (Alpha, n = 200 études), B.1.351 (Bêta, n = 163) ou P.1 (Gamma, n = 91) depuis la dernière mise à jour du 28 avril 2021 sont incluses dans le jeu de données.

Points clés

En date du 1er juin 2021, 548 études faisaient état des VP ou des VI. 501 études portaient sur les variants B.1.1.7 (Alpha), B.1.351 (Bêta) et P.1 (Gamma) et ont été prises en compte dans les résumés présentés ci-dessous. Les études sur les VI (n = 47 études), les rapports de cas et les estimations ponctuelles de la prévalence (n = 35), ainsi que les études sur l'infectivité cellulaire, l'affinité de liaison ou la caractérisation génomique (n = 77) n'ont pas été résumées dans les profils des éléments de preuve. Des résumés généraux sont présentés dans le tableau des points clés (tableau 2) alors que des résumés plus détaillés de chacun des VP figurent dans les sections correspondantes du résumé. Les détails de chacune des études figurent dans le jeu de données en Excel accessible ici. Dans l'ensemble, les éléments de preuve portaient surtout sur le variant Alpha (n = 342) comparativement au Bêta (n = 229) et au Gamma (n = 125).

Transmissibilité :

- Toutes les études ont montré une augmentation de la transmissibilité pour les variants Alpha (tableau 5), Bêta (tableau 4) et Gamma (tableau 3) comparativement au variant original, bien que la portée soit très variable. En ce qui concerne le variant Alpha, deux études canadiennes utilisant des données de surveillance sur la population générale et des données sur la transmission intrafamiliale ont indiqué une augmentation de 34 % de la transmissibilité et de 31 % des taux d'attaque secondaires, respectivement. Le variant Alpha avait une plus grande efficacité de transmission que les variants Bêta et Gamma.

Gravité clinique :

- En ce qui concerne le variant Alpha, les différentes études ont présenté des preuves contradictoires à propos des probabilités d'admission à l'hôpital, alors qu'un petit nombre d'études ont signalé des probabilités plus élevées d'hospitalisation pour les variants Bêta et Gamma. Des associations conflictuelles ont été signalées pour les admissions aux soins intensifs avec les variants Bêta et Alpha, alors que les probabilités étaient plus élevées en ce qui concerne le variant Gamma. Par rapport au variant original, les variants Alpha et Bêta n'ont pas été associés au risque de devoir être mis sous ventilation mécanique ou d'avoir un score de sévérité plus élevé pendant le séjour à l'USI. Toutefois, ces données sont fondées sur un nombre limité d'études ayant analysé rétrospectivement la surveillance et les données sur les hospitalisations.
- En ce qui concerne les indicateurs de sévérité
    - Quelques études sur les variants Alpha, Bêta et Gamma ont fait état d'un risque d'hospitalisation stratifié selon l'âge et d'une augmentation des probabilités chez les adultes de 20 à 59 ans, tandis que d'autres n'ont signalé aucune association.
    - Plusieurs études ont également rapporté une proportion plus faible de conditions préexistantes, à l'exception de l'obésité, parmi les cas associés aux VP.
- Les associations avec la mortalité étaient conflictuelles entre les études portant sur les variants Alpha, Bêta et Gamma. Une étude a fait état d'une augmentation de la mortalité à l'USI pour le variant Bêta. Le

risque de mortalité aurait également augmenté dans certains groupes d'âge adulte pour les variants Alpha et Gamma.

- Comparativement au variant original, la charge virale était toujours de 2 à 10 fois plus élevée pour le variant Alpha. Elle était également plus élevée pour les variants Gamma et Bêta que le variant original, mais inférieur à celui du variant Alpha.
- Aucune étude n'a évalué la période infectieuse pour les variants Gamma et Bêta. Une petite étude, portant sur 7 personnes ayant été infectées par le variant Alpha, a révélé que l'infection moyenne, un virus cultivé, a duré 13,3 jours avec le variant Alpha comparativement à 8,2 jours pour les autres variants. Des recherches supplémentaires sont nécessaires pour augmenter la confiance dans ce résultat.
- Aucune étude n'a cependant été effectuée sur la période d'incubation des VP.

Échappement immunitaire :

- Rien n'indique que le taux de réinfection pour le variant Alpha a changé par rapport au variant original, aucune donnée n'est disponible pour le variant Bêta. Deux études effectuées au Brésil indiquent qu'il pourrait y avoir d'importantes réinfections associées au variant Gamma, mais ces études sont fondées sur des analyses écologiques et études plus poussées à ce sujet seront donc requises.
- Les données tirées des études sur l'efficacité des vaccins indiquent un niveau de protection réduit après la première dose du vaccin, mais une protection équivalente après la deuxième dose dans la plupart des études portant sur les variants Alpha et Gamma, alors que les études sur le variant Bêta ont donné des résultats variables.

Autres catégories :

- D'autres catégories liées à la performance diagnostique et à la recherche épidémiologique sur la diffusion et l'incidence des interventions non pharmaceutiques sont résumées dans les sections approfondies sur les VP.
    - Aucune étude évaluant les tests de diagnostic ou de détection du SRAS-CoV-2 n'a décrit de problèmes d'échec ou de performance pour la détection des VP, à l'exception de la perte bien caractérisée du gène S pour le variant Alpha.
    - Plusieurs études de modélisation prédictives ont mentionné les interventions non pharmaceutiques (p. ex., limitation des rassemblements, fermetures, port du couvre-visage et confinement). Bien qu'une plus grande rigueur, un plus grand nombre de fermetures et de restrictions, ait été nécessaire pour contrôler les VP en raison d'une transmissibilité plus élevée, aucune modification des interventions individuelles n'a cependant été nécessaire.
    - Les études sur l'introduction et la propagation des VP dans une région géographique n'ont pas été incluses dans le tableau ci-dessous, mais des résumés à ce sujet sont disponibles dans les profils des VP individuels, tout comme les résumés portant sur les modèles animaux et les études in vitro sur la réinfection, l'efficacité des vaccins et l'incidence potentielle des VP sur les traitements.

Les catégories de preuve indiquées dans les tableaux ci-dessous comprennent les preuves suivantes, lorsqu'elles sont déclarées :

La **transmissibilité** comprend les changements dans la transmissibilité, les taux d'attaque secondaires et les estimations de l'avantage sélectif.

La **gravité clinique** comprend la proportion des infections qui sont symptomatiques, la proportion d'atteinte grave et de mortalité, ainsi que les facteurs de risque pour les atteintes graves ou la mortalité, la charge virale,

la période infectieuse et la période d'incubation. Il faut cependant noter que les facteurs de risque d'une atteinte grave incluraient les populations spéciales, p. ex., les femmes enceintes, si elles sont déclarées.

L'**échappement immunitaire** comprend les changements dans l'efficacité du vaccin, le risque de réinfection chez les humains, les modèles animaux, les expériences *in vitro* ou *in silico*, ainsi que les répercussions sur les thérapies si elles sont déclarées.

Les **échecs des tests de diagnostic/détection** sont saisis dans les sections individuelles, et ne seront inclus dans le tableau 2 que si la performance du test est préoccupante.

La mention **Autres épidémiologies** inclut toutes les études qui documentent l'émergence et la propagation des VP dans une région géographique, les études écologiques qui examinent la propagation des VP et les facteurs de risque pour les points chauds, ainsi que les études sur les interventions en santé publique efficaces contre les VP et l'épidémiologie génomique comme sous-catégories.

TABLEAU 2 : RÉSUMÉ DES PREUVES CLÉS DU VP P.1 (GAMMA) (N = 125), DU VP B.1.351 (BÊTA) (N = 229) ET DU VP B.1.1.7 (ALPHA) (N = 342)

Catégorie	P.1 (Gamma)	B.1.351 (Bêta)	B.1.1.7 (Alpha)
EFFICACITÉ DE LA TRANSMISSION			
Transmissibilité Comparativement au variant original ou au variant Alpha	Trois analyses de données de surveillance, une étude transversale et un modèle prédictif : • 27 % de plus en France (variants Gamma et Bêta combinés) (3) • 160 % à 100 % plus élevé au Brésil (4, 5) • Un modèle qui a examiné le variant Gamma en Italie a signalé une transmissibilité de 12 à 39 % plus élevée selon que ce variant présentait ou non un échappement immunitaire (6). D'autres études placent la transmissibilité du variant Gamma entre celle du variant original et celle du variant Alpha (7).	Cinq rapports de données de surveillance : • 27 % de plus en France (variants Gamma et Bêta combinés) (3) par rapport au variant original. • 55 % (8, 9) et entre 20 et 100 % plus élevé en Afrique du Sud (10) par rapport au variant original. • Avantage de transmission de 15,8 % à 17,1 % par rapport au variant Alpha dans certaines régions de la France entre avril et mai 2021 (11). Faible niveau de preuve.	34 études de surveillance et d'observation : • Les estimations de l'augmentation de la transmissibilité relative du variant Alpha (1-$R_{VP}/R_{Variant\ original}$) variaient entre 34 et 118 % entre les différentes études, une partie de cette variation étant due à l'époque (12) et au pays (plus élevée au Royaume-Uni) (9) : ○ Canada : 34 % (IC à 95 %, 31 à 38) (13), É.-U. : 35 à 59 % (14, 15). ○ Royaume-Uni : de 43 à 118 % (9, 12, 14, 16 à 18), de 13,4 à 41,3 % dans les régions du Royaume-Uni en décembre 2020 (19). ○ Europe : France 41 à 52 % (3, 20), Danemark 55 %, Suisse 54 à 74 % (14), (21), Norvège 24 % (22), Italie 55 à 57 % (23), Pays de Galles et É.-U. 65 à 72 % (9). ○ Israël 45 % (24). ○ Le Japon a estimé une augmentation de 60 % de la transmissibilité relative des VP (aucune précision indiquée) (25). ○ Le variant Alpha avait une plus grande efficacité de transmission que les variants Bêta et Gamma (7).

Catégorie	P.1 (Gamma)	B.1.351 (Bêta)	B.1.1.7 (Alpha)
	Faible niveau de preuve.		• De même, les ratios des taux d'attaque secondaire parmi les études sur la transmission intrafamiliale étaient de 30 à 70 % plus élevés au Canada (26), en Norvège (22) et au Danemark (27). Niveau de preuve faible à modéré.
SÉVÉRITÉ CLINIQUE			
Virulence/gravité ou durée de la maladie Comparativement au variant original ou au variant Alpha	Deux études de surveillance : • Une proportion plus élevée de cas qui ont été hospitalisés (p < 0,001) (28). • Une plus grande probabilité d'être admis à l'hôpital (RCa 2,6, IC à 95 %, 1,4 à 4,8) (28). • Une plus grande probabilité d'être admis aux soins intensifs (RCa 2,2, IC à 95 %, 1,8 à 2,9) (28). • Une croissance exponentielle du nombre d'hospitalisations a été signalée à Rio Grande do Sul et à Porto Alegre (29).	Quatre (4) études, incluant des études de surveillance et d'observation : • Une plus grande probabilité d'hospitalisation en raison du variant Bêta comparativement au variant original (RCa 3,6, IC à 95 %, 2,1 à 6,2) (28) ou au variant Alpha (RC 1,56) dans plusieurs pays européens (11). Données contradictoires sur les admissions aux soins intensifs associées au variant Bêta, avec des probabilités plus élevées (RCa 3,3, IC à 95 %, 1,9 à 5,7) dans les pays européens (30) et une proportion plus faible (35 % contre 48,5 %, p = 0,03) en Afrique du Sud (31) comparativement au variant original.	17 études de surveillance et d'observation : • Des données contradictoires sur la prévalence de la maladie symptomatique n'ont révélé aucune différence dans une étude et moins de cas symptomatiques (p < 0,001) dans une autre (28, 32). • Sept études ont révélé une probabilité plus élevée d'admission à l'hôpital (RCa 1,36 à 1,7 et RRa 1,34) (28, 33 à 39) alors qu'une autre n'a indiqué aucune différence (39). • Deux études ont révélé une probabilité plus élevée d'admission aux soins intensifs (RCa 2,3, RRa 1,99) (28, 40). • Une étude n'a indiqué aucune association entre le variant Alpha et la forme grave de la maladie (RPa 1 02) parmi les cas ayant été hospitalisés (41). • Il n'y avait aucune différence significative entre les scores de l'unité de soins intensifs ou les exigences associées à la ventilation mécanique entre les variants Alpha, Bêta et le variant original (42).

Catégorie	P.1 (Gamma)	B.1.351 (Bêta)	B.1.1.7 (Alpha)
	Faible niveau de preuve.	Faible niveau de preuve.	• Des taux plus élevés d'hypoxie à l'admission à l'hôpital ont été signalés dans deux études (43, 44). Niveau de preuve modéré.
Facteurs de risque sur la gravité Comparativement au variant original ou au variant Alpha	Une étude de surveillance européenne : • Les cas associés au variant Gamma avaient une probabilité d'hospitalisation de 3,0 à 13,1 fois plus élevée dans les groupes d'âge 20 à 79 ans (28). • L'admission à l'USI était 2,9 à 13,9 fois plus élevée dans les groupes d'âge ≥ 40 ans (28). • Les conditions préexistantes étaient moins nombreuses, soit 27,8 % pour le variant Gamma contre 89 % pour le variant original, p < 0,001 (28). Faible niveau de preuve. Trois autres études d'observation ont été effectuées	Trois études comprenant des études de surveillance et d'observation : • La probabilité d'hospitalisation était plus élevée dans plusieurs pays européens (28) chez les adultes de 40 à 59 ans et de 60 à 79 ans (RC 3,5 à 3,6) infectés par le variant Bêta alors qu'en Afrique du Sud, les patients qui ont été hospitalisés après avoir été infectés par ce variant étaient beaucoup plus âgés (57 contre 54 ans, p = 0,03) (31) que ceux qui ont été infectés par le variant original. • Les preuves sont contradictoires en ce qui concerne l'âge de l'admission à l'unité des soins intensifs en raison du variant Bêta puisqu'on a vu une probabilité plus élevée chez les adultes âgés de 40 à 59 ans (RCa 8, IC à 95 %, 3,7 à 17,3) dans plusieurs pays européens (28), mais aucune différence significative d'âge (63 contre 67 ans, p = 0,15) en France (42), par rapport au variant original.	Dix études d'observation : • Une étude sur les cas de patients atteints de COVID-19 et hospitalisés a indiqué une plus grande proportion de femmes (48,0 % contre 41,8 %, p = 0,01), un plus petit nombre de patients fragiles (14,5 % contre 22,4 %, p = 0,001) et une plus grande proportion de personnes atteintes d'obésité (30,2 % contre 24,8 %, p = 0,048), mais aucune différence en ce qui concerne l'âge ou l'ethnie (43). • Les études n'ont signalé aucune différence significative en ce qui concerne l'âge et le sexe des patients, ainsi que la durée médiane du séjour à l'hôpital (35, 42). La différence d'âge était cependant statistiquement significative dans une autre étude (37 et 39 ans) (45). • Une étude a indiqué un ratio de probabilité d'hospitalisation 3,0 fois plus élevé chez les 20 à 39 ans et 2,3 fois plus élevé chez les 40 à 59 ans alors que les conditions préexistantes étaient moins nombreuses (44,8 % contre 89 % p < 0,001) (28). • Une étude réalisée dans les hôpitaux en France a révélé que l'âge moyen était de

Catégorie	P.1 (Gamma)	B.1.351 (Bêta)	B.1.1.7 (Alpha)
	sans séquençage du génome entier (très faible niveau de preuve).	• Les cas infectés par le variant Bêta étaient moins susceptibles d'avoir des comorbidités comparativement aux cas infectés par le variant original en Europe et en Afrique du Sud (28, 31). Faible niveau de preuve.	59,2 ans, en baisse par rapport à 70,7 ans, et que le nombre de patients sans comorbidité avait augmenté de 16 % à 42 % (p = 0,007) (44). Niveau de preuve faible à modéré.
Mortalité Comparativement au variant original ou au variant Alpha	Deux études observationnelles et un modèle prédictif : • Le variant Gamma présentait une probabilité de mortalité globale plus faible (RCa 0,6, IC à 95 %, 0,3 à 1,0) (28). • Taux de mortalité à l'hôpital plus élevé chez les jeunes adultes de 18 à 50 ans (46). • Le modèle prédictif a estimé que la mortalité moyenne était 1,5 fois (50 %, intervalle de crédibilité 1,2 à 1,9) plus élevée après l'émergence du variant Gamma (5).	Trois études comprenant des études de surveillance et d'observation : • Des études effectuées dans différents pays et contextes à propos de la mortalité liée au variant Bêta ont donné des données contradictoires. Ainsi, l'Afrique du Sud a indiqué une proportion accrue de mortalité (36,4 % contre 32,6 %, p = 0,26) (31) alors que plusieurs pays européens n'ont signalé aucune différence dans les probabilités de décès (RCa 1,1, IC à 95 %, 0,4 à 3,4) (28) par rapport au variant original. • Une proportion plus élevée de mortalité liée au variant Bêta à l'USI (74,4 % contre 57,1 %, p = 0,002) comparativement au variant original en Afrique du Sud (31) et probabilité de décès à l'USI plus élevée (RC 5,67, IC à 95 %, 1,04 à 30,81, P = 0,04)	16 études de surveillance et d'observation : • Cinq études n'ont signalé aucune différence significative en matière de mortalité globale (2,1 contre 4,1 %) (32, 35, 38, 39) ou après 28 jours (RC : 0,90, IC à 95 %, 0,57 à 1,41, p = 0,64) (36). • Une étude a fait état de probabilités de mortalité plus faibles (RCa 0,5, IC à 95 %, 0,3 à 0,9) (28). • Huit études ont fait état d'un risque de mortalité plus élevé : risque plus élevé de décès après 28 jours (55 %, IC à 95 %, 39 à 72 %) (47), RRa 1,59 (IC à 95 %, 1,25 à 2,03) (40), RRa 1,67 (IC à 95 %, 1,34 à 2,09; P < 0,0001) (41). RR 1,64 (IC à 95 %, 1,32 à 2,04, p < 0,001) (48), ce qui équivaut à une augmentation de 2,5 à 4,1 décès par 1 000 cas détectés (37, 49, 50). Une étude écologique a estimé qu'au Royaume-Uni, le variant Alpha était 33 % plus meurtrier (51).

Catégorie	P.1 (Gamma)	B.1.351 (Bêta)	B.1.1.7 (Alpha)
	Faible niveau de preuve.	comparativement aux données enregistrées en France avec le variant Alpha (42). Faible niveau de preuve.	• Parmi les patients qui se trouvaient dans l'USI en France, les cas associés au variant Bêta présentaient des probabilités plus élevées de mourir dans les 60 jours suivant l'admission à l'USI comparativement aux cas infectés par le variant Alpha (RC 5,67, IC à 95 %, 1,04 à 30,81) (42). Niveau de preuve modéré.
Facteurs de risque de mortalité comparativement au variant original	Une étude de surveillance au Brésil : • La mortalité chez les personnes atteintes de la COVID-19 et âgées de moins de 60 ans est passée de 18 % en novembre 2020 à 28 % en février 2021 (52). • La mortalité chez les personnes ne présentant aucune condition préexistante était plus élevée chez les femmes (RR 5,65, IC à 95 %, 2,9 à 11,03; p < 0,0001) et chez les personnes âgées de 40 à 59 ans (RR 7,7, IC à 95 %, 5,01 à 11,83; p < 0,0001) après l'émergence du variant Gamma (52). Faible niveau de preuve.	Aucune étude	Deux études de surveillance et de cohorte rétrospective : • Une étude a révélé que la mortalité était plus élevée dans les groupes d'âge plus jeunes que dans les groupes plus âgés (59,0 % chez les 1 à 34 ans contre 55,4 % chez les 85 ans ou plus) et qu'elle était plus élevée chez les Noirs (69,6 %), les personnes d'origine ethnique mixte ou inconnue (64,8 %), les Blancs (58,0 %) et les Asiatiques (57,6 %) (47). • Une autre étude n'a trouvé aucune augmentation de la mortalité en fonction du sexe (p = 0,90), du groupe ethnique (p = 0,64) ou du groupe d'âge (p = 0,15) (40). Faible niveau de preuve.

Catégorie	P.1 (Gamma)	B.1.351 (Bêta)	B.1.1.7 (Alpha)
Charge virale Comparativement au variant original	Deux études de surveillance : • La charge virale des cas associés au variant Gamma était environ 10 fois plus élevée que celle des cas non associés à ce variant (variants originaux) (53). • La charge virale était plus élevée que celle associée au variant original, mais était inférieure à celle associée au variant Alpha (3). Faible niveau de preuve.	Aucune étude	Vingt-deux études d'observation et analyses de surveillance : • On a toujours trouvé des valeurs de Ct plus faibles ou des charges virales estimées plus élevées. L'ordre de grandeur médian supérieur varie selon les études et la protéine cible de 2 à 10 fois la différence (3, 32, 35, 45, 54 à 59, 59 à 61). Niveau de preuve faible à modéré.
Période infectieuse par rapport au variant original	Aucune étude	Aucune étude	Une petite étude (n = 7 cas infectés par le variant Alpha) effectuée aux É.-U. a calculé que les infections durent en moyenne 13,3 jours comparativement à 8,2 jours pour les autres variants (57). Très faible niveau de preuve.
Période d'incubation	Aucune étude	Trois études comprenant des études de surveillance et d'observation : • La probabilité d'hospitalisation était plus élevée dans plusieurs pays européens (28) chez les adultes de 40 à 59 ans et de 60 à 79 ans (RC 3,5 à 3,6) infectés par le variant Bêta alors qu'en Afrique du Sud, les patients qui ont été hospitalisés après avoir été infectés par ce variant étaient beaucoup plus âgés	Aucune étude.

Catégorie	P.1 (Gamma)	B.1.351 (Bêta)	B.1.1.7 (Alpha)
		(57 contre 54 ans, p = 0,03) (31) que ceux qui ont été infectés par le variant original. • Les preuves sont contradictoires en ce qui concerne l'âge de l'admission à l'unité des soins intensifs en raison du variant Bêta puisqu'on a vu une probabilité plus élevée chez les adultes âgés de 40 à 59 ans (RCa 8, IC à 95 %, 3,7 à 17,3) dans plusieurs pays européens (28), mais aucune différence significative d'âge (63 contre 67 ans, p = 0,15) en France (42), par rapport au variant original. • Les cas infectés par le variant Bêta étaient moins susceptibles d'avoir des comorbidités comparativement aux cas infectés par le variant original en Europe et en Afrique du Sud (28, 31). Faible niveau de preuve.	
ÉCHAPPEMENT IMMUNITAIRE – Incidence potentielle sur l'efficacité du vaccin, possibilité de réinfection			
Réinfection par infection naturelle comparativement au variant original	Deux études de surveillance : • En supposant que 78 % de la population était déjà infectée, on estime que 28 % des cas à Manaus signalés entre novembre 2020 et janvier 2021 étaient des réinfections (4).	Trois études, incluant des exposés de cas et des études d'observation : • Trois cas de réinfection par le variant Bêta ont été signalés (62 à 64).	Trois études ont montré que le variant Alpha n'échappait pas à l'immunité naturelle : • un taux de réinfection estimé à 0,7 % (IC 95 % : 0,6 à 0,8) (65). • Dans une étude menée aux États-Unis, le taux de séropositivité antérieur chez les personnes atteintes du variant Alpha était

Catégorie	P.1 (Gamma)	B.1.351 (Bêta)	B.1.1.7 (Alpha)
	• On estime que 16,9 % des cas associés au P.1 (IC à 95 %, 9,48 à 28,5) à Manaus signalés entre janvier 2021 et mars 2021 étaient des réinfections (81). Faible niveau de preuve.	Très faible niveau de preuve.	de 0,7 % comparativement aux infections sans VP qui était de 0,9 % (38). • Une étude britannique n'a trouvé aucune preuve que le variant Alpha modifiait l'étendue de la protection positive à l'infection par PCR chez les personnes séropositives (RTIa 0,40, IC à 95 %, 0,10 à 1,64, p = 0,20) (66). Niveau de preuve modéré.
Infection sporadique après la vaccination, efficacité réelle ou prévue du vaccin comparativement au variant original	Deux études cas-témoins : Une dose du vaccin : • La vaccination avec au moins une dose de CoronaVac a été associée à une réduction d'un facteur de 0,50 (EV ajustée, 49,6 %; IC à 95 %, 11,3 à 71,4) des probabilités d'infection symptomatique par le SRAS-CoV-2 14 jours après administration de la première dose (82). Deux doses du vaccin : • Sept jours ou plus après la deuxième dose, le vaccin Moderna ou Pfizer avait une EV ajustée de 88 % (IC à 95 %, 61 à 96) contre une infection symptomatique au variant P.1 comparativement	Sept études, incluant des essais cliniques randomisés (ECR) et des études d'observation : Infection ayant percé après la vaccination : • Aucune infection ayant percé n'a été identifiée plus de 14 jours après l'administration de la deuxième dose (principalement Pfizer) dans une étude cas/témoins menée en Israël (67) • 50 % (13 sur 26) des résidents des maisons de soins infirmiers et 5,2 % (1 sur 19) des membres du personnel qui ont reçu le vaccin Pfizer-BioNTech ont été atteints par des infections ayant percé associées au variant Bêta (64). Deux doses du vaccin :	Treize études comprenant des ECR, des cohortes et des études de surveillance : Infection ayant percé après la vaccination : • Une enquête sur une éclosion chez des travailleurs de la santé a révélé que deux médecins pleinement vaccinés par Pfizer-BioNTech ont été infectés par le variant Alpha. Ils ont reçu la deuxième dose un mois avant l'apparition des symptômes (73). • Aux États-Unis, les cas d'infection ayant percé associée au variant Alpha n'étaient pas plus courants que ceux associés au variant original (1,29 fois, IC à 95 %, 0,75 à 2,20, p = 0,468) (74). Une dose du vaccin : • Pfizer-BioNTech (BNT162b2) en Israël, où 94 % des cas étaient associés au variant Alpha, efficacité du vaccin contre l'infection symptomatique entre la première dose et

Catégorie	P.1 (Gamma)	B.1.351 (Bêta)	B.1.1.7 (Alpha)
	à une infection par la souche sauvage (93 %, IC à 95 %, 87 à 96). L'EV ajustée pour une dose contre le variant P.1 était de 43 % (IC à 95 %, 22 à 59) par rapport à la souche sauvage (61 %, IC à 95 %, 53 à 67) (72). Faible niveau de preuve.	• AstraZeneca (ChAdOx1-S) : 10,4 % d'efficacité pour la prévention de la maladie symptomatique (68). • Johnson et Johnson : EV de 52 % et de 64 % pour la forme modérée de la maladie et de 73 % et de 82 % pour la forme grave après 14 jours et 28 jours respectivement (69). • Novavax (NVX-CoV2373) : EV de 51,0 % (IC à 95 %, -0,6 à 76,2) contre la maladie symptomatique chez les personnes séronégatives (70). • Pfizer-BioNTech (BNT162b2) :Au Qatar, EV de 75,0 % (IC à 95 %, 70,5 % à 78,9 %) contre l'infection par le variant Bêta 2 semaines après la deuxième dose (71). Une EV de 50 % (IC à 95 %, 34 % à 73 %) chez les résidents des maisons de soins infirmiers (âge médian : 87,0 ±8,2 ans) avec deux doses espacées de 19 jours (64). • Moderna/Pfizer-BioNTech : EV comparable de 88 % contre l'infection symptomatique associée au variant Bêta 7 jours après avoir reçu la deuxième dose (72).	jusqu'à 14 jours après la deuxième dose (RCa 2,4 (IC à 95 %, 1,2 à 5,1) (67). • Pfizer-BioNTech (BNT162b2) ou AstraZeneca (ChAdOx1-S) La première dose du vaccin a réduit le risque d'hospitalisation d'urgence chez les adultes de 70 ans et plus de 43 % (33 % à 52 %) et de 37 % (3 % à 59 %) en Angleterre, respectivement (75). • Le risque de décès a été réduit de 51 % (37 % à 62 %) chez les adultes de 70 ans et plus en Angleterre qui avaient reçu une dose de Pfizer-BioNTech (75). • Une étude menée au Royaume-Uni n'a révélé aucune différence dans la protection contre le variant Alpha par rapport aux autres variants après une première dose de vaccin (RTIa = 1,84, IC à 95 %, 0,75 à 4,49, p = 0,18) (66). Deux doses du vaccin : • Dans un ECR effectué au Royaume-Uni, l'efficacité du vaccin AstraZeneca/ COVISHIELD (ChAdOx1) était de 70,4 % (IC à 95 %, 43,6-84,5) comparativement à 81,5 % (67,9 à 89,4) pour les variants originaux (76). • Dans un ECR effectué au Royaume-Uni, l'efficacité du vaccin Novavax (NVX-CoV2373) contre le variant Alpha était de 86,3 % (71,3 à 93,5) alors qu'elle était de

Catégorie	P.1 (Gamma)	B.1.351 (Bêta)	B.1.1.7 (Alpha)
			96,4 % (73,8 à 99,5) pour le variant original (77). • Pfizer-BioNTech (BNT162b2) En Israël, où 94 % des cas étaient associés au variant Alpha, l'efficacité du vaccin était supérieure à 96 % 14 jours après la deuxième dose (78) et supérieure à 90 % chez les 70 ans et plus (79). • Au Canada, deux doses du vaccin Moderna (ARNm-1273) ou Pfizer-BioNTech avaient une efficacité comparable ajustée (≥88 %) contre les infections symptomatiques associées aux variants Alpha, Bêta et Gamma, ≥7 jours après l'administration de la deuxième dose (72).
		Niveau de preuve faible à modéré.	Niveaux de preuve variables, allant des ECR (modérés à élevés) aux observations cliniques (très faibles).

IC = intervalle de confiance, Ct = seuil du cycle, USI = unité de soins intensifs, RC = rapport des cotes, PCR = réaction en chaîne par polymérase, EV = efficacité du vaccin, RCa = rapport de cotes ajusté, RRa = rapport de risque ajusté, RPa = rapport de prévalence ajusté

Vue d'ensemble des éléments de preuve

Les modèles d'étude inclus dans ce résumé vont des essais cliniques randomisés en double aveugle à faible risque de biais à un certain nombre de modèles d'étude par observation différents ayant différents niveaux de preuves. Les études d'observation permettent d'obtenir des éléments de preuve de qualité faible à modérée selon la méthodologie particulière utilisée et de la cohérence entre les études. Les études descriptives incluses dans le présent examen, ce qui inclut les séries de cas et rapports de cas, les modèles prédictifs, les études écologiques, les modèles animaux et les études *in vitro*, présentent de faibles à très faibles éléments de preuve et ne peuvent généralement pas être utilisés pour générer des hypothèses, car celles-ci devront être examinées plus à fond avec une méthodologie distincte. Compte tenu de la très grande variation observée, une indication du niveau de confiance des éléments de preuve est donc requise pour s'assurer d'obtenir un résultat particulier. Les méthodologies sont indiquées, mais aucune évaluation officielle du risque de biais n'a été effectuée.

Il y a plusieurs lacunes dans les connaissances ou des domaines où très peu de recherche figure dans le tableau des points clés, et des recherches supplémentaires sont nécessaires pour améliorer la confiance dans les résultats sommaires, en particulier pour les variants Bêta et Gamma.

TABLE DES MATIÈRES

P.1 (GAMMA)

Le jeu de données en Excel comprend des résumés de chacune des études et est accessible ici. Vous trouverez ci-dessous le profil détaillé des éléments de preuve élaboré pour le variant Gamma. Il porte notamment sur les données sur les changements dans l'efficacité de la transmission, les changements dans la gravité clinique, l'échappement immunitaire, les tests et diagnostics, ainsi que d'autres études épidémiologiques portant principalement sur la propagation des VP.

Tableau 3 : Profil fondé sur les éléments de preuve pour le VP P.1 (Gamma) (n = 125)

CATÉGORIE	RÉSUMÉ DES PRINCIPAUX RÉSULTATS	VUE D'ENSEMBLE DES ÉLÉMENTS DE PREUVE
Efficacité de transmission		
Transmissibilité comparativement au variant original	Une transmissibilité accrue par rapport au variant original : • 27 % de plus en France pour les variants Gamma et Bêta combinés (3). • 2,6 (IC à 95 % : 2,4 à 2,8) fois plus élevé (4) et 2,0 (50 % intervalle de crédibilité 1,7 à 2,4) fois plus transmissible avec une immunité croisée médiane estimée à 68 % (50 % intervalle de crédibilité 54 à 79) au Brésil (5). • 1,12 (IC à 95 %, 1,03 à 1,23) fois plus transmissible avec un échappement immunitaire complet à 1,39 (IC à 95 %, 1,26 à 1,56) et protection complète en Italie (6). • D'autres études placent la transmissibilité du variant Gamma entre celle du variant original et celle du variant Alpha et montrent que la transmissibilité du variant Gamma a légèrement diminué au fil du temps entre janvier 2021 et avril 2021 partout dans le monde (7).	Cinq études ont fourni des estimations de la transmissibilité du variant Gamma, notamment : trois analyses de données de surveillance portant sur le Brésil (2) et à l'échelle mondiale (1), une étude transversale provenant de la France et un modèle prédictif établi en Italie. Il y a peu de cohérence entre les études. L'hétérogénéité des estimations de la transmissibilité accrue peut être due à des facteurs tels que l'emplacement géographique et les moments où les estimations ont été faites. Faible niveau de preuve.
Interventions non pharmaceutiques comparativement au variant original	• Gamma est apparu à Manaus, au Brésil, à la fin de novembre 2020, et a montré un taux de reproduction effectif (Rt) élevé de 2,6 (densité postérieure la plus élevée (DPÉ) de 95 % : 1,5 à 4,5) en décembre 2020. Après un renforcement des restrictions en ce qui concerne la distanciation sociale, on a estimé que le Rt avait diminué à 1,2 (DPÉ de 95 % : 0,9 à 1,6) à	Une analyse de données de surveillance au Brésil.

CATÉGORIE	RÉSUMÉ DES PRINCIPAUX RÉSULTATS	VUE D'ENSEMBLE DES ÉLÉMENTS DE PREUVE
	la fin de décembre 2020 et en janvier 2021 (53). En comparaison, un variant précédent avait également un Rt de 2,6 (DPÉ 1,6 à 3,8) en mars 2020 qui a ensuite diminué pour atteindre 1,0 (DPÉ 0,8 à 1,2) en avril 2020, une fois que la distanciation sociale a été augmentée de plus de 50 % à Manaus (en raison de la mise en œuvre des interventions non pharmaceutiques (INP)).	Faible niveau de preuve.
Gravité clinique		
Virulence / gravité ou durée de la maladie comparativement au variant original	• Une proportion plus élevée de cas associés au variant Gamma ayant été hospitalisés a été signalée par rapport au nombre d'hospitalisations pour le variant original (20 % contre 7,5 % p<0,001) (28). • Une étude a signalé un rapport de cotes ajusté (RCa 2,6, IC à 95 % 1,4 à 4,8) plus élevé pour les cas associés au variant Gamma ayant été admis à l'hôpital ou à l'USI (RCa 2,2, IC à 95 % 1,8 à 2,9) par rapport au variant original (28). • Il y a eu croissance exponentielle des hospitalisations dans le Rio Grande do Sul, avec un temps de doublement moyen de 13,4 jours et un taux de croissance quotidien de 5,3 % entre février 2021 et mars 2021 (29). • Une croissance exponentielle similaire (temps de doublement de 13,3 jours, taux de croissance quotidien de 5,4 %) pour les hospitalisations a été signalée dans la ville de Porto Alegre (29).	Deux analyses de données de surveillance effectuées en Europe et au Brésil. Faible niveau de preuve.
Facteurs de risque de la gravité comparativement au variant original	• Dans l'analyse stratifiée par âge, les cas associés au variant Gamma avaient une probabilité d'hospitalisation 3,0 à 13,1 fois plus élevée dans les groupes d'âge de 20 à 39 ans, de 40 à 59 ans et de 60 à 79 ans (28). • Les probabilités d'admission à l'USI étaient 2,9 à 13,9 fois plus élevées dans les groupes d'âge	Deux analyses de données de surveillance provenant de pays européens et du Brésil, une étude écologique effectuée au Brésil et une étude de cohorte rétrospective menée au Brésil.

CATÉGORIE	RÉSUMÉ DES PRINCIPAUX RÉSULTATS	VUE D'ENSEMBLE DES ÉLÉMENTS DE PREUVE
	de 40 à 59 ans, de 60 à 79 ans et chez les personnes âgées de 80 ans et plus (28). • Les conditions préexistantes étaient moins nombreuses pour les cas associés au variant Gamma (27,8 %) que pour les cas associés au variant original (89 %), p < 0,001 (28). Dans trois études, comme le génome entier n'a pas été séquencé pour tous les cas, la lignée n'a donc pas été déterminée (très faible niveau de preuve) : • parmi les cas graves, le nombre de personnes de moins de 60 ans est passé de 39 % dans la première vague (novembre et décembre 2020) à 47 % dans la deuxième vague (février 2021) alors que le variant Gamma était prédominant (52). • Il n'y a pas eu d'augmentation de la proportion d'hospitalisations dans aucun des groupes d'âge avant (février à octobre 2020) et après (octobre 2020 à février 2021) l'apparition du variant Gamma au Brésil (46). • Il n'y avait pas de différence significative dans l'âge moyen des patients hospitalisés infectés avant et après mars 2021 au moment où le variant Gamma est devenu dominant à Sao Paulo, au Brésil (80).	Faible niveau de preuve.
Mortalité comparativement au variant original	• Diminution du risque de mortalité dû au variant Gamma comparativement au variant original dans l'analyse multivariable (RCa 0,6, IC à 95 % 0,3 à 1,0) (28). • Une augmentation différenciée de la mortalité associée à la COVID-19 chez les adultes âgés de 18 à 50 ans après l'apparition du variant Gamma au Brésil suggère la possibilité que le variant Gamma ait des répercussions plus sévères dans cette population. Les jeunes adultes présentaient des taux de mortalité à l'hôpital supérieurs à 10 % (46). • Le modèle prédictif a estimé que le risque médian de mortalité des suites des infections	Une analyse de données de surveillance provenant de pays européens, et une étude écologique et un modèle prédictif effectués au Brésil.

CATÉGORIE	RÉSUMÉ DES PRINCIPAUX RÉSULTATS	VUE D'ENSEMBLE DES ÉLÉMENTS DE PREUVE
	associées au variant Gamma à Manaus était 1,5 (50 % intervalle de crédibilité 1,2 à 1,9) plus élevé après qu'avant l'émergence du variant Gamma en novembre 2020 (5). Il n'est cependant pas possible de déterminer si l'augmentation estimée du risque de mortalité relatif est due à une infection associée au variant Gamma, aux pressions exercées sur le système de santé de Manaus, ou aux deux.	Faible niveau de preuve.
Facteurs de risque de mortalité comparativement au variant original	Une étude dans laquelle le génome entier n'a pas été séquencé pour tous les cas, ce qui veut dire que la lignée n'a pas été déterminée (très faible niveau de preuve) : • La mortalité dans les cas de COVID-19 chez les personnes de moins de 60 ans est passée de 18 % en novembre 2020 à 28 % en février 2021 alors que le variant Gamma était prédominant (52). • La plus forte augmentation du taux de létalité s'est produite chez les personnes âgées de 20 à 59 ans et chez les patients sans condition à risque préexistante. Parmi les cas graves, la proportion de patients qui n'avaient aucun problème de santé préexistant était plus élevée en février 2021 (33 % comparativement à 25 % en novembre 2020) (52).	Une analyse de données de surveillance au Brésil.
	• Comparativement à novembre et à décembre 2020, les femmes âgées de 20 à 39 ans, sans condition de risque préexistante, étaient 5,65 (IC à 95 %, 2,9 à 11,03; $p < 0,0001$) fois plus à risque de décéder en février 2021 alors que les personnes de 40 à 59 ans étaient 7,7 (IC à 95 %, 5,01 à 11,83; $p < 0,0001$) fois plus à risque de subir le même sort (52).	Faible niveau de preuve.
Charge virale comparativement au variant original	• La charge virale (mesurée à l'aide des valeurs Ct) des échantillons du variant Gamma était inférieure à celle des échantillons du variant Alpha et supérieure à celle des variants originaux (3).	Deux analyses de données de surveillance provenant de la France et du Brésil, une étude de cohorte rétrospective menée au Brésil.

CATÉGORIE	RÉSUMÉ DES PRINCIPAUX RÉSULTATS	VUE D'ENSEMBLE DES ÉLÉMENTS DE PREUVE
	• La charge virale (mesurée à l'aide des valeurs Ct) des infections associées au variant Gamma était environ 10 fois plus élevée que dans les infections non associées au variant Gamma (53). • La charge virale liée aux infections associées au variant Gamma était considérablement inférieure à celle des infections non associées au variant Gamma chez les hommes (18 à 59 ans) (P = 0,0005), les femmes adultes (P<0,0001) et les femmes âgées (plus de 59 ans) (P = 0,0149), mais pas significativement différente chez les hommes âgés (P = 0,4624) (53). Une étude dans laquelle le génome entier n'a pas été séquencé pour tous les cas, ce qui veut dire que la lignée n'a pas été déterminée (très faible niveau de preuve) : • Il n'y avait pas de différence significative dans les valeurs Ct moyennes chez les patients hospitalisés infectés et chez les travailleurs de la santé avant et après mars 2021, au moment où le variant Gamma est devenu dominant au Brésil (80).	Faible niveau de preuve.
Période infectieuse	Aucune étude	
Période d'incubation	Aucune étude	
Échappement immunitaire - incidence potentielle sur l'efficacité du vaccin, possibilité de réinfection		
Réinfection par infection naturelle comparativement au variant original	• On a estimé que 28 % des cas à Manaus au Brésil signalés entre novembre 2020 et janvier 2021 étaient des réinfections, étant donné que 78 % de la population avait déjà été infectée (4). • On estime que 16,9 % des cas associés au variant Gamma (IC à 95 %, 9,48 à 28,5) à Manaus déclarés entre janvier 2021 et mars 2021 étaient des réinfections. Si les réinfections probables sont également	Deux analyses de données de surveillance du Brésil.

CATÉGORIE	RÉSUMÉ DES PRINCIPAUX RÉSULTATS	VUE D'ENSEMBLE DES ÉLÉMENTS DE PREUVE
	incluses, le total passe alors à 25,8 % de réinfections (IC à 95 %, 16,7 à 37,4). Si les réinfections possibles sont aussi incluses, alors 31,0 % de ces cas étaient des réinfections (IC à 95 %, 21,4 à 42,5) (81).	Faible niveau de preuve.
Infection sporadique après la vaccination, efficacité réelle ou prévue du vaccin comparativement au variant original	• À Manaus, au Brésil, où plus de 75 % des cas étaient des cas associés au variant Gamma pendant la période à l'étude, la vaccination avec au moins une dose de CoronaVac a été associée à une réduction de 0,50 fois (EV ajustée, 49,6 %; IC à 95 %, 11,3 à 71,4) des probabilités d'infection symptomatique par le SRAS-CoV-2 pendant la période de 14 jours ou plus après avoir reçu la première dose. Le sexe féminin (RC 0,50; IC à 95 %, 0,38 à 0,81) et un résultat positif au test RT-PCR ou à l'antigène du SRAS-CoV-2 au cours de la période précédant l'étude (RC 0,38; IC à 95 %, 0,17 à 0,87) ont été associés à une probabilité réduite d'infection symptomatique par le SRAS-CoV-2 (82). • Sept jours ou plus après la deuxième dose du vaccin Moderna ou Pfizer, on a obtenu une EV ajustée de 88 % (IC à 95 %, 61 à 96) pour une infection symptomatique au variant Gamma comparativement à une infection par la souche sauvage (93 %, IC à 95 %, 87 à 96). L'EV ajustée pour l'infection symptomatique au variant Gamma pour une dose était de 43 % (IC à 95 %, 22 à 59) comparativement à la souche symptomatique sauvage (61 %, IC à 95 %, 53 à 67) (72).	Deux études cas-témoins en provenance du Brésil et du Canada. Faible niveau de preuve.
Études in vitro sur les traitements Comparativement au variant original	• Il a été démontré que les traitements multiples sont moins efficaces contre le variant Gamma que contre le variant original, ce qui inclut le casirivimab (83-85), le bamlanivimab (85), l'etsevimab et l'imdevimab (83). • Il a aussi été démontré que la combinaison d'imdevimab et de casirivimab inhibe efficacement le variant Gamma (85).	Les études *in vitro* constituent des preuves de bas niveau qui donnent un aperçu préliminaire des résultats que l'on s'attend à obtenir avec les études *in vivo*.

CATÉGORIE	RÉSUMÉ DES PRINCIPAUX RÉSULTATS	VUE D'ENSEMBLE DES ÉLÉMENTS DE PREUVE
Études *in vitro* effectuées avec du sérum de phase convalescente et du sérum provenant de personnes vaccinées Comparativement au variant original	La plupart des études ont montré que les sérums de phase convalescente et provenant de personnes vaccinées (Pfizer, Coronavac, Sinopharm, Moderna) ont réduit l'activité neutralisante du variant Gamma comparativement au variant original (86 à 89). *Remarque : De nombreuses études in vitro ont été relevées. Veuillez consulter le jeu de données Excel pour plus de détails sur chacune des études.*	Très faible niveau de preuve. La réponse immunitaire est complexe, et l'absence d'anticorps neutralisants ou le manque de ces derniers ne signifie pas un manque de protection immunitaire. D'autres recherches sont nécessaires (voir la revue effectuée par le Groupe des sciences émergentes de l'ASPC sur l'immunité protectrice).
Tests et diagnostics		
Test et détection comparativement au variant original	• Aucun échec dans les tests n'a été déclaré pour le PCR du variant Gamma, les tests d'antigènes ou les tests sérologiques (90).	Une étude visant à évaluer la fiabilité des tests de diagnostic a examiné la performance de ces tests. Faible niveau de preuve.
Épidémiologie de la propagation		
Émergence des VP **Au fil du temps**	• De nombreuses études utilisent le séquençage du génome entier pour déclarer la prévalence ponctuelle ou à un moment donné du variant Gamma dans une région spécifique, élément qui n'a pas été résumé ici (11, 91). • La prévalence du variant Gamma est passée de 0 % en novembre 2020 à 73,8 % à Amazonas, au Brésil (53) et à près de 30 % à Amazonas, en Colombie, en janvier 2021 (92). • La prévalence du variant Gamma en Italie est demeurée relativement stable de février 2021 (5,0 %, IC à 95 %, 3,9 à 6,4) à mars 2021 (4,8 %, IC à 95 %, 3,9 à 5,9), comparativement à celle du variant Alpha, qui est passée de 53,1 % (IC à 95 %, 50,3 à 55,9) à 85,7 % (IC à 95 %, 84,1 à 87,3) (23).	Trois analyses de données de surveillance au Brésil (2) et en Italie (1). Faible niveau de preuve.
Prédictions en ce qui concerne la propagation	• Si l'on tente de revenir au niveau des contacts prépandémiques une fois que 50 % de la population des États-Unis aura été vaccinée en juillet 2021, on prévoit que le variant Gamma surpassera alors les souches Alpha et Bêta et deviendra la souche dominante dans 2 à	Deux modèles prédictifs. L'une des limites associées à ces modèles est le fait qu'ils ne tiennent pas compte du B.1.617 (delta) et qu'ils ne comparent que la propagation prévue du variant

CATÉGORIE	RÉSUMÉ DES PRINCIPAUX RÉSULTATS	VUE D'ENSEMBLE DES ÉLÉMENTS DE PREUVE
	3 mois. Le modèle suppose que le variant Gamma possède une efficacité immunitaire de 68 % en réponse au vaccin ou à la souche sauvage (93). • Si les variants Gamma et Bêta s'établissent simultanément dans la population de New York, on prévoit que le variant Gamma sera supplantera le variant Alpha et deviendra co-dominant avec le variant Bêta d'ici août 2021. Si, toutefois, le variant Gamma s'établit dans la population avant le variant Bêta, le variant Gamma éliminerait le variant Bêta et deviendrait alors dominant. Le modèle suppose que le variant Gamma a la même EV que la souche sauvage (94).	Gamma avec les valeurs pour les variant Alpha et variant Bêta. Faible niveau de preuve.

IC = intervalle de confiance, Ct = seuil du cycle, USI = unité des soins intensifs, RC = rapport de cotes, PCR = réaction en chaîne de la polymérase, EV = efficacité du vaccin, RC = rapport de cotes, RCa = rapport de cotes ajusté

B.1.351 (BÊTA)

Le jeu de données en Excel comprend des résumés de chacune des études et est accessible ici. Vous trouverez ci-dessous le profil détaillé des éléments de preuve élaboré pour le variant Bêta. Il porte notamment sur les données sur les changements dans l'efficacité de la transmission, les changements dans la gravité clinique, l'échappement immunitaire, les tests et diagnostics, ainsi que d'autres études épidémiologiques portant principalement sur la propagation des VP.

Tableau 4 : Profil fondé sur les éléments de preuve pour le VP B.1.351 (Bêta) (n = 229)

CATÉGORIE	RÉSUMÉ DES PRINCIPAUX RÉSULTATS	VUE D'ENSEMBLE DES ÉLÉMENTS DE PREUVE
Efficacité de transmission		
Transmissibilité comparativement au variant original ou au variant Alpha	• Une transmissibilité accrue par rapport au variant original : 27 % en France pour les variants Bêta et Gamma combinés (3), 55 % (8, 9) et 20 à 100 % (jusqu'à 175 %) en Afrique du Sud (10) • Augmentation de l'avantage de transmission par rapport au variant Alpha en Île-de-France (15,8 %, IC à 95 % : 15,1 % à 16,1 %) et dans la région Hauts-de-France (17,1 %, IC à 95 % : 16,1 % à 18,8 %) en avril et en mai 2021 (11).	Ces chiffres ont été estimés à partir de cinq analyses de données de surveillance. Il y a peu de cohérence entre les études. L'hétérogénéité des estimations de la transmissibilité accrue peut être due à de nombreux facteurs, notamment le moment où sont effectuées les estimations de la pandémie. Faible niveau de preuve.
Taux d'attaque secondaire comparativement au variant original	• TAS = 76,9 %, ce qui équivaut à (R_{eff} = 4) dans la présente enquête (95).	Une enquête épidémiologique. Faible niveau de preuve.
Gravité clinique		
Virulence / gravité ou durée de la maladie comparativement au variant original	• Proportion des cas symptomatiques : les cas associés au variant Bêta (90,3 %; 28 sur 31) par rapport aux cas associés au variant original (81,4 %; 547 sur 672, p = 0,2) (28) dans plusieurs pays européens (28). Augmentation des hospitalisations et des admissions à l'USI : • Une plus grande probabilité d'hospitalisation en raison du variant Bêta (19,3 %) comparativement au variant original (7,5 %) p<0,001 dans une analyse multivariable (RCa = 3,6, IC à 95 % : 2,1 à 6,2) dans plusieurs pays européens (28).	Quatre études sur la gravité, dont deux études de surveillance et deux études de cohortes rétrospectives menées en France et en Afrique du Sud. Les études de cohorte sont centrées sur un seul centre et ont donc une validité externe limitée et risquent d'être faussées. Faible niveau de confiance en ce qui concerne l'augmentation ou la diminution de la gravité de la maladie associée au variant Bêta.

CATÉGORIE	RÉSUMÉ DES PRINCIPAUX RÉSULTATS	VUE D'ENSEMBLE DES ÉLÉMENTS DE PREUVE
	• Augmentation de la proportion de cas associés au variant Bêta dans l'USI (2,3 %) comparativement au variant original (0,6 %) p = 0,001, et plus grande probabilité d'être admis à l'USI pour les cas associés au variant Bêta comparativement à ceux qui sont associés au variant original (RCa = 3,3, IC à 95 % : 1,9 à 5,7) dans plusieurs pays européens (28). • En France, les cas associés au variant Bêta étaient plus susceptibles d'être hospitalisés (RC = 1,56, p < 0,0001) que ceux qui sont liés au variant Alpha (11). Diminution des admissions à l'USI : • En Afrique du Sud, parmi les patients hospitalisés, il y a eu moins d'admissions à l'USI (35 % contre 48,5 %, p = 0,03) et moins de recours à la ventilation mécanique (8,9 % contre 15,5 %, p = 0,009) pendant la vague associée au variant Bêta comparativement aux vagues associées au variant original (31). Aucune différence : • Dans un hôpital en France, on n'a vu aucune différence significative dans les scores des soins intensifs et les exigences de ventilation mécanique pour ce qui est des cas associés au variant Bêta, au variant original ou au variant Alpha (42).	Faible niveau de preuve.
Facteurs de risque de la gravité comparativement au variant original	Âge : • Dans une analyse stratifiée par âge, les cas associés au variant Bêta présentaient une probabilité d'hospitalisation 3,5 à 3,6 fois plus élevée pour les groupes d'âge de 40 à 59 ans et de 60 à 79 ans par rapport aux cas associés au variant original dans les mêmes groupes d'âge dans plusieurs pays européens (28). • L'admission à l'USI était significativement plus probable pour les cas associés au variant Bêta (RCa 8, IC à 95 % : 3,7 à 17,3) âgés de 40 à 59 ans (28).	Trois études sur les facteurs de risque de gravité, y compris une étude de surveillance établie dans certains pays d'Europe et deux études de cohortes rétrospectives menées en France et en Afrique du Sud. Les études de cohorte sont centrées sur un seul centre et ont donc une validité externe limitée et risquent d'être faussées. Faible niveau de preuve.

CATÉGORIE	RÉSUMÉ DES PRINCIPAUX RÉSULTATS	VUE D'ENSEMBLE DES ÉLÉMENTS DE PREUVE
	• En Afrique du Sud, les cas hospitalisés pendant la vague associée au variant Bêta étaient beaucoup plus âgés (âge médian de 57 ans comparativement à 54 ans, p = 0,03) comparativement aux cas vus pendant la vague associée au variant original (31). • En France, on n'a vu aucune différence significative entre l'âge (63 ans contre 67 ans, p = 0,15) ou le sexe des personnes admises à l'USI parmi les cas associés au variant Bêta comparativement aux cas associés au variant original ou au variant Alpha (42). Comorbidités : • Les conditions préexistantes étaient moins nombreuses pour les trois VP (79,6 % pour le variant Bêta contre 89 % pour le variant original, p<0,001) (28). • Un plus grand nombre de cas vus pendant la vague liée au variant Bêta n'avaient aucune comorbidité (47 % contre 36,9 %, p = 0,008) et moins d'hypertension (32,2 % contre 45,2 %, p < 0,001) comparativement aux personnes touchées dans la vague liée au variant original en Afrique du Sud (31). • Il n'y avait pas non plus de différence entre les personnes atteintes de diabète sucré, de maladies respiratoires chroniques, de maladies cérébrovasculaires et séropositives (31).	
Mortalité comparativement au variant original ou au variant Alpha	Augmentation de la mortalité : • Augmentation de la mortalité globale (36,4 % contre 32,6 %, p = 0,26) et augmentation significative de la mortalité dans l'USI (74,4 % contre 57,1 %, p = 0,002) pendant la vague associée au variant Bêta comparativement à la vague associée au variant original en Afrique du Sud (31). • L'admission à l'hôpital pendant la vague associée au variant Bêta (p = 0,006) a été indépendamment associée à la mortalité, dans une analyse multivariée (31).	Trois études sur la mortalité, dont une étude de surveillance réalisée dans les pays européens et deux études de cohortes rétrospectives menées en France et en Afrique du Sud. Les études de cohorte sont centrées sur un seul centre et ont donc une validité externe limitée et risquent d'être faussées. Faible niveau de preuve.

CATÉGORIE	RÉSUMÉ DES PRINCIPAUX RÉSULTATS	VUE D'ENSEMBLE DES ÉLÉMENTS DE PREUVE
	• Plus grande probabilité de décès dans les 60 jours suivant l'admission à l'USI (RC = 5,67, IC à 95 % : 1,04 à 30,81, p = 0,04) pour les cas associés au variant Bêta comparativement aux cas liés au variant Alpha en France (42). Aucune différence : • Aucune différence dans les probabilités de décès pour les cas associés au variant Bêta comparativement à ceux qui sont liés au variant original dans l'analyse multivariable (RCa 1,1, IC à 95 % 0,4 à 3,4) (28).	
Facteurs de risque de mortalité Comparativement au variant original	Aucune étude	
Charge virale comparativement au variant original	• La charge virale (mesurée à l'aide des valeurs Ct) des échantillons du variant Bêta était inférieure à celle des échantillons du variant Alpha et supérieure à celle des variants originaux (3, 54).	Deux études, résultats secondaires. Très faible niveau de preuve.
Période infectieuse	Aucune étude	
Période d'incubation	Aucune étude	
Échappement immunitaire - incidence potentielle sur l'efficacité du vaccin, possibilité de réinfection		
Réinfection par infection naturelle comparativement au variant original	• Trois cas de réinfection par le variant Bêta ont été signalés (62 à 64).	Trois études déclarent une réinfection, y compris deux exposés de cas et une étude de cohorte prospective. Ces études présentent un niveau de preuve très faible.
Infection sporadique après la vaccination, efficacité réelle ou prévue du vaccin comparativement au variant original	Efficacité et efficacité du vaccin : • AstraZeneca : 10,4 % d'efficacité pour la prévention de la maladie symptomatique (68). • Johnson et Johnson : Les estimations d'efficacité étaient plus faibles en Afrique du Sud que dans les autres pays. L'efficacité du vaccin (EV) contre le variant Bêta était de 52 % et de 64 % pour la forme modérée de la	Sept études sur les infections ayant percé et l'efficacité des vaccins, dont trois ECR, une étude de cohorte prospective et trois études de cas/témoins. Ces études présentent un niveau de preuve faible à modéré. Il n'y a eu qu'une seule étude par vaccin

CATÉGORIE	RÉSUMÉ DES PRINCIPAUX RÉSULTATS	VUE D'ENSEMBLE DES ÉLÉMENTS DE PREUVE
	maladie et de 73 % et de 82 % pour la forme grave après 14 jours et 28 jours respectivement (69). • Novavax : EV de 51,0 % (IC à 95 %, -0,6 à 76,2) contre la maladie symptomatique chez les personnes séronégatives (70). • Pfizer-BioNTech : EV de 75,0 % (IC à 95 %, 70,5 % à 78,9 %) contre l'infection par le variant Bêta ≥2 semaines après la deuxième dose et de 97,4 % (IC à 95 % : 92,2 % à 99,5 %) contre les formes graves, critiques ou mortelles des variants du SRAS-CoV-2 au Qatar (71). Une EV de 50 % (IC à 95 %, 34 % à 73 %) chez les résidents des maisons de soins infirmiers (âge médian : 87,0 ±8,2 ans) avec deux doses espacées de 19 jours (64). • Moderna/Pfizer-BioNTech : EV comparable de ≥88 % contre l'infection symptomatique associée au variant Bêta ≥7 jours après avoir reçu la deuxième dose (72). Infection ayant percé après la vaccination : • Aucune infection ayant percé associée au variant Bêta n'a été identifiée plus de 14 jours après la deuxième dose (principalement Pfizer) dans une étude cas-témoins menée en Israël (67). • 50 % (13 sur 26) des résidents des maisons de soins infirmiers et 5,2 % (1 sur 19) des membres du personnel qui ont reçu le vaccin Pfizer-BioNTech ont été atteints par des infections ayant percé associées au variant Bêta. Les résidents ont été infectés de 24 à 41 jours après avoir reçu la deuxième dose (15,4 % étaient asymptomatiques, 69,2 % ont présenté des symptômes légers à modérés et 15,4 % présentaient un syndrome de détresse respiratoire aiguë) (64).	provenant d'essais cliniques aléatoires, de sorte que des essais supplémentaires sont nécessaires pour améliorer la confiance dans ces estimations.

CATÉGORIE	RÉSUMÉ DES PRINCIPAUX RÉSULTATS	VUE D'ENSEMBLE DES ÉLÉMENTS DE PREUVE
Traitements Comparativement au variant original	• Le casirivimab et l'etesevimab ont montré une réduction de la neutralisation (83, 85, 96), le bamlanivimab n'a montré aucune neutralisation (85), et il y avait des preuves contradictoires sur la neutralisation associée à l'imdevimab (83, 96) contre le variant Bêta.	Trois études *in vitro* sur les traitements. Très faible niveau de preuve.
Modèles animaux pour la protection convalescente ou la vaccination	• Dans des modèles animaux soumis à l'épreuve du variant Bêta, des hamsters préalablement infectés ou vaccinés ont montré une protection contre la maladie clinique (97, 98).	Deux modèles animaux. Très faible niveau de preuve.
Études *in vitro*	• La plupart des sérums vaccinaux et de phase convalescente ont montré une activité neutralisante réduite pour le variant Bêta par rapport au variant original ou au variant Alpha. Dans la plupart des études, le variant Bêta avait une neutralisation plus réduite que le variant Gamma. Les expériences de neutralisation ne sont pas résumées, mais on peut les trouver dans le jeu de données.	Très faible niveau de preuve. La réponse immunitaire est complexe, et l'absence d'anticorps neutralisants ou le manque de ces derniers ne signifie pas un manque de protection immunitaire. D'autres recherches sont nécessaires (voir la revue effectuée par le Groupe des sciences émergentes de l'ASPC sur l'immunité protectrice).
Tests et diagnostics		
Test et détection comparativement au variant original	• La PCR, les tests de détection des antigènes, les tests sérologiques et les méthodes de séquençage sont efficaces pour détecter ou distinguer le variant Bêta (90, 99 à 108). • Le test antigénique TRF-ELISA basé sur S1 a détecté le variant Bêta avec une sensibilité réduite de 2 à 3 fois comparativement au résultat obtenu avec le variant original et le variant Alpha (109).	Douze études sur les tests et la détection, dont dix études sur la précision des tests de diagnostic et deux études in vitro. Comme elles décrivent toutes des tests différents, les études sont considérées comme individuelles et ne peuvent être résumées ensemble. Faible niveau de preuve.
Épidémiologie de la propagation		
Émergence des VP au fil du temps	• Les études qui font état de la prévalence ponctuelle ou à un moment donné du variant Bêta n'ont pas été résumées. • Deux études montrent la croissance du variant Bêta dans différentes régions d'Afrique du Sud et de Colombie-Britannique au Canada (110, 111).	Seize études sur l'émergence et la propagation du variant Bêta, dont douze études de surveillance, une enquête sur l'éclosion, un modèle prédictif et deux études de cohorte rétrospectives.

CATÉGORIE	RÉSUMÉ DES PRINCIPAUX RÉSULTATS	VUE D'ENSEMBLE DES ÉLÉMENTS DE PREUVE
	• En Afrique du Sud, le variant Bêta a émergé vers août 2020 et été détecté pour la première fois en octobre 2020. En mars 2021, le variant Bêta est devenu le variant dominant et représentait environ 20 % (1 769 sur 8 746) des génomes (112). • Des études effectuées dans des pays autres que l'Afrique du Sud ont indiqué que le variant Bêta avait été déclaré la première fois en décembre 2020 (113 à 115).	Faible niveau de preuve.

IC = intervalle de confiance, Ct = seuil du cycle, USI = unité de soins intensifs, RC = rapport des cotes, PCR = réaction en chaîne par polymérase, EV = efficacité du vaccin, RCa = rapport de cotes ajusté, RRa = rapport de risque ajusté, RPa = rapport de prévalence ajusté

B.1.1.7 (ALPHA)

Le jeu de données en Excel comprend des résumés de chacune des études et est accessible ici. Vous trouverez ci-dessous le profil détaillé des éléments de preuve élaboré pour le variant Alpha. Il porte notamment sur les données sur les changements dans l'efficacité de la transmission, les changements dans la gravité clinique, l'échappement immunitaire, les tests et diagnostics, ainsi que d'autres études épidémiologiques portant sur principalement sur la propagation des VP.

Tableau 5 : Profil fondé sur les éléments de preuve pour le VP B.1.1.7 (Alpha) (n = 342)

CATÉGORIE	RÉSUMÉ DES PRINCIPAUX RÉSULTATS	VUE D'ENSEMBLE DES ÉLÉMENTS DE PREUVE
Efficacité de transmission		
Transmissibilité comparativement au variant original	Les estimations de l'augmentation de la transmissibilité relative du variant Alpha (1-$R_{VP}/R_{Variant\ original}$) variaient entre 34 et 118 % entre les différentes études, une partie de cette variation étant due au moment où les données ont été obtenues en ce qui concerne l'émergence du variant Alpha. Une étude note une variation dans le temps (12) et la plupart des estimations du Royaume-Uni sont plus élevées que celles des autres pays (9) : • Canada : 34 % (IC à 95 % : 31 à 38) (13). • Royaume-Uni : 50 à 100 % (12), 75 % (IC à 95 %, 70 à 80 %) (16), 52 % (IC 46 à 58 %) (17), 43 à 90 % (fourchette de l'intervalle de crédibilité : 38 à 130 %) (14), 44 à 55 % (IC 38 à 61 %) (18), 83 à 118 % (71 à 140 %) au Royaume-Uni (9), 13,4 à 41,3 % dans les régions du Royaume-Uni en décembre 2020 (19), transmissibilité supérieure de 62 % (IC à 95 %, 59 à 65 %) à 45 % (IC 43 à 48 %) (116), taux de reproduction de 0,3 unité supérieur à celui des autres lignées (117). • Europe : France 41 % (IC à 95 % 38 à 44) (3) et 52 % (IC à 95 % 54 à 66 %) (20), Danemark 55 % (intervalle de crédibilité 45 à 66 %), Suisse 74 % (intervalle de crédibilité 66 à 82 %) (14) et 54 % (IC à 95 % 49 à 65 %) (21), Norvège 24 % (IC à 95 % 0 à 52 %) (22), Italie 55 à 57 % (IC à 95 % 45 à 66 %) (23), Pays de Galles et États-Unis 65 à 72 % (46 à 104 %) (9).	Cette section s'appuie sur 35 études par observation, y compris des analyses des données de surveillance, des études transversales, des études de cohorte rétrospectives, des études écologiques et des modèles prédictifs. On s'accorde pour dire que le variant Alpha est plus transmissible et il y a un chevauchement assez important dans les estimations de l'ampleur. La transmissibilité peut être influencée par des mesures de santé publique restrictives et par l'augmentation de la vaccination. Ces études risquent de présenter un biais de sélection, d'information et de confusion qui n'a pas été pris en compte de manière cohérente dans toutes les études. Faible niveau de preuve.

CATÉGORIE	RÉSUMÉ DES PRINCIPAUX RÉSULTATS	VUE D'ENSEMBLE DES ÉLÉMENTS DE PREUVE
	• États-Unis : 59 % (intervalle de crédibilité 56 à 63 %) (14), 35 à 46 % (15). • Israël : 45 % (IC à 95 %, 20 à 60) (24). • Le Japon a estimé une augmentation de 60 % de la transmissibilité relative des VP (non spécifiés) par rapport aux variants originaux (25). • Une étude qui n'a pas donné d'estimations indique que la transmissibilité du variant Alpha est plus élevée que celle du variant Bêta ou du variant Gamma (7). • Dans certaines régions de la France (avril et mai) où le variant Bêta augmentait, on a estimé que l'avantage de transmission était de 15,8 % (IC à 95 %, 15,1 à 16,1) à l'île de France et de 17,1 % (IC à 95 %, 16,1 à 18,8) dans les Hauts de France comparativement au variant Alpha (11). • Un modèle prédictif a examiné l'incidence de l'augmentation de la vitesse de transmission et de la transmissibilité sur l'épidémiologie du variant Alpha (118). Certaines études ne fournissent pas suffisamment de données pour calculer l'efficacité accrue de la transmission, mais indiquent qu'elle était plus élevée (119). D'autres études ont indiqué que la transmissibilité diminuait au fil du temps (7, 120) ou ne changeait pas (121), ce qui peut être associé à la rigueur du confinement ou à l'augmentation de la vaccination (121, 122). Un examen systématique de la transmissibilité a inclus des études disponibles jusqu'au 21 février 2021 (8).	
Avantage sélectif Comparativement au variant original	• Selon un modèle d'avantage sélectif, on a estimé que le variant Alpha présentait un avantage sélectif de 0,337 (0,336 à 0,339) par rapport aux variants originaux au Royaume-Uni (123).	Un modèle prédictif. Faible niveau de preuve.
Taux d'attaque secondaire comparativement au variant original	• Dans une étude canadienne sur la transmission intrafamiliale, le taux d'attaque secondaire (TAS) du variant Alpha était plus élevé (RR = 1,31 (IC à 95 %, 1,14 à 1,49) que celui des autres VP, et le risque était accentué pour les cas index	Cinq études sur la transmission intrafamiliale, y compris une éclosion dans des classes de maternelle.

CATÉGORIE	RÉSUMÉ DES PRINCIPAUX RÉSULTATS	VUE D'ENSEMBLE DES ÉLÉMENTS DE PREUVE
	asymptomatiques (RR = 1,91, IC à 95 %, 0,96 à 3,80) et les cas présymptomatiques (RR = 3,41, IC à 95 %, 1,13 à 10,26) (26). • Dans les ménages norvégiens, le variant Alpha était 60 % (20 % à 114 %) plus transmissible que les variants originaux et, dans l'ensemble, le TAS était de 0,13 pour le variant original et de 0,15 pour le variant Alpha, ce qui veut dire qu'il est 16 % (-6 % à 43 %) plus infectieux (ratio du TAS), même en tenant compte de l'âge (22). • Une étude réalisée au Danemark a révélé une transmission de 50 à 70 % plus élevée parmi les ménages infectés par le variant Alpha comparativement aux variants originaux. La transmissibilité selon l'âge suivait un modèle en forme de U avec la transmission la plus faible provenant des cas primaires dans la tranche d'âge des 10 à 30 ans, une transmission plus élevée chez les enfants plus jeunes et encore plus élevée chez les personnes âgées (27). • Une étude allemande a révélé que le TAS des enfants et des adultes des ménages s'établissait à 37 % (IC de 95 %, 28 à 47) et était semblable chez les enfants (32 %) par rapport aux adultes (39 %) (124). Parmi les gens qui ont été en contact dans les services de garde, le TAS pour les enfants (23 %) était semblable à celui des adultes (30 %) (124). • Au Royaume-Uni, les cas associés au variant Alpha étaient presque deux fois plus susceptibles de créer des grappes de ménages que le variant original (RC ajusté = 1,88, IC à 95 %, 1,67 à 2,08, p<0,001) (125).	Le ratio des taux d'attaque secondaire a également été fourni comme mesure d'une transmissibilité plus élevée pour le variant Alpha dans certaines études basées sur des études de recherche de contacts. Les résultats étaient contradictoires d'une étude à l'autre. Ces études comprennent trois analyses de données de surveillance et une étude rétrospective. Faible niveau de preuve.
Interventions non pharmaceutiques comparativement au variant original	Rigueur : • Au Royaume-Uni, un modèle bayésien hiérarchique a été utilisé pour montrer que le niveau 1 de mesures restrictives (restrictions légères) avait un effet négligeable sur les cas, tandis que les niveaux 2 (restrictions modérées) et 3 (restrictions sévères) avaient permis de réduire la transmission 6 % (5 % à 7 %) et de	Sept modèles prédictifs, une étude écologique et une analyse des données de surveillance. Les modèles prédictifs sont d'excellents outils pour comparer les options, mais il convient de faire preuve

CATÉGORIE	RÉSUMÉ DES PRINCIPAUX RÉSULTATS	VUE D'ENSEMBLE DES ÉLÉMENTS DE PREUVE
	23 % (21 % à 25 %), respectivement (120). Une autre analyse souligne qu'en décembre 2020, au Royaume-Uni, les valeurs les plus élevées de Rt (environ 1,8) ont été enregistrées dans les régions ayant mis en œuvre le plus bas niveau de mesures restrictives. Malgré le fait que ces valeurs étaient les plus faibles, lorsque ces régions les ont combinées avec des mesures restrictives plus rigoureuses et des mesures de confinement, cela a effectivement permis de réduire le Rt qui a ainsi pu atteindre environ 0,9 en mars 2021 (116). • Un modèle prédictif basé sur le variant Alpha paramétré au Canada (augmentation de 50 % de la transmission chez les enfants et de 70 % chez les adultes) a également été utilisé. Si l'on compare ces données à celles obtenues avec les mesures de confinement restrictives, on peut voir que le nombre de cas estimatif était trois fois plus élevé à Toronto lorsque les écoles étaient fermées et que les entreprises restaient ouvertes, mais devaient se conformer à des restrictions modérées, qu'il était sept fois plus élevé si les écoles étaient fermées et qu'il était 7,5 fois plus élevé si les écoles étaient ouvertes et que les entreprises étaient soumises à des mesures restrictives légères (126). • Un modèle SEIR basé sur la situation en France décrit l'incapacité des interventions non pharmaceutiques telles que le couvre-feu et les mesures de distanciation physique à réduire le Ro du variant Alpha à un niveau inférieur à 1, alors que ces mêmes interventions, lorsqu'utilisées contre les variants originaux, ont permis de réduire ce Ro (127). • Un modèle de transmission structuré par région et stratifié selon l'âge afin de contrôler la transmission du variant Alpha estime que le respect de mesures de confinement plus restrictives à court terme entraînerait une diminution du nombre d'admissions à l'hôpital alors qu'un confinement modéré réduirait la	de prudence lors de l'extrapolation des résultats au-delà des scénarios de comparaison des modèles. Faible niveau de preuve.

CATÉGORIE	RÉSUMÉ DES PRINCIPAUX RÉSULTATS	VUE D'ENSEMBLE DES ÉLÉMENTS DE PREUVE
	détresse et améliorerait la viabilité de cette mesure (128). Quarantaine : • Un modèle permettant d'examiner les scénarios de quarantaine et de test pour contrôler les importations de SRAS-CoV-2 aux États-Unis indique que le variant Alpha ne modifie pas l'efficacité des stratégies de quarantaine et de test (129). Mesures de protection individuelle : • Ce modèle est basé sur les données américaines et examine l'incidence de l'utilisation du couvre-visage pour le contrôle à la source et la protection de l'utilisateur grâce à des données sur la transmission du variant original et du variant Alpha. Ainsi, le Ro de base de 2,5 pourrait diminuer jusqu'à obtenir un Rt inférieur à 1,0 alors que le Ro de 4 pourrait permettre d'obtenir un Rt d'environ 1,6 respectivement si les règles en ce qui concerne le port du couvre-visage étaient plus strictes et plus rigoureuses (130). • Ce modèle de transmission de la maladie a estimé le risque de transmission en milieu de travail pour le variant Alpha (0,041 transmission ou contact contre 0,014 pour le variant original). Malgré le port du couvre-visage, le risque était toujours deux fois plus important qu'avec le variant original (131). Vaccination : • On a examiné les stratégies de vaccination avec une plus grande transmissibilité du variant Alpha et prédit que même si 100 % de la population avait reçu le vaccin AstraZeneca, la valeur R ne diminuerait que pour atteindre 1,33 % de la population vaccinée et pourrait atteindre 1,98 si 79 % de la population était vaccinée. Le vaccin Pfizer-BioNTech nécessiterait la vaccination de 81,9 % de la population pour réduire à 1 la valeur de R (122).	

CATÉGORIE	RÉSUMÉ DES PRINCIPAUX RÉSULTATS	VUE D'ENSEMBLE DES ÉLÉMENTS DE PREUVE
	• Un modèle prédictif a montré que la diminution de la transmission du variant Alpha par la vaccination avait l'effet le plus important une fois que la transmission avait déjà commencé à diminuer grâce à des stratégies d'atténuation en matière de santé publique (132).	
Gravité clinique		
Virulence / gravité ou durée de la maladie comparativement au variant original	Cinq études montrent qu'il y a eu plus de cas d'hospitalisations liés au variant Alpha alors que deux études effectuées sur la population en général montrent qu'il y a eu plus d'admissions à l'USI. • Les preuves sont contradictoires quant à savoir si le variant Alpha entraîne davantage d'infections asymptomatiques : La prévalence de la maladie symptomatique était la même dans une étude italienne (32). Proportion des cas symptomatiques : 72,6 % cas associés au variant Alpha (5 365 sur 7 390) comparativement aux cas liés aux variants originaux (81,4 %; 547 sur 672; p < 0.001) (28). • La majorité des études ont signalé un nombre plus élevé d'hospitalisations avec une infection causée par le variant Alpha : • Plus grand nombre d'hospitalisations avec le variant Alpha comparativement au variant original (11 % contre 7,5 % p<0,001) (28) ; (5,8 % contre 4,1 % p = 0,04) (38). Nombre d'hospitalisations plus élevé, soit 2,39 % pendant la vague liée au variant Alpha, alors qu'il a atteint 1,55 % pendant la vague initiale en Espagne (37). • Plus grande probabilité d'hospitalisation des cas associés au variant Alpha comparativement à la probabilité recensée avec le variant original (RCa 1,7, IC à 95 % 1,0 à 2,9) (28); RC 1,64 (IC à 95 % 1,32 à 2,04) (33); RC 1,58 (IC à 95 % 1,50 à 1,67) (34); (RC 1,36 IC à 95 % 1,16 à 1,60, p = 0,0002) (35). Le rapport de risque pour l'hospitalisation associée au variant Alpha comparativement au variant original (RRa 1,34, IC à 95 % 1,07 à 1,66). La durée du séjour était	Quatorze études sur la sévérité, incluant des analyses de données de surveillance, des cohortes prospectives, des cohortes rétrospectives et des études transversales, dont la plupart ont été menées au Royaume-Uni. Niveau de preuve modéré.

CATÉGORIE	RÉSUMÉ DES PRINCIPAUX RÉSULTATS	VUE D'ENSEMBLE DES ÉLÉMENTS DE PREUVE
	cependant similaire dans les deux groupes p = 0,07 (36). • Une étude menée en République tchèque n'a révélé aucun changement dans le nombre d'hospitalisations (39). • Plusieurs études ont fait état d'un nombre plus élevé d'admissions à l'USI en raison des infections associées au variant Alpha : • Le taux d'admission à l'USI était de 1,4 % pour le variant Alpha alors qu'il était de 0,6 % pour le variant original, p = 0,002, ce qui représente une probabilité plus élevée d'admission à l'USI pour le variant Alpha RCa 2,3 (IC 95 % 1,4 à 3,5) (28). Admission à l'USI pour le variant Alpha : RRa 1,99 IC à 95 % 1,59 à 2,49 comparativement au variant original (40). • Parmi les cas hospitalisés, il n'y avait pas d'association entre la forme grave de la maladie, le décès, le variant Alpha et les variants originaux, RPa 1,02 (IC à 95 % : 0,76 à 1,38) (41); scores aux soins intensifs ou besoin d'une ventilation mécanique (42). Symptômes : • L'hypoxie (70,0 % contre 62,5 %, p = 0,029) et des taux respiratoires plus élevés (p = 0,001) ont été signalés parmi les cas associés au variant Alpha inclus dans deux études (43, 44). • Une fièvre de plus de 38 °C était beaucoup plus commune chez les patients hospitalisés infectés par le variant Alpha que chez ceux qui avaient contracté le variant original (46 % contre 22, p = 0,015) (133)	
Facteurs de risque de la gravité comparativement au variant original	Il n'y avait pas de cohérence entre les études pour savoir si des facteurs de risque étaient associés à la gravité du variant Alpha, y compris l'âge et le sexe, mais plusieurs études ont rapporté que les personnes infectées par le variant Alpha étaient moins susceptibles d'avoir des comorbidités : • Une étude réalisée aux États-Unis n'a pas signalé de différence significative en ce qui	Neuf études sur les facteurs de risque de gravité. Il s'agit notamment d'analyses de données de surveillance, de cohortes prospectives, de cohortes rétrospectives et d'études transversales,

CATÉGORIE	RÉSUMÉ DES PRINCIPAUX RÉSULTATS	VUE D'ENSEMBLE DES ÉLÉMENTS DE PREUVE
	concerne l'âge et le sexe des patients ni en ce qui concerne la durée médiane du séjour à l'hôpital (35). • Dans une autre étude, la différence d'âge était statistiquement significative (37 contre 39 ans) (39). Une étude menée en République tchèque a révélé que des patients beaucoup plus jeunes ont été hospitalisés en raison du variant Alpha (différence médiane de 58 ans par rapport à 64 ans) comparativement au variant original (39). • Dans les modèles stratifiés par âge, les cas associés au variant Alpha dans les groupes d'âge de 20 à 39 ans et de 40 à 59 ans avaient, respectivement, une probabilité d'hospitalisation 3,0 et 2,3 fois plus élevée que les cas associés au variant original (28). • Une étude de cohorte prospective menée auprès de patients hospitalisés a révélé une différence statistiquement significative entre l'âge des personnes infectées par le variant Alpha (39 ans, EI : 30,50 à 62,50) et celui des personnes infectées par la souche B.1.470 (qui n'est pas un variant) (31 ans, EI : 27,50 à 41,00) (P = 0,014) (133). • Parmi les patients aux soins intensifs en France, aucune différence significative pour l'âge ou le sexe entre le variant Alpha et le variant original ou le variant Bêta n'a été documentée (42). • Une cohorte hospitalière entre décembre 2020 et janvier 2021 en France décrit des patients plus jeunes (63 % de personnes ayant moins de 65 ans, contre 50 %) avec un âge moyen de 59,2 ans contre 70,7 ans; les patients sans comorbidité ont augmenté de 16 % à 42 % (p = 0,007) (44). Les conditions préexistantes étaient plus faibles avec le variant Alpha comparativement au variant original (44,8 % contre 89 % p<0,001) (28). • Une étude sur les cas de COVID-19 ayant été hospitalisés a rapporté une plus grande	dont la plupart ont été menées au Royaume-Uni. Niveau de preuve modéré.

CATÉGORIE	RÉSUMÉ DES PRINCIPAUX RÉSULTATS	VUE D'ENSEMBLE DES ÉLÉMENTS DE PREUVE
	proportion de femmes atteintes du variant Alpha (48,0 % contre 41,8 %, p = 0,01), moins de patients fragiles (14,5 % contre 22,4 %, p = 0,001) et une plus grande proportion de personnes souffrant d'obésité (30,2 % contre 24,8 %, p = 0,048), mais aucune différence en fonction de l'âge ou de l'ethnie (43).	
Mortalité comparativement au variant original	Il existe des preuves contradictoires sur l'association entre la mortalité et l'infection causée par le variant Alpha : • Cinq études n'ont rapporté aucune différence significative dans la mortalité globale : Italie (2,1 % contre 4,1 %) (32), États-Unis (35, 38) et aucun lien avec la mortalité après 28 jours au Royaume-Uni (RC : 0,90, IC à 95 %, 0,57 à 1,41, p = 0,64) (36) ou la légalité (RC = 1,37; IC : 0,5808 à 3,215, p = 0,52) (39). • Une étude a estimé que le variant Alpha présentait une probabilité de mortalité plus faible que le variant original dans l'analyse multivariable (RCa 0,5, IC à 95 % 0,3 à 0,9) (28). • Quatre études ont fait état d'un risque de mortalité plus élevé : risque plus élevé de décès après 28 jours (55 %, IC à 95 %, 39 à 72 %) (47), RRa 1,59 (IC à 95 %, 1,25 à 2,03) (40), RRa 1,67 (IC à 95 %, 1,34 à 2,09; P < 0,0001) (41). HR 1,64 (IC 95 % 1,32 à 2,04, p < 0,001), ce qui équivaut à une augmentation de 2,5 à 4,1 décès par 1 000 cas détectés (48). La méta-analyse de ces quatre études indiquait un risque de mortalité combiné avec RR = 1,45 (IC à 95 %, 1,18 à 1,78) (134). • Des études écologiques effectuées au Royaume-Uni estiment que le variant Alpha est 33 % plus mortel (51) et que son taux de mortalité est plus élevée (49).	Treize études ont fait état de la mortalité; il s'agissait d'analyses de données de surveillance, d'études écologiques, de cohortes prospectives, de cohortes rétrospectives et d'études transversales, dont la plupart ont été menées au Royaume-Uni. Niveau de preuve modéré.

CATÉGORIE	RÉSUMÉ DES PRINCIPAUX RÉSULTATS	VUE D'ENSEMBLE DES ÉLÉMENTS DE PREUVE
Facteurs de risque de mortalité comparativement au variant original	• Les données démographiques sur les décès liés au variant Alpha étaient similaires chez les hommes et les femmes, mais la prévalence était plus élevée dans les groupes d'âge plus jeune que dans les groupes d'âge plus âgés (59,0 % chez les 1 à 34 ans contre 55,4 % chez les 85 ans ou plus) (47). Il y avait également des variations selon l'origine ethnique : noire (69,6 %), mixte ou d'origine ethnique inconnue (64,8 %), blanche (58,0 %) et asiatique (57,6 %). La variation était la plus faible dans le quintile le plus défavorisé de l'indice de privation multiple (53,9 %) (47). • Il n'y avait aucune preuve d'une association significative entre le variant Alpha et le sexe (p = 0,90), le groupe ethnique (p = 0,64) ou le groupe d'âge (p = 0,15) (40).	Deux études, y compris une analyse des données de surveillance et une cohorte rétrospective. Faible niveau de preuve.
Charge virale comparativement au variant original	• Plusieurs études (n = 14) ont mesuré la charge virale en tant que Ct ou copies estimées/ml pour différentes protéines cibles (généralement N et ORF1ab). Elles indiquent systématiquement que les échantillons de variant Alpha sont plus susceptibles de présenter des valeurs Ct plus faibles ou des charges virales estimées plus élevées. L'ordre de grandeur médian supérieur varie de 2 à 10 fois selon les études et la protéine cible (3, 32, 35, 39, 45, 54 à 59, 59 à 61, 117, 133, 135, 136).	22 études qui étaient principalement des analyses de données de surveillance, des études de cohorte ou transversales qui ont analysé les valeurs Ct de la PCR entre les échantillons de variant Alpha et les échantillons du variant original. Cette mesure est indirecte et toutes les études sont conçues sur la base d'observations. La conclusion selon laquelle les cas associés au variant Alpha ont des valeurs Ct plus basses était cohérente entre les études. Niveau de preuve faible à modéré.

CATÉGORIE	RÉSUMÉ DES PRINCIPAUX RÉSULTATS	VUE D'ENSEMBLE DES ÉLÉMENTS DE PREUVE
Modèle animal pour la charge virale Comparativement au variant original et à d'autres VP/VI	• Une étude sur les animaux effectuée chez les macaques rhésus a révélé une charge virale plus élevée d'ARN génomique dans la muqueuse nasale des animaux infectés par le variant Alpha comparativement à ceux qui étaient infectés par la souche sauvage et le variant Bêta et des antigènes viraux plus faibles dans les tissus pulmonaires comparativement à la souche sauvage (137). • Une autre étude a démontré que les hamsters infectés par le variant Alpha présentaient un taux élevé d'excrétion d'ARN viral par les sécrétions nasales pendant les premières semaines d'infection (138). • Un modèle avec souris a révélé que la charge virale était beaucoup plus faible pour le variant Alpha dans les poumons des souris infectées que pour les variant Bêta et variant Gamma dans les poumons C57BL/6 et BALB/c, et qu'aucun virus infectieux n'avait été détecté dans les poumons BALB/c (139).	Trois études sur des modèles animaux démontrent toutes une diminution de la charge virale dans les poumons et une augmentation de la charge virale dans la muqueuse nasale. Faible niveau de preuve.
Période infectieuse	Une étude prospective portant sur des cas associés au variant Alpha (n = 7) a révélé que les infections duraient en moyenne 13,3 jours comparativement à 8,2 jours pour d'autres variants (57).	Une petite cohorte prospective. Ce résultat nécessite une évaluation plus approfondie avec un échantillon plus grand et une gamme de cas plus étendue. Très faible niveau de preuve.
Période d'incubation	*Aucune étude*	
Échappement immunitaire - incidence potentielle sur l'efficacité du vaccin, possibilité de réinfection		
Réinfection par infection naturelle comparativement au variant original	Trois études ont estimé le taux de réinfection. Une étude menée au Royaume-Uni a révélé un taux de réinfection de 0,7 % (IC à 95 % : 0,6 à 0,8) (65) alors qu'aux États-Unis, le taux de séropositivité antérieur chez les personnes atteintes du variant Alpha était de 0,7 % comparativement aux infections associées aux variants originaux dont le taux était de 0,9 % (38). Une étude prospective menée auprès des travailleurs de la santé du Royaume-Uni a révélé	Trois études de réinfection ont inclus une analyse du variant Alpha et conviennent que ce variant n'échappe pas à l'immunité naturelle. Ces études incluent notamment une analyse des données de

CATÉGORIE	RÉSUMÉ DES PRINCIPAUX RÉSULTATS	VUE D'ENSEMBLE DES ÉLÉMENTS DE PREUVE
	qu'il n'y avait aucune preuve indiquant que variant Alpha avait modifié l'étendue de la protection contre une infection par PCR positive chez les personnes séropositives (RTI 0,40, IC à 95 %, 0,10 à 1,64, p = 0,20) (66).	surveillance, ainsi que des études de cohorte et des études écologiques. Niveau de preuve modéré.
Modèle animal de réinfection comparativement au variant original	Les hamsters infectés par le SRAS-CoV-2 original et guéris ont tous été protégés contre une réinfection par le variant Alpha (97, 140).	Deux modèles animaux ont donné des résultats cohérents qui appuient les données probantes documentées dans des études sur les humains et *in vitro*. Faible niveau de preuve.
Études *in vitro* avec sérums de phase convalescente comparativement au variant original	La majorité des études *in vitro* ont systématiquement montré des réductions minimes ou faibles de la neutralisation du variant Alpha par rapport au variant original. Les études sont présentées dans le jeu de données. On voit des résultats cohérents, mais les éléments de preuve proviennent d'études de faible qualité.	Il existe de nombreuses études *in vitro* et la liste n'est pas exhaustive à ce jour. Faible niveau de preuve.
Infection sporadique après la vaccination, efficacité réelle ou prévue du vaccin comparativement au variant original	Infection ayant percé après la vaccination : • Les exposés de cas et les rapports sur les séries de cas indiquent une rupture asymptomatique des infections associées au variant Alpha ayant percé chez les adultes (73, 74, 141, 142) et les personnes âgées (143), les travailleurs de la santé au Brésil après la vaccination avec Sinopharm (144) et les travailleurs de la santé en Inde après la vaccination avec Covishield (AZD1222) (145). • Comparativement au taux de cas associé au variant original, le taux associé au variant Alpha était 1,29 fois plus élevé (IC à 95 % [0,75, 2,20], p = 0,468) dans les cas d'infection ayant percé après la vaccination (74). • À New York, parmi les personnes pleinement vaccinées contre le SRAS-CoV-2, 22 % ont été infectées par le variant Alpha comparativement à 44 % dont les infections n'étaient pas liées aux VP (38).	Vingt études ont fait état d'une infection ayant percé après la vaccination ou ont porté sur l'efficacité du vaccin. Le caractère généralisable dépend de la représentativité de la preuve pour la population générale. Des conclusions cohérentes entre les études améliorent la certitude des résultats. Ces études comprennent les ECR, les cohortes prospectives, les études cas-témoins, les études longitudinales et l'analyse des données de surveillance. Niveau de preuve élevé pour les études de cohorte

CATÉGORIE	RÉSUMÉ DES PRINCIPAUX RÉSULTATS	VUE D'ENSEMBLE DES ÉLÉMENTS DE PREUVE
	• Un nombre disproportionné d'infections ayant percé entre la première dose et jusqu'à 14 jours après la deuxième dose du vaccin Pfizer-BioNTech (BNT162b2) en Israël a entraîné une probabilité plus élevée ajustée d'être positif à la PCR avec le variant Alpha (RCa 2,4 (IC à 95 % : 1,2 à 5,1) (67). • Des études en situation réelle au Royaume-Uni n'ont signalé aucune différence dans l'efficacité du vaccin (données combinées avec AstraZeneca et Pfizer-BioNTech) avec le variant Alpha (146). • Après l'administration du vaccin Pfizer-BioNTech, la probabilité ajustée d'une activité de neutralisation inadéquate contre le variant Alpha dans le groupe d'âge le plus élevé (plus de 80 ans) par rapport aux travailleurs de la santé adultes était de RCa 4,4 (1,5 à 12,6, p<0,007) (147). Une dose du vaccin : • Dans une étude prospective britannique sur les travailleurs de la santé, rien n'indiquait que le variant Alpha avait modifié l'étendue de la protection offerte par la première dose du vaccin comparativement au variant original (RTIa = 1,84, IC à 95 %, 0,75 à 4,49, p = 0,18) (66). • Après la première dose de Pfizer-BioNTech ou d'AstraZeneca, la réduction de la probabilité d'être admis à l'urgence a été estimée à 43 % (33 % à 52 %) et à 37 % (3 % à 59 %), respectivement, sans oublier une réduction de 51 % (37 % à 62 %) du risque de décès chez les adultes de 70 ans et plus en Angleterre (75). Deux doses du vaccin : • On a pu voir une efficacité comparable ajustée (≥88 %) contre les infections symptomatiques associées aux variants Alpha, Bêta et Gamma ≥7 jours après l'administration de la deuxième	avec ECR, niveau modéré pour les études de cohorte prospectives et faible niveau pour tous les autres plans d'étude. Dans l'ensemble, le niveau de preuve varie de modéré à élevé. Les séries de cas et les rapports constituent des niveaux de preuve très faibles, mais peuvent être utilisés pour formuler des hypothèses en vue de recherches ultérieures.

CATÉGORIE	RÉSUMÉ DES PRINCIPAUX RÉSULTATS	VUE D'ENSEMBLE DES ÉLÉMENTS DE PREUVE
	dose des vaccins Moderna ou Pfizer-BioNTech (72). • L'efficacité du vaccin AstraZeneca (ChAdOx1-S) dans un ECR du Royaume-Uni était de 70,4 % (IC à 95 %, 43,6 à 84,5) contre la COVID-19 symptomatique causée par le variant Alpha et de 81,5 % (67,9 à 89,4) contre la COVID-19 symptomatique causée par les variants originaux (76). Dans le cas d'une infection asymptomatique ou à symptôme inconnu, l'efficacité du vaccin était plus élevée pour les infections non liées au variant Alpha (69,7 %, 33,0 à 86,3) que pour les infections associées au variant Alpha (28,9 %, -77,1 à 71,4) (76). • L'efficacité du vaccin Novavax (NVX-CoV2373) dans un ECR au Royaume-Uni était de 86,3 % (71,3 à 93,5) comparativement à 96,4 % (73,8 à 99,5) pour le variant original (77). • En Israël, où 94 % des cas étaient associés au variant Alpha, on a pu voir que l'efficacité du vaccin Pfizer-BioNTech (BNT162b2) était supérieure à 96 % 14 jours après la deuxième dose (78) et supérieure à 90 % chez les 70 ans et plus (79). • Une méta-analyse des essais d'efficacité du vaccin Pfizer-BioNTech VE a indiqué une efficacité de 51 % (IC à 95 % : 47 à 55 %) après la première dose, de 93 % (IC à 95 % : 90 à 96 %) après la deuxième dose alors que le vaccin AstraZeneca VE a obtenu une efficacité de 49 % (IC à 95 % : 43 à 55 %) après une première dose et de 66 % (IC à 95 % : 54 à 75 %) après une deuxième dose (149).	
Modèle animal de vaccination comparativement au variant original	• Les hamsters vaccinés avec l'AstraZeneca, puis exposés au B.1.1.7 n'ont pas perdu de poids, n'ont pas présenté de pathologie pulmonaire, et aucun virus n'a été détecté dans les échantillons de tissus, alors que les témoins présentaient une pathologie pulmonaire étendue (98) Une autre étude a signalé que des hamsters ayant reçu l'AstraZeneca et infectés par le variant Alpha ont	Neuf études effectuées des animaux différaient en ce qui concerne la perte de poids, mais avaient des résultats pathologiques qui concordaient avec les études effectuées sur des

CATÉGORIE	RÉSUMÉ DES PRINCIPAUX RÉSULTATS	VUE D'ENSEMBLE DES ÉLÉMENTS DE PREUVE
	continué de prendre du poids alors que les animaux témoins perdaient du poids et avaient une importante pathologie pulmonaire causée par le variant Alpha (150). • On a pu voir chez les animaux ayant reçu d'autres candidats vaccins, y compris le RBD de la protéine spicule (151 à 154) et le plasma humain infecté par le SRAS-CoV-2, les vaccins à l'ADN (155) et les vaccins circulaires d'ARNc (156), une activité de neutralisation contre le variant Alpha.	humains et les études *in vitro*. Faible niveau de preuve.
Étude *in vitro* des sérums provenant de personnes vaccinées comparativement au variant original	De nombreuses études *in vitro* sont disponibles dans le jeu de données. Ces études ont systématiquement indiqué des réductions minimes ou faibles de la neutralisation du variant Alpha comparativement au variant original. Elles n'ont pas été résumées dans le profil des éléments de preuve.	Il existe de nombreuses études *in vitro* et la liste n'est pas exhaustive à ce jour. Faible niveau de preuve.
Modèle animal de traitement comparativement au variant original	• Un certain nombre d'anticorps monoclonaux testés ont protégé les souris et les hamsters contre le variant Alpha (157). • Les oligonucléotide antisens de l'acide nucléique verrouillé (158) et la 4'-fluorouridine, un ribonucléoside analogue (159) ont efficacement supprimé la réplication virale chez les hamsters et les furets, respectivement. • Le traitement au sérum en phase convalescente a entraîné une diminution du nombre de copies virales dans les poumons des souris infectées par la souche sauvage ou le variant Alpha. Comparativement aux résultats obtenus avec la souche sauvage, le traitement n'a cependant pas réduit le nombre de copies virales dans les tissus cérébraux des souris infectées par le variant Alpha.	Quatre modèles animaux. Faible niveau de preuve.
Étude *in vitro* du traitement comparativement au variant original	Perte minime d'activité : plusieurs anticorps monoclonaux (160 à 162), antigènes polyclonaux de la CP ou préparations d'anticorps hCoV-2-IG purifiés (163).	Les études *in vitro* donnent un aperçu préliminaire des résultats que l'on s'attend à obtenir avec les études *in vivo*. Faible niveau de preuve.

CATÉGORIE	RÉSUMÉ DES PRINCIPAUX RÉSULTATS	VUE D'ENSEMBLE DES ÉLÉMENTS DE PREUVE
Étude *in vitro* de l'infectivité comparativement au variant original	La capacité du pseudovirus porteur de la mutation UK-N501Y à transduire ses cellules cibles par rapport au variant original a été considérablement augmentée, jusqu'à neuf fois (164).	Les études *in vitro* donnent un aperçu préliminaire des résultats que l'on s'attend à obtenir avec les études *in vivo*. Faible niveau de preuve.
Tests et diagnostics		
Test et détection	La PCR est efficace pour détecter et distinguer le variant (90, 165 à 171). Détection du variant Alpha dans les eaux usées à dans des proportions aussi faibles que 0,1 % de SRAS-CoV-2 (172). Plusieurs études font état de tests fiables pour la détection rapide des variants, y compris la détection dans des échantillons d'eaux usées (90, 100, 101, 172, 173).	32 études, 28 études sur l'exactitude des tests de diagnostic, trois analyses de données de surveillance qui décrivaient également un nouveau test ou un ensemble d'amorces, et une étude *in silico* sur les amorces. Comme elles décrivent toutes des tests différents, les études sont considérées comme individuelles et ne peuvent être résumées ensemble. Faible niveau de preuve.
Épidémiologie de la propagation		
Émergence des VP au fil du temps	• Trois études canadiennes précisent que les cas associés au variant Alpha initialement regroupés dans deux régions ont rapidement augmenté (174). De même, deux études réalisées en Ontario ont documenté l'augmentation rapide du variant Alpha (13, 175). Les études provenaient de nombreux pays du monde dont la plupart décrivaient la première détection du variant Alpha à la mi-décembre ou à la fin de ce mois, suivie d'une augmentation rapide du nombre de cas associés au variant dans les 3,5 à 10 semaines suivantes. On a alors constaté que ce variant était devenu la souche dominante dans plusieurs études. • Une étude israélienne a documenté un plateau et un déclin dans le groupe d'âge des plus de	116 études rendent compte de l'émergence et de la propagation du variant Alpha dans un pays ou une région au fil du temps. La plupart de ces études sont basées sur des données de surveillance, des cohortes prospectives souvent constituées de travailleurs de santé, des cohortes rétrospectives de dossiers hospitaliers, des études longitudinales et des études écologiques. Les rapports de prévalence ponctuelle ou de cas de

CATÉGORIE	RÉSUMÉ DES PRINCIPAUX RÉSULTATS	VUE D'ENSEMBLE DES ÉLÉMENTS DE PREUVE
	60 ans, alors que plus de 50 % de la population avait été vaccinée (première dose de Pfizer > 14 jours) (24). Les États-Unis ont documenté plusieurs introductions du variant Alpha dans l'ensemble du pays (15). Une étude menée aux États-Unis a indiqué que les résultats positifs quotidiens aux tests de dépistage du variant Alpha du SARS-CoV-2 sont passés de 0,25 % à 0,5 % entre octobre et décembre 2020 (176). Plusieurs études documentent la détection du variant Alpha dans les eaux usées (172, 177 à 179).	voyageurs infectés ont été exclus de ce résumé. Niveau de preuve faible à modéré.
Attribution au variant Alpha	On a constaté qu'une augmentation de 0,1 dans la proportion du variant Alpha, lorsqu'on tient compte de la période préalable au sommet, était associée à une augmentation de 35,8 % de la hauteur du sommet de la deuxième vague. Au cours de la période du 1er janvier au 25 février 2021, une augmentation de 0,1 de la proportion du variant Alpha a été liée à une augmentation de 15,3 % du nombre cumulé de décès au cours de cette période (180).	Un modèle a été utilisé pour estimer le fardeau supplémentaire associé à la COVID-19 en raison du variant Alpha. Preuve de faible niveau.
Facteurs de risque de propagation	• Une étude écologique menée dans les régions de Toronto et de Peel, en Ontario, a montré que le taux de croissance du variant Alpha (11,3 %, 19,8 % et 30,8 %), l'ensemble des cas (19,0 %, 32,7 % et 48,3 %) et les cas associés aux VP (18,4 %, 30,8 % et 50,8 %) étaient positivement corrélés avec la proportion de travailleurs essentiels (30,4 %, 47,9 % et 63,2 %) et le revenu médian (33 000 $, 45 000 $ et 60 000 $ CAN) de la communauté, respectivement (181). • Les données de surveillance de la France ont révélé que comparativement au variant Bêta ou au B.1.525, les infections associées au variant Alpha étaient plus fréquentes chez les personnes âgées. Dans les milieux hospitaliers, il y avait une sous-représentation du variant Alpha par rapport au variant Bêta. Dans certaines régions de la France, la probabilité d'être infecté par le variant original ou par le B.1.525 était	Cinq études ont évalué les facteurs de risque. Il s'agit notamment d'études écologiques, de cohortes prospectives, de modèles prédictifs et d'analyses de données de surveillance. Niveau de preuve modéré pour les études de cohorte prospectives. Faible niveau de preuve pour tous les autres plans d'étude.

CATÉGORIE	RÉSUMÉ DES PRINCIPAUX RÉSULTATS	VUE D'ENSEMBLE DES ÉLÉMENTS DE PREUVE
	identique ou inférieure à celle d'être infecté par le variant Alpha (11).	
Analyse génomique de la propagation	Les résultats ne suggèrent pas que les mutations canoniques du variant Alpha ont évolué indépendamment dans différents endroits, et indiquent une origine et une propagation du variant Alpha à partir du Royaume-Uni (182).	Une étude des données de la surveillance génomique. Faible niveau de preuve.

IC = intervalle de confiance, Ct = seuil du cycle, USI = unité de soins intensifs, RC = rapport des cotes, PCR = réaction en chaîne par polymérase, EV = efficacité du vaccin, RCa = rapport de cotes ajusté, RRa = rapport de risque ajusté, RPa = rapport de prévalence ajusté

Méthodologies :

Une analyse documentaire quotidienne (ouvrages publiés et en prépublication) est effectuée par le Groupe des sciences émergentes de l'ASPC. L'analyse a compilé les ouvrages sur la COVID-19 depuis le début de l'éclosion et est mise à jour quotidiennement. Les recherches visant à extraire les ouvrages pertinents sur la COVID-19 sont menées dans Pubmed, Scopus, BioRxiv, MedRxiv, ArXiv, SSRN et Research Square, et les résultats sont recoupés avec les ouvrages figurant sur la liste de la documentation sur la COVID de l'Organisation mondiale de la Santé et des centres d'information sur la COVID-19 gérés par Lancet, BMJ, Elsevier, Nature et Wiley. Le résumé quotidien et les résultats complets de l'analyse sont conservés dans une base de données RefWorks et dans une liste Excel consultable. L'un des objectifs vise à déterminer si les études portent sur des variants préoccupants ou des variants d'intérêt. Les études correspondantes sont présentées plus en détail dans notre base de données sur les VP et VI alors que les résultats associés aux VP figurent dans le présent résumé. Une contre-vérification afin de trouver des articles pertinents a également été effectuée dans les bases de données en utilisant pour ce faire des recherches ciblées par mot clé. Ce tableau évolue au fur et à mesure que les preuves évoluent.

Variant préoccupant	**Termes de recherche**
Alpha, B.1.1.7, 202012/01, 501Y.V1, variant Kent (Mutations : Δ69/70, Δ144Y, (E484K*), (S494P*), N501Y, A570D, D614G, P681H) * de nouveaux variants avec des mutations ont été signalés et sont classés dans la catégorie B.1.1.7 + E484K	B.1.1.7 OU 202012/02 OU 501Y.V1 OU Alpha
Bêta, B.1.351, 501Y.V2, 20H/501.V2, Variant sud-africain (mutations : K417N, E484K, N501Y, D614G)	B.1.351 OU 501Y.V2 OU Bêta
Gamma, P.1, B.1.1.28.1, 501Y.V3, 20J/501Y.V3, variant du Brésil (mutations : K417N/T, E484K, N501Y, D614G)	P.1 OU B.1.1.28 OU 501Y.V3 OU Gamma
Delta, nouveau VP au Royaume-Uni : 202102/02, B.1.1.7 avec mutation E484K (nom?)	Voir B.1.1.7 OU Delta
Variants à l'étude	
États-Unis : Epsilon, B.1.429 et B.1.427, 20C/S:452R, (mutations : L452R, D614G et S13I, W152C en 429 uniquement)	B.1.429 et B.1.427, 20C/S:452R, CAL.20C, L452R OU Epsilon
Zeta P.2, B.1.1.28.2, au Brésil B.1.1.33	P.2 OU B.1.1.28 OU B.1.1.33 OU Zeta
Royaume-Uni : A.28.1	A.28.1
Royaume-Uni, Mexique, Nigeria : Êta, B.1.525	B.1.525 OU Êta
Royaume-Uni : B.1.318	B.1.318
Russie : B.1.317	B.1.317
New York : Iota B.1.526	B.1.526 OU Iota
Autres aux États-Unis : B.1.426, recombinant B.1.1.7 + B.1.429	B.1.426 et autres capturés avec la chaîne du B.1.429

Thêta, P.3, VUI-21MAR-02 nommé aux Philippines (et inclut les mutations E484, N501Y, P681H, LGV141-143)	P.3 OU Theta
B.1.617 Inde, sous-lignées : Kappa/B.1.617.1 Delta/B.1.617.2 B.1.617.3 (double mutant E484Q et L452R)	B.1.617 OU Delta OU Kappa
B.1.618 Inde (triple mutant)	B.1.618

La présente revue contient des recherches publiées jusqu'au 1er juin 2021.
Chaque référence potentiellement pertinente a été examinée pour confirmer qu'elle comportait des données pertinentes, qui ont été extraites dans la revue.

Examen par les pairs

Ce document a fait l'objet d'un examen par les pairs dirigé par un expert en la matière et d'un examen en ce qui concerne la rédaction et la science par le Bureau de la Conseillère scientifique en chef.

Préparé par : Kusala Pussegoda, Melanie Katz, Tharani Raveendran et Lisa Waddell, LNM, Groupe des sciences émergentes, ASPC.

Connaissances mobilisées par le Bureau de la Conseillère scientifique en chef phac.ocsoevidence-bcscdonneesprobantes.aspc@canada.ca

NERVTAG. Update note on B.1.1.7 severity [Internet]. Février 2021	Il est probable que l'infection causée par le VP Alpha soit associée à un risque accru d'hospitalisation et de décès par rapport à l'infection découlant des virus du variant original.

Emerging Evidence on COVID-19

Living Summary of SARS-CoV-2 Variants of Concern: The Beta Variant (B.1.351) profile

Highlights up to July 1, 2021

Introduction

SARS-CoV-2 **variants of concern** (VOCs) are circulating variants that have been flagged by national or global public health organizations. VOCs are of concern when compared to the original SARS-CoV-2 variants, as their complement of mutations lead to increased transmissibility, increased virulence (morbidity or mortality), changes in clinical disease presentation, immune evasion, reduced effectiveness of treatments, vaccines and/or public health measures and/or are associated with diagnostic detection failures (1-3). Canada has established a national definition (2). In May 2021, the World Health Organization (WHO) released a naming system for VOCs and variants of interest (VOIs) using Greek letters to improve the ease of communication on variants and potential stigma related to places where variants were first identified, which has been adopted in this report (1).

TABLE 1: CURRENT VARIANTS OF CONCERN (VOCs)*

WHO name (05-21)	Pango lineage	Nextstrain clade	GISAID clade	Alternate name	First detected in	Earliest samples	Characteristic spike mutations
Alpha	B.1.1.7	20I/501Y.V1	GR/501Y.V1	VOC 202012/01	United Kingdom	Sep 2020	69/70del, 144del, N501Y, A570D, D614G, P681H, T716I, S982A, D1118H

Gamma	P.1, P.1.1 P.1.2	20J/501Y.V3	GR/501Y.V3	VOC 202101/02	Brazil and Japan	Nov 2020	L18F, T20N, P26S, D138Y, R190S, K417T, E484K, N501Y, D614G H655Y, T1027I, V1176F
Delta	B.1.617.2 AY.1 AY.2	21A	G/478K.V1		India	Oct 2020	L452R, D614G, P681R, ± (E484Q, Q107H, T19R,

	AY.3						del157/158, T478K, D950N)

* A VOC/VOI lexicon and other resources are available in the appendix.

The goal of this living summary on the SARS-CoV-2 VOC literature is to highlight new data on the VOC B.1.351 (Beta), its epidemiology, and how the attributes of this variant may impact the management of the pandemic. This living evidence profile on Beta is part of a larger project that summarizes the data on each VOC as well as captures data on VOIs. The focus will be on changes to epidemiological parameters (e.g., transmission rates, clinical outcomes of severity and mortality, shifts in age groups affected or asymptomatic proportions), impacts on diagnostic tests, immune evasion/vaccine effectiveness and impacts on other public health measures. The full dataset in Excel can be accessed here and filtered by the VOCs and VOIs of interest. The recent living evidence reviews on other VOCs (Alpha, Gamma and Delta) and a high level contrasting table of VOC evidence can be requested here.

In this summary, "original variant" refers to any variant that was not designated as a VOC or VOI.

Key Points

As of July 1, 2021, there were 341 studies that report on the Beta variant of concern. 65 studies were summarized in the profile including studies describing transmission efficiency (n=8), clinical severity (n=7), immune escape (n=24), testing and diagnostics (n=21), and epidemiology including spread (n=8). Some studies reported outcomes for more than one category. 276 studies were not summarized in the profile, including: studies on case reports or case series (n=5), point or period prevalence estimates (n=25), studies reporting the detection of Beta or phylogenetic analysis (n=12), cell infectivity, binding affinity, or genomic characterization studies (n=29), *in vitro studies* with no extractable outcomes and neutralization experiments on convalescent or vaccinated sera (n=154), predictive models with no extractable outcomes or in which the time for projections has already passed (n=8), animal models with no extractable outcomes or neutralization experiments on convalescent or vaccinated protection (n=23), studies of non-commercialized therapeutics (n=9), diagnostic test accuracy studies evaluating a new test/method to detect VOCs (n=10), and vaccine breakthrough data with no control group to compare the VOC proportion of breakthrough cases vs. VOC proportion of all COVID-19 cases (n=1).

However, details for all 341 studies that report on Beta can be found in the Excel dataset accessed here.

Transmissibility:

- Studies from multiple countries demonstrate the increased transmissibility of Beta compared to the original variant and Alpha, although the extent ranged greatly; 20%-175% above the original variant across multiple countries and 9.12%-17.21% above Alpha in France (4-7). One Canadian surveillance study

on household transmission reported that Beta has 58% increased transmissibility and a 31% higher secondary attack rate compared to the original variant (8).

Clinical Severity:

- Studies from several European countries reported higher odds of hospitalization for Beta compared to the original variant and Alpha (10, 11). There are conflicting findings regarding ICU admissions due to Beta compared to the original variant. A surveillance study of European countries reported an increased proportion (2.3% for Beta vs. 0.6% for the original variant) and odds (aOR 3.3, 95% CI 1.9-5.7) of ICU admission among Beta cases compared to original variant cases, while a retrospective cohort study from South Africa reported a lower proportion of ICU admissions (35% for Beta vs. 48.5% for the original variant) (10, 12).
- For severity indicators, there is conflicting evidence on the age of hospital and ICU admission due to Beta infection. A surveillance study of several European countries reported an increased odds of hospitalization and ICU admission in adults aged 40-59 due to Beta infection (10). Two studies reported a lower proportion of pre-existing conditions among Beta cases compared to original variant cases (10, 12).
- Two retrospective cohort studies from South Africa and France reported increased overall mortality and higher ICU mortality among Beta cases compared to original variant and Alpha cases (12, 13).
- A cross-sectional study and a surveillance study using data from France reported that Beta has a higher viral load compared to the original variant (4, 14), and a surveillance study from France reported that the viral load of Beta was lower compared to Alpha (5).
- One surveillance study using data from France reported no significant difference in the infectious period for combined Beta and Gamma case data compared to the original variant (HR 95% CI 0.79-1.06) (4).
- There were no studies on incubation period for Beta.

Immune Escape:

- Single dose vaccination: The vaccine effectiveness (VE) against severe disease or mortality due to Beta was 56.5% for BNT162b2 (Pfizer-BioNTech) 15 to 21 days following the first dose in Qatar (15, 16). VE against moderate and severe disease caused by Beta was 52%-64% and 73-82%, respectively, for the Ad26.COV2.5 (Janssen) vaccine in South Africa (22).
- Two dose vaccination: The VE against Beta infection was 50%-93.48% for BNT162b2 (Pfizer-BioNTech) in Qatar, France, and Canada, where the lower estimate was for long term care residents (median age=87 years) (15-18). The VE against symptomatic infection was ≥ 88% for BNT162b2 (Pfizer) or mRNA-1273 (Moderna) in Ontario, Canada (19), 10.4% for ChAdOx1 (AstraZeneca) in South Africa (20), and 51% for NVX-CoV2373 (Novavax) in South Africa (21). VE against severe disease or mortality due to Beta was 97.4%-100%, greater than 14 days following the second dose of the BNT162b2 (Pfizer-BioNTech) vaccine in Qatar (15, 16) (22).

Testing and Diagnostics:

- Several diagnostic test accuracy studies report effectively detecting and/or distinguishing Beta (41-60).
- One study describes the failed detection of a Beta sample carrying the R246I mutation (58).

Spread Epidemiology:

- In South Africa, Beta was first detected in October 2020, and became the dominant variant by March 2021 (64).
- The prevalence of Beta is expected to outgrow Alpha in regions where the seroprevalence of the original variant exceeds 20%-40% (9).

Overview of the Evidence

Study designs on VOC research range widely from observational studies with a high risk of bias to double blind randomized controlled trials (RCTs) with a lower risk of bias. The highest level of evidence was from double-blind randomized controlled trials that were done to evaluate vaccine efficacy. The observational studies, including surveillance data analyses, retrospective cohorts and case control studies, are generally considered low levels of evidence, but may be upgraded for a given outcome when multiple studies are in agreement and when they have a prospective design. Other studies including predictive models, ecological studies, animal models, *in vitro* studies and *in silico* studies are low to very low evidence**.** Generally these types of studies are used to generate hypotheses that are then tested with a more rigorous study design. For this profile, study designs were identified, but no formal risk of bias assessment was conducted for each study. A summary indication of the level of confidence of the evidence was given for each category of study.

The greatest amount of evidence was on the transmissibility and spread of Beta over time. There were gaps in knowledge regarding epidemiological parameters including infectious period and incubation period, impact on public health measures, and vaccine effectiveness. There are several knowledge gaps or areas where there is very little research noted in the key points table, and additional research is needed to improve confidence in summary results, and to fill in current knowledge gaps regarding the Beta variant.

CONTENTS

BETA

The excel dataset includes summaries of individual studies and can be accessed here. Below is the detailed evidence profile developed for Beta.

Categories of evidence in the tables below include the following if reported:

Transmissibility includes changes in transmissibility, secondary attack rates, and estimates of selective advantage.

Clinical Severity includes proportion of infections that are symptomatic, proportion of severe disease and mortality as well as risk factors for severe disease or mortality, viral load, infectious period, incubation period. Note risk factors for severe disease would include special populations e.g. persons who are pregnant (when reported).

Immune Escape includes changes to vaccine efficacy, risk of re-infection in humans, animal models, *in vitro* or *in silico* experiments as well as impacts on therapeutics if reported.

Diagnostic / Detection Test Failure is captured in the individual sections, and will only be included in Table 2 if there is a concern about test performance.

Other Epidemiology includes all studies that document the emergence and spread of VOCs in a geographic area, ecological studies that examine VOC spread and risk factors for hot spots, and studies on effective public health interventions against VOCs, genomic epidemiology as subcategories when reported.

Table 2: Evidence Profile of B.1.351 (Beta) VOC (n=341)

CATEGORY	KEY SUMMARY OUTCOMES	OVERVIEW OF THE EVIDENCE
Transmission Efficiency		
Transmissibility Compared to Original Variant or B.1.1.7 (Alpha)	Beta vs. Original Variant: • Increased transmissibility above the original variant: 58% (95%CI -7%-167%) in Ontario, Canada (8), 55% in multiple countries (6), 20-100% (as high as 175%) in South Africa (7), and 26%-27% in Niger and France that combined Beta and Gamma case data (4, 5) Beta vs. Alpha: • France: Between April to May 2021, Beta had a significant transmission advantage over Alpha in Ile-de-France (15.8%, 95%CI 15.1%-16.1%) and Hauts-de-France (17.1%, 95%CI 16.1% - 18.8%) compared to January to March 2021(11). • France: Between May to June 2021, combined Beta, Gamma and Eta data indicated a significant transmission advantage over Alpha in Ile-de-France (17.2%, 95%CI 15.6%-18.9%), Hauts-de- France (16.1%, 95%CI 4.63%-28.5%), and Normandie (9.12%, 95%CI 7.34%-10.9%) (23).	7 studies on transmissibility, including 6 surveillance data analyses from France (n=3), Canada (n=1), Niger (n=1), multiple countries (n=1), and 1 predictive model from South Africa. Across studies there is little consistency. Heterogeneity in increased transmissibility estimates may be due to many factors including the point in the pandemic estimates are taken and public health measures in place. Low level of evidence.
Secondary Attack Rates	• Canada: An Ontario household transmission investigation reported that Beta had a 31%	2 studies including 1 surveillance data analysis from Canada, and 1

Compared to Original Variant	higher secondary attack rate (SAR) (26.4%) compared to the original variant (20.2%) from March to April 2021 (8). • France: In an outbreak investigation of Beta, involving 20 secondary cases among 31 confirmed/probable cases, the SAR was 76.9%, equivalent to an R_{eff} of 4 (24).	outbreak investigation from France. Low level of evidence.
Clinical Severity		
Virulence / Severity or Duration of Disease Compared to Original Variant or B.1.1.7 (Alpha)	• European countries: There was no difference in the symptomatic proportion among Beta cases (90.3%; 28/31) vs. original variant cases (81.4%; 547/672, p = 0.2) (10). Increased hospitalization: • European countries: A higher odds of hospitalization with Beta (19.3%) vs. the original variant (7.5%) p<0.001.0, in a multivariable analysis (aOR = 3.6, 95% CI: 2.1-6.2) (10). • France: Beta cases were more likely to be hospitalized (OR=1.56, p<0.0001) compared to Alpha cases (11). Conflicting evidence on ICU admission: • European countries: Increased proportion of Beta cases in the ICU (2.3%) vs. the original variant (0.6%) p=0.001, and higher odds of ICU admission among Beta cases compared to original variant cases (aOR = 3.3, 95%CI 1.9-5.7) (10). • South Africa: In hospitalized cases, there were lower ICU admissions (35% vs. 48.5%, p=0.03) and mechanical ventilation (8.9% vs. 15.5%, p=0.009) during the Beta wave compared to the original variant wave. Although patients were of older age, they had less comorbidities during the Beta wave. The shortage of ICU beds was not a factor influencing this finding (12). France: No significant difference in ICU scores and mechanical ventilation requirements between Beta, original variant or Alpha cases in a hospital (13).	4 studies on severity, including 2 surveillance studies from multiple European countries and France, and 2 retrospective cohort studies from France and South Africa. The cohort studies are single-centered, therefore have limited external validity and are at risk of confounding bias. Low confidence in the increased/decreased severity of the Beta variant. Low level of evidence.
Severity Risk Factors	Age:	3 studies on severity risk factors, including 1 surveillance study of

Compared to Original Variant or B.1.1.7 (Alpha)	• European countries: In an age-stratified analysis, Beta cases had 3.5–3.6 times higher odds of hospitalization for age groups 40–59 and 60–79 years compared to original variant cases of the same age (10). • European countries: Admission to the ICU was significantly more likely for Beta cases (aOR 8, 95%CI 3.7–17.3) aged 40–59 years (10). • South Africa: Hospitalized cases during the second wave, Oct 2020- Jan 2021, where Beta was dominant, were significantly older (median age 57 vs. 54 years, p = 0.03) compared to cases during the original variant wave (12). • France: No significant difference in the age (63 years vs. 67 years, p = 0.15) or sex of ICU admissions among Beta cases compared to original variant or Alpha cases (13). Comorbidities: • European countries: Pre-existing conditions were lower in Beta cases (79.6%) vs. original variant cases (89%), p<0.001 (10). • South Africa: More cases during the Beta wave had no comorbidities (47% vs. 36.9%, p=0.008) and less hypertension (32.2% vs. 45.2%, p<0.001) compared to the original variant wave, and there was no difference in diabetes mellitus, chronic respiratory disease, cerebrovascular disease, and HIV positivity (12).	European countries and 2 retrospective cohort studies from France and South Africa. The cohort studies are single-centered, therefore have limited external validity and are at risk of confounding bias. Low level of evidence.
Mortality Compared to Original Variant or B.1.1.7 (Alpha)	Increased mortality: • South Africa: During the Beta wave, hospital admission was independently associated with mortality (p=0.006), there was increased overall mortality (36.4% vs. 32.6%, p=0.26), and significantly higher ICU mortality (74.4% vs. 57.1%, p=0.002) compared to the original variant wave. Lack of ICU capacity may have contributed to increased mortality (12). • France: Higher odds of death within 60 days of ICU admission (OR=5.67, 95% CI: 1.04-30.81,	3 studies on mortality, including 1 surveillance study of European countries and 2 retrospective cohort studies from South Africa and France. The cohort studies are single-centered, therefore have limited external validity and are at risk of confounding bias. Low level of evidence.

	p=0.04) for Beta cases compared to Alpha cases (13). No difference: • European countries: No difference in the odds of death for Beta cases compared to original variant cases in a multivariable analysis (aOR 1.1, 95% CI: 0.4-3.4) (10).	
Mortality Risk Factors Compared to Original Variant	No studies	
Viral Load Compared to Original Variant or B.1.1.7 (Alpha)	Beta vs. Original Variant: • France: The viral load of Beta was 2 times higher than the original variant (14), and Beta had a CT value difference of 0.754 (p<0.0072) lower (indicating higher viral load) compared to the original variant (4). Beta vs. Alpha: • France: Viral load (measured by CT values) in Beta samples was lower than Alpha samples (CT values: 22.2 for Beta vs. 21.9 for Alpha) (5).	3 studies including 2 surveillance data analysis using data from France, and 1 cross sectional study from France. Viral load is reported as a secondary outcome in these studies. Very low level of evidence.
Infectious Period Compared to Original Variant	• No significant difference in the infectious period duration of decline in viral load of combined Beta/Gamma data compared to the original variant (95% CI of the HR: 0.79-1.06) (4).	1 surveillance data analysis from multiple countries. Low level of evidence.
Incubation Period	No studies	
Immune Escape - Potential Impact on Vaccine Efficacy, Possibility of Re-infection		
Re-infection from Infection Compared to Original Variant	• Only case reports have been reported and are not summarized.	
Breakthrough Infection After Vaccination / Vaccine Efficacy or Effectiveness Compared to Original Variant	Vaccine Efficacy/Effectiveness: BNT162b2 (Pfizer-BioNTech): • Qatar: 75.0% (95% CI: 70.5% – 78.9%) VE against any Beta infection ≥ 2 weeks after the second dose. 56.5% (95% CI: 0.0% – 82.8%) VE 15 to 21 days following the first dose and 97.4% (95% CI: 92.2%-99.5%)/100.0% (95% CI: 73.7% - 100.0%) VE ≥14 days following the	10 studies on breakthrough infections and vaccine efficacy/effectiveness, including 3 RCTs from South Africa, 1 prospective cohort study from France, 1 retrospective cohort study from Israel, 3 case control studies from Qatar (n=2) and Canada (n=1), 1 surveillance data

	second dose against severe, critical, or fatal outcomes due to Beta infection (15, 16). • France: A VE against infection of 50% (95% CI: 34%-73%) among nursing home residents (median age: 87.0±8.2 years) for two doses spaced 19 days apart was observed in an outbreak investigation (17). • Canada: In Ontario, fully vaccinated long-term care residents had a VE of 93.48% against Beta infection (18). • Canada: A study from Ontario reported BNT162b2 (Pfizer)/mRNA-1273 (Moderna), had a VE of ≥ 88% against symptomatic Beta infection ≥ 7 days after receiving the second dose (19). ChAdOx1 (AstraZeneca): • South Africa: 10.4% (95%CI: -76.8%-54.8%) VE for prevention of symptomatic disease > 14 days following the second dose (20). Ad26.COV2.S (Johnson and Johnson): • In South Africa, where Beta is the dominant variant, the reported VE was 52% and 64% for moderate disease and 73% and 82% for severe disease at 14 days and 28 days, respectively, following a single dose (22). NVX-CoV2373 (Novavax): • South Africa: 51.0% (95%CI -0.6 – 76.2) VE against symptomatic disease in HIV-negative individuals (21). Breakthrough Infection after Vaccination: • Studies from France and Canada describe Beta breakthrough infections among fully vaccinated long term care (LTC) residents and fully/partially vaccinated LTC staff, however there is no indication that the Beta breakthrough rate is higher than expected compared to its representation in all COVID-19 cases in the community (17, 18). • USA: In an underpowered study (n=20 breakthrough cases), Beta was overrepresented among breakthrough infections (5%, 1/20) compared to its	analysis from the USA, and 1 outbreak investigation from Canada. Most VE estimates for each vaccine are only based on one study, therefore additional trials are needed to improve confidence in these estimates. These studies have a low to moderate level of evidence.

	representation in COVID-19 cases (1%) from February to April 2021 in Washington State (25). Israel: There was a significantly higher proportion of Beta breakthrough infections among cases who received the second dose of the Pfizer-BioNTech vaccine vs. unvaccinated controls (OR=8:1, p=0.02), of which 7/8 cases were identified 7 to 13 days after the second dose and 1/8 cases were identified14 days after the second dose (26).	
Studies of Therapeutics Compared to Original Variant	• In *in vitro* experiments, Casirivimab and Etesevimab showed reduced neutralization (27-30), Bamlanivimab showed no neutralization and failed to inhibit binding of the Beta spike to ACE2 (29-32), and there was conflicting evidence on the neutralization of Imdevimab (27, 28) against Beta. • In mice and hamster models, combination monoclonal antibody treatment involving Casirivimab and Imdevimab showed protection against Beta infection, and higher doses (35 mg kg^{-1}) could compensate for the loss in neutralization potency (30).	6 studies on therapeutics including 5 *in vitro* studies and 1 animal model. Very low level of evidence.
Animal Models of convalescent or vaccinated protection	• Animal models challenged with Beta concluded that previously infected or vaccinated hamsters and mice have shown protection from clinical disease (33-40).	8 animal models. Very low level of evidence.
***In vitro* Studies** Compared to Original Variant or B.1.1.7 (Alpha)	• Most vaccine and convalescent sera have shown reduced neutralizing activity for Beta compared to the original variant or Alpha. In most studies Beta has more reduced neutralization than Gamma. The neutralization experiments are not summarized, but can be found in the dataset.	95 *in vitro* experiments have been identified with results specific to Beta neutralization. Very low level of evidence. The immune response is complex, and lack of or reduced neutralizing antibodies does not mean a lack of immune protection. Further research is needed (see the PHAC Emerging Science Group review on protective immunity).
Testing and Diagnostics		

Testing and Detection Compared to Original Variant or B.1.1.7 (Alpha)	• PCR, antigen tests, serological assays and sequencing methods are effective at detecting and/or distinguishing Beta, including detection in wastewater samples (41-60). • The TRF-ELISA S1-based antigen assay detected Beta with a 2 to 3-fold reduced sensitivity compared to the original variant and Alpha (61). • The ADESSO assay, which uses specific high-sensitivity enzymatic reporter unlocking, failed to detect one Beta sample carrying the R246I mutation among 13 Alpha/Beta samples (58).	21 studies on testing and detection, including 20 diagnostic test accuracy studies and 1 *in silico* study. As these are all describing different tests, the studies are considered to be individual and cannot be summarized together. Low level of evidence.
Spread Epidemiology		
VOC Emergence Over Time	• Two studies show the growth of Beta in different areas of South Africa from October to November 2020 and British Columbia, Canada from January to February 2021 (62, 63). • In South Africa, Beta emerged around August 2020, and was first detected in October 2020. By March 2021, it became the dominant variant representing approximately 20% (1769/8746) of genomes (64). • Studies from countries outside of South Africa, report the first detection of Beta since December 2020. Beta emerged in North America in January 2021 (65-68).	7 studies including 6 surveillance data analysis from South Africa (n=1), Canada (n=1), Comoros Islands (n=1), Bangladesh (n=1), multiple countries (n=2), and 1 predictive model from multiple North American countries. Low level of evidence.
Predictions of Spread	• Based on predictive models, the frequency of Beta will remain stable (<5%) from July 2021 onwards in North America, assuming that vaccination will not affect the proportion of variants and there will be equal and sustained rates of infectivity. The frequency of Beta will gradually increase to 5% by March 2022 in North America, assuming that herd immunity will be reached in July 2021 with 75% of the population being vaccinated (68). • Due to the assumed immune evasion of Beta (25% to 75%), it is predicted to outgrow Alpha (no immune evasion assumed for Alpha) in regions where the seroprevalence of the original variant exceeds 20% to 40% (9).	2 predictive models from multiple North American countries and South Africa. Low level of evidence.

CFR = case fatality rate, CI = confidence interval, Ct = cycle threshold, ICU = intensive care unit, , PCR = polymerase chain reaction, VE = vaccine effectiveness, OR= odds ratio, aOR= adjusted odds, HR=Hazard Ratio, ratio, aHR = adjusted Hazard Ratio, aPR= adjusted Prevalence Ratio

Methods:

A daily scan of the literature (published and pre-published) is conducted by the Emerging Science Group, PHAC. The scan has compiled COVID-19 literature since the beginning of the outbreak and is updated daily. Searches to retrieve relevant COVID-19 literature are conducted in Pubmed, Scopus, BioRxiv, MedRxiv, ArXiv, SSRN, Research Square and cross-referenced with the COVID-19 information centers run by Lancet, BMJ, Elsevier, Nature and Wiley. The daily summary and full scan results are maintained in a Refworks database and an excel list that can be searched. One of the foci is to identify studies as variants of concern or under investigation. Studies identified under this foci are further characterized in our VOC/VOI database and Beta results were extracted into this review. A cross check for relevant articles is also conducted within the databases using targeted keyword searching (B.1.351 OR Beta). This table is evolving as the evidence evolves.

This review contains research published up to July 1, 2021.
Each potentially relevant reference was examined to confirm it had relevant data and relevant data was extracted into the review.

Peer-review
This document underwent peer-review by a subject matter expert, and editorial and science to policy review by the Office of the Chief Science Officer.

Nouveaux éléments de preuve sur la COVID-19

Résumé évolutif à propos des variants préoccupants du SRAS-CoV-2 : Le profil du variant Delta (B.1.617.2)

Faits saillants jusqu'au 30 juin 2021

Introduction

Les variants préoccupants (VP) du SRAS-CoV-2 sont des variants en circulation qui ont été signalés par les organisations nationales ou mondiales de santé publique. Ces variants deviennent préoccupants lorsqu'on les compare aux variants originaux du SRAS-CoV-2, puisque la complémentation de leurs mutations crée une transmissibilité et une virulence accrues (morbidité ou mortalité), des changements dans la présentation clinique de la maladie, de l'évasion immunitaire, une diminution de l'efficacité des vaccins, des thérapies ou des mesures de santé publique disponibles ou des échecs dans la détection aux fins de diagnostic (1, 2). Ce résumé évolutif axé sur la littérature sur les VP du SRAS-CoV-2 vise à présenter de nouvelles données sur le VP B.1.617.2 (Delta), leur épidémiologie et la façon dont leurs attributs peuvent influer sur la gestion de la pandémie. Ce résumé porte sur les changements dans les paramètres épidémiologiques (p. ex., taux de transmission, résultats cliniques en ce qui concerne la gravité et la mortalité, changements dans les groupes d'âge touchés ou proportions de personnes asymptomatiques), les répercussions sur les tests de diagnostic, l'évasion immunitaire ou et l'efficacité des vaccins, ainsi que les répercussions des VP sur d'autres mesures de santé publique. En mai 2021, l'OMS a publié un système de nomenclature des variants préoccupants (VP) et des variants d'intérêt (VI) utilisant des lettres grecques afin de simplifier la communication à propos des variants et d'éliminer la stigmatisation potentielle découlant des endroits où les variants ont été identifiés la première fois, système qui a été adopté dans ce rapport (3).

TABLEAU 1 : VARIANTS ACTUELS PRÉOCCUPANTS (VP)

Dénomination de l'OMS (05-2021)	Lignée Pango	Clade Nextstrain	Clade GISAID	Nom alternatif	Détecté initialement dans	Premiers échantillons	Mutations caractéristiques du spicule
Alpha	B.1.1.7	20I/501Y.V1	GR/501Y.V1	VP 202012/01	Royaume-Uni	Sept. 2020	69/70del, 144del, N501Y, A570D, D614G, P681H, T716I, S982A, D1118H
Bêta	B.1.351	20H/501Y.V2	GH/501Y.V2	VP 202012/02	Afrique du Sud	Août 2020	D80A, D215G, 241/243del, K417N,

							E484K, N501Y, D614G, A701V
Gamma	P.1, B.1.1.28.1	20J/501Y.V3	GR/501Y.V3	VP 202101/02	Brésil et Japon	Déc. 2020	L18F, T20N, P26S, D138Y, R190S, K417T, E484K, N501Y, D614G H655Y, T1027I, V1176F
Delta	B.1.617.2		G/452R.V3		Inde	Oct. 2020	L452R, D614G, P681R, ± (E484Q, Q107H, T19R, del157/158, T478K, D950N)

Cette revue évolutive des éléments de preuve présente les éléments de preuve clés sur le variant Delta et fait partie d'un projet plus vaste qui résume les données sur chacun des VP et enregistre les données sur les VI, ce qui inclut les changements dans l'épidémiologie, dans l'évasion immunitaire et dans l'efficacité des vaccins, ainsi que les répercussions sur les tests diagnostiques et les mesures de santé publique. L'ensemble complet de données en Excel est accessible ici et peut être filtré par les variants préoccupants ou les variants d'intérêt. La récente revue des preuves vivantes sur les autres VP (Alpha, Beta, Gamma) peut être demandée ici.

Points clés

Au 30 juin 2021, quarante-sept études font état du variant préoccupant Delta (dont 30 ont été ajoutées depuis la dernière mise à jour du 7 juin 2021). Treize d'entre elles ne sont pas incluses dans cette revue, car l'une d'entre elles était un rapport de cas, deux étaient des études *in silico* et dix ne spécifiaient pas la lignée étudiée (c'est-à-dire qu'elles étaient rapportées B.1.617). En outre, quatre rapports de littérature grise pertinents du Royaume-Uni ont été inclus, car ils fournissent des données sur le variant Delta qui n'ont pas encore été rapportées dans la littérature. Les détails individuels de toutes les études pour la lignée B.1.617 (n=51) se trouvent dans l'ensemble de données Excel accessible ici.

- Les données de surveillance du Royaume-Uni et de l'Inde sur l'introduction et le taux de croissance du variant Delta entre février et juin 2021 indiquent que le variant Delta représente désormais 91 à 96 % des cas (4 à 9). Des études menées aux États-Unis et au Japon ont révélé que le variant Delta est en train de remplacer B.1.1.7 (Alpha) comme variant dominant (10, 11). La prévalence du variant Delta devrait dépasser Alpha au Japon vers le 12 juillet 2021, avant le début des Jeux olympiques de Tokyo (11). Les projections de modèles visant à examiner l'impact potentiel du variant Delta en Inde au cours des six prochains mois montrent qu'alors que le pays entre dans la saison de la mousson à partir de juin, les infections pourraient ressurgir si les mesures d'intervention sont levées prématurément (12).

- Public Health England a signalé qu'un petit nombre de séquences Delta ont été détectées qui ont acquis la mutation K417N de la protéine du spicule qui a été associée à l'échappement immunitaire dans le variant B.1.351 (Bêta) où elle a été identifiée pour la première fois) (13, 14). Au 22 juin 2021, 161 génomes de cette nouvelle sous-lignée Delta, désignée comme B.1.617.2.1, Delta+ ou AY.1, ont été classés sur GISAID en provenance du Canada (1), de l'Inde (8), du Japon (15), du Népal (3), de la Pologne (9), du Portugal (22), de la Russie (1), de la Suisse (18), de la Turquie (1), ainsi que des États-Unis (83) et de l'Angleterre (41). B.1.617.2.1 est inclus dans la classification du VP Delta par l'Organisation mondiale de la santé (15).
- En Ontario, au Canada, le profil de mutation N501Y-/E484K- (qui représente le variant Delta ou le variant original) est passé d'un déficit de transmission de 29 % par rapport à Alpha le 1er avril à un avantage de transmission de 50 % le 12 juin. Le séquençage du génome entier des cas N501Y-/E484K a confirmé que cette augmentation de la transmissibilité coïncidait avec le remplacement du variant original par le variant Delta (16).
- D'après deux études de surveillance menées au Royaume-Uni et en Inde, le variant Delta a augmenté la transmissibilité par rapport au variant Alpha de 43 à 115 % (7, 17). Une étude japonaise rapporte une transmissibilité 1,2 fois plus élevée pour le variant Delta par rapport au variant Alpha (11). Les données de recherche des contacts recueillies au Royaume-Uni ont permis d'estimer que le taux de transmission secondaire parmi les contacts non liés à un voyage était supérieur de 35 % à celui du variant Alpha (14).
- Trois études utilisant la valeur Ct (seuil de cycle) comme indicateur de la charge virale ont signalé que les charges virales de Delta pouvaient être plus élevées que celles du variant Alpha et du variant original (7, 18, 19). Un rapport de surveillance britannique suggère qu'il pourrait y avoir un risque plus élevé d'hospitalisation avec Delta par rapport au variant Alpha (13, 20). En outre, un rapport de surveillance de Singapour a montré que l'infection par Delta était associée à un risque plus élevé de besoin d'oxygène supplémentaire, d'admission en unité de soins intensifs ou de décès (RCa 4,90, IC à 95 % de 1,43 à 30,78) par rapport à l'infection par le variant original de type sauvage (18). Une surveillance et des recherches supplémentaires sont nécessaires pour confirmer ces résultats dans d'autres contextes.
- La 12e ronde de l'étude REACT-1 au Royaume-Uni a noté une croissance exponentielle du variant Delta en mai-juin 2021, ce dernier étant devenu dominant, et l'analyse montre que la plupart des infections se produisaient dans des groupes plus jeunes qui n'étaient pas non plus vaccinés (9).
- Les données sur l'évasion immunitaire montrent qu'il peut y avoir une réduction modérée de la neutralisation de Delta par rapport aux variants Alpha et original (19, 21 à 25) et les modèles prédictifs ont estimé que Delta est capable d'échapper à environ 20 à 55 % de la protection immunitaire fournie par une infection antérieure avec des lignées non Delta (12, 19). Une étude de cohorte prospective à long terme a fait état d'une légère augmentation des taux de réinfection en juin au Royaume-Uni, où la plupart des cas de SRAS-CoV-2 en circulation sont des cas Delta. Malgré cette légère hausse, les

réinfections restent à un niveau très bas (14). Une étude sur l'efficacité d'un vaccin dans le monde réel, réalisée au Royaume-Uni à l'aide d'un modèle de témoins ayant obtenu un résultat de test négatif pour étudier l'efficacité des vaccins BNT162b2 (Pfizer) et ChAdOx1 (AstraZeneca), a révélé que l'efficacité était nettement inférieure contre le variant Delta après une dose de l'un ou l'autre des vaccins par rapport au variant Alpha; toutefois, après deux doses de l'un ou l'autre des vaccins, il n'y avait pas de différence significative dans l'efficacité du vaccin avec les cas du variant Delta (20, 26).

Vue d'ensemble des éléments de preuves

La conception des études sur les VP est très variée, allant des études d'observation avec un risque élevé de biais aux essais contrôlés randomisés (ECR) à double insu avec un risque plus faible de biais. Aucun essai clinique n'a été identifié pour cette revue sur le variant Delta. Il y avait des études d'observation, y compris des analyses de données de surveillance et des études de cas-témoins qui sont considérées comme des niveaux de preuve faibles. La certitude des preuves fournies par ces études d'observation peut être améliorée pour un résultat donné lorsque plusieurs études concordent et sont de conception prospective. Cette revue ne comportait qu'une seule étude prospective. Les autres études identifiées étaient des expériences *in vitro* qui sont considérées comme ayant un niveau de preuve faible à très faible. En général, ces types d'études sont utilisés pour générer des hypothèses qui sont ensuite testées avec un plan d'étude plus rigoureux. Pour cette revue, les modèles d'étude ont été identifiés, mais aucune évaluation formelle du risque de biais n'a été réalisée pour chaque étude. Une indication sommaire du niveau de confiance des preuves a été donnée pour chaque catégorie d'étude. Le plus grand nombre de preuves concernait la transmissibilité, la propagation de Delta dans certaines zones géographiques, les résultats cliniques de la gravité et l'échappement immunitaire. Dans les données publiées actuellement, il y avait des lacunes dans les connaissances sur les paramètres épidémiologiques, notamment la période infectieuse et la période d'incubation, les impacts sur la précision des tests de diagnostic, les impacts sur la thérapeutique et les impacts sur d'autres mesures de santé publique.

Dans l'ensemble, le niveau de preuve concernant le variant Delta est faible et il existe des lacunes dans la base de données bibliographiques existante. Des études supplémentaires sont donc nécessaires pour améliorer la confiance dans les résultats sommaires et pour combler les lacunes dans les connaissances actuelles concernant le variant Delta.

TABLE DES MATIÈRES

DELTA

L'ensemble de données en Excel comprend des résumés de chacune des études et est accessible ici. Vous trouverez ci-dessous le profil détaillé des preuves élaboré pour Delta.

Les catégories de preuve indiquées dans le tableau ci-dessous comprennent les données suivantes :

La **transmissibilité** comprend les changements dans la transmissibilité, les taux d'attaque secondaire, l'intervalle sériel (intervalle de temps entre l'apparition des symptômes dans le cas primaire et secondaire) et les estimations de l'avantage sélectif.

La **gravité clinique** comprend la proportion d'infections qui sont symptomatiques, la proportion de maladies graves et de mortalité ainsi que les facteurs de risque de maladie grave ou de mortalité, la charge virale (la valeur Ct est souvent utilisée comme indicateur de la charge virale, une valeur Ct plus faible indiquant une charge virale plus élevée), la période infectieuse, la période d'incubation. Veuillez noter que les facteurs de risque d'une atteinte grave incluraient les populations spéciales, p. ex., les femmes enceintes (lorsqu'elles sont déclarées).

L'**échappement immunitaire** comprend les changements dans l'efficacité du vaccin, le risque de réinfection chez les humains, les modèles animaux, les expériences *in vitro* ou *in silico*, ainsi que les répercussions sur les thérapies lorsqu'elles sont déclarées.

L'**échec du test de diagnostic ou de la détection** est indiqué dans le tableau.

La mention **Autre épidémiologie** inclut toutes les études qui documentent l'émergence et la propagation des VP dans une région géographique, les études écologiques qui examinent la propagation des VP et les facteurs de risque pour les points chauds, ainsi que les études sur les interventions en santé publique efficaces contre les VP, avec l'épidémiologie génomique comme sous-catégories, lorsqu'elle est déclarée.

Tableau 2 : Profil fondé sur les éléments de preuve pour le VP Delta (n = 38)

CATÉGORIE	RÉSUMÉ DES PRINCIPAUX RÉSULTATS	VUE D'ENSEMBLE DES ÉLÉMENTS DE PREUVES
Efficacité de transmission		
Transmissibilité par rapport au variant B.1.1.7 (Alpha)	• En Ontario (Canada), le profil de mutation N501Y-/E484K- (qui représente Delta ou le variant original de type sauvage) est passé d'un déficit de transmission de 29 % par rapport à Alpha (Re relatif = 0,71, IC à 95 % de 0,64 à 0,77) le 1er avril à un avantage de transmission de 50 % le 12 juin (Re relatif = 1,50, IC à 95 % de 1,31 à 1,71). Le séquençage du génome entier des cas N501Y-/E484K a confirmé que cette augmentation de la transmissibilité coïncide	5 analyses de données de surveillance et un modèle prédictif, tous prépubliés. Faible niveau de preuve.

	avec le remplacement du type sauvage par le variant Delta (16). • Une étude britannique estime que Delta était de 43 à 115 % plus transmissible qu'Alpha sur des périodes hebdomadaires (du 3 avril au 22 mai) (17). • Des études menées en Inde estiment que la transmissibilité de Delta était 1,1 à 1,4 fois plus élevée que celle des lignées circulant précédemment à Mumbai en janvier 2021 (19), 50 % plus élevée que celle d'Alpha (7) et 60 % plus infectieuse que celle des variants originaux (12). • L'étude japonaise estime que Delta est 94,8 % et Alpha 43,7 % plus transmissible que les variants non préoccupants. Cela se traduit par une transmissibilité 1,4 fois plus élevée pour Delta par rapport à Alpha (11).	
Taux d'attaque secondaire par rapport au variant B.1.1.7 (Alpha)	• TAS 35 % supérieur : 10,7 % (IC à 95 % de 10,5 % à 10,9 %) pour B.1.617.2 (Delta) comparativement à 7,9 (de 7,7 % à 8,0 %) pour B.1.1.7 (Alpha) en ce qui concerne les cas sans lien avec les voyages (14). • TAS 39,5 % supérieur : 12,0 % (de 11,7 % à 12,2 %) des contacts à domicile sans lien avec les voyages pour Delta comparativement à 8,6 % (8,4 % à 8,8 %) (14). • L'augmentation de la transmission par contact à domicile pour Delta par rapport à Alpha était un RCa 1,64 (IC à 95 % de 1,26 à 2,13, p<0,001) (27)	1 rapport résumant l'analyse des données de la surveillance provenant de plusieurs études (du 29 mars au 7 juin). 1 étude nationale de cas-témoins. Faible niveau de preuve.
Intervalle de série par rapport au variant original	• Une étude de Singapour et un rapport d'Angleterre indiquent que l'intervalle de série n'a pas changé (données d'avril à mai) par rapport aux intervalles de série antérieurs au VP (13, 28). • Médiane de 3 jours (IQR de 2 à 4) (28) • La médiane de 4 jours pour les contacts à domicile et hors domicile (13) est la même que celle d'Alpha.	1 analyse des données de surveillance et 1 rapport résumant l'analyse des données de surveillance de plusieurs études. Faible niveau de preuve.

Études *in vitro* de l'infectiosité par rapport au variant original	• On pense que l'augmentation de la transmissibilité est au moins partiellement due à une mutation du gène P618R dans la protéine S qui améliore la capacité de la furine à dissocier le peptide (29).	2 études *in vitro*. Très faible niveau de preuve.
Gravité clinique		
Virulence, gravité ou durée de la maladie par rapport au B.1.1.7 (Alpha) ou au variant original	• L'analyse effectuée en Angleterre indique une augmentation significative du risque d'hospitalisation dans les 14 jours suivant la date de prélèvement du spécimen (TR 2,26, IC à 95 % de 1,32 à 3,89, p < 0,001), et de la demande de soins d'urgence ou d'hospitalisation dans les 14 jours (TR 1,45, IC à 95 % de 1,08 à 1,95, p < 0,001) pour les cas de personnes infectées par Delta comparativement à Alpha après ajustement pour les variables confondantes (âge, sexe, origine ethnique, région de résidence, indice de privation multiple, semaine du diagnostic et état de vaccination) (13). • Une étude effectuée en Écosse rapportant le délai d'admission à l'hôpital a révélé que les cas Delta étaient associés à un risque accru d'admission à l'hôpital en raison de la COVID-19 : taux de risque (TR) 1,85 (IC à 95 % de 1,39 à 2,47) par rapport au variant B.1.1.7 (Alpha), après ajustement pour l'âge, le sexe, la privation, la tendance temporelle et les comorbidités rapportées (20). • Singapour, l'infection par Delta a été associée à une probabilité plus élevée de gravité de la maladie qui incluait les cas nécessitant une oxygénation supplémentaire, une admission en unité de soins intensifs ou le décès (rapport de cotes ajusté (RCa) 4,90, IC à 95 % de 1,43 à 30,78) (18). Le RCa pour la pneumonie était 1,88 fois plus élevé (IC à 95 % de 0,95 à 3,76) pour les personnes infectées par Delta par rapport à l'infection par le variant original, bien que non significatif (18).	1 rapport résumant l'analyse des données de surveillance de plusieurs études et 2 analyses de données de surveillance. Faible niveau de preuve.

Facteurs de risque de la gravité par rapport au variant original	• L'analyse préliminaire de l'étude EAVE II en Écosse a suggéré que les cas Delta étaient plus jeunes et appartenaient à des groupes sociodémographiques plus élevés que les autres cas, mais il n'est pas clair si ces observations sont basées sur des analyses contrôlant les facteurs confondant, notamment la vaccination. Des recherches supplémentaires sont nécessaires pour tirer la moindre conclusion (20).	1 analyse des données de surveillance. Très faible niveau de preuve.
Mortalité par rapport au variant original	• Aucune étude	
Facteurs de risque de mortalité par rapport au variant original	• Aucune étude	
Charge virale par rapport au B.1.1.7 (Alpha) ou au variant original	• La charge virale peut être plus élevée chez Delta que chez Alpha. Par rapport à la base de référence créée entre décembre 2020 et février 2021 en Inde, les valeurs Ct ont chuté en mars lorsque Alpha est devenu dominant avant de diminuer encore davantage en avril lorsque B.1.617 a pris la relève (il s'agissait principalement de la souche Delta) (7). La variation des valeurs Ct (-6) correspond à une augmentation de 50 fois la charge virale (7). • Parmi les travailleurs de la santé vaccinés dans trois hôpitaux de Delhi et testés positifs pour le SRAS-CoV-2, la valeur médiane de Ct des infections par le variant Delta était de 16,5 contre 19 pour les variants non Delta ($p<0,05$), ce qui indique une charge virale plus élevée (19). • À Singapour, le variant Delta a été associé à des valeurs Ct significativement plus faibles et à une durée plus longue de maintien de faibles valeurs Ct (≤30) (durée médiane de 18 jours) par rapport aux lignées de variants non préoccupants du SRAS-CoV-2 (13 jours) (18).	2 analyses de données de surveillance et 1 étude d'enquête sur les éclosions utilisant les valeurs Ct comme indicateur de la charge virale. Faible niveau de preuve.
Période infectieuse	• Aucune étude	
Période d'incubation	• Aucune étude	

Échappement immunitaire – incidence potentielle sur l'efficacité du vaccin, possibilité de réinfection		
Réinfection après infection par rapport au variant original	• La cohorte SIREN a signalé une légère augmentation des réinfections au cours du mois de juin après des chiffres très bas de mars à mai, mais le nombre de cas de réinfection reste faible (14). • Deux modèles prédictifs estiment que Delta est capable d'échapper à environ 20 à 55 % de la protection immunitaire fournie par une infection antérieure avec des lignées non Delta (12, 19).	1 étude de cohorte prospective et 2 modèles prédictifs. Faible niveau de preuve.
Infection percée après la vaccination / efficacité ou efficience du vaccin par rapport au B.1.1.7 (Alpha), B.1.617.1 (Kappa) ou au variant original	Infections parmi les vaccinés : • Dans une étude menée en Inde entre novembre 2020 et mai 2021, 19 sur 27 cas infectés après vaccination étaient des Delta. Ce chiffre est plus élevé que ce à quoi on pourrait s'attendre compte tenu des variants en circulation et correspond à un risque d'infection après vaccination plus élevé pour Delta que pour Alpha (7). L'analyse des infections après vaccination chez plus de 100 travailleurs de la santé dans trois centres en Inde a conclu qu'il y avait un risque plus élevé d'infection chez les travailleurs de la santé ayant reçu en grande partie le vaccin ChadOx-1 (Covishield) par rapport à Alpha ou B.1.617.1 (Kappa) (p=0,02) (19). • Au Royaume-Uni, les cas séquentiels détectés après une ou deux doses de vaccin présentaient un risque plus élevé d'infection au variant B.1.617.2 (Delta) que les cas non vaccinés (RC 1,40; IC à 95 % de 1,13 à 1,75) (26). • En Écosse, la vaccination (> 28 jours après la première dose) a été associée à une diminution du risque d'hospitalisation pour les cas Delta TR= 0,38 (IC à 95 % de 0,24 à 0,58), légèrement diminuée par rapport à Alpha (20), et le taux de risque chez les patients Delta vaccinés était TR 0,37 (IC à 95 % de 0,22 à 0,63) après une dose et TR 0,29 (IC à 95 % de 0,11 à 0,72) après deux	4 analyses de données de surveillance, 1 étude d'investigation d'épidémie et 2 études de contrôle de cas négatifs. Faible niveau de preuve.

	doses de n'importe quel vaccin par rapport aux non-vaccinés (30). • Aux États-Unis, une infection Delta (après la vaccination avec JNJ-78436735 (J&J)) a été signalée parmi 2 551 tests d'amplification de l'acide nucléique effectués sur des personnes entièrement vaccinées sur un campus universitaire (31). Efficacité après une dose de vaccin : • Royaume-Uni : Après une dose, on a constaté une réduction absolue de 14 % de l'efficacité du vaccin (EV) contre la maladie symptomatique due au Delta par rapport à Alpha (14). • Royaume-Uni : L'EV de BNT162b2 (Pfizer) ou de ChAdOx1 (AstraZeneca) contre la maladie symptomatique était d'environ 33,5 % (IC à 95 % de 20,6 à 44,3), une réduction de 15 à 20 % par rapport au variant B.1.1.7 (Alpha). • Royaume-Uni : L'EV de ChAdOx1 (AstraZeneca) contre l'hospitalisation était de 92 % (IC à 95 % de 75 à 97) après 1 dose (30). • Royaume-Uni : L'EV de BNT162b2 (Pfizer) contre l'hospitalisation était de 94 % (IC à 95 % de 46 à 99) après 1 dose (30). Efficacité du vaccin après deux doses : • Royaume-Uni : L'EV de ChAdOx1 (AstraZeneca) contre la maladie symptomatique était de 59,8 % (IC à 95 % de 28,9 à 77,3) (26). L'efficacité contre l'hospitalisation était de 92 % (IC à 95 % de 75 à 97) (30); Écosse : L'EV de prévention de l'infection confirmée >14 jours après la vaccination était de 60 % (IC à 95 % de 53 à 66) (20). • Royaume-Uni : L'EV de BNT162b2 (Pfizer) contre la maladie symptomatique était de 87,9 % (IC à 95 % de 78,2 à 93,2) (26). L'efficacité contre l'hospitalisation était de 96 % (IC à 95 % de 86 à 99) (30); Écosse :	

	L'EV de prévention de l'infection confirmée >14 jours après la vaccination était de 79 % (IC à 95 % de 75 à 82) (20). • Les résultats d'EV après 2 doses étaient similaires à ceux d'Alpha (26) avec une réduction de 10 % pour la maladie symptomatique causée par Delta par rapport à Alpha dans un autre rapport (14).	
Études *in vitro* du sérum de phase convalescente par rapport au B.1.1.7 (Alpha) ou au variant original	• Les sérums de phase convalescente prélevés chez des cas présentaient une neutralisation réduite de 1,2 à 6 fois pour Delta par rapport à Alpha ou au variant original selon les études (19, 21 à 25).	6 études *in vitro*. Très faible niveau de preuve.
Études *in vitro* du sérum des personnes vaccinées par rapport au B.1.1.7 (Alpha) ou au variant original	• Après la vaccination, la neutralisation des sérums était 5 à 8 fois plus faible pour Delta que pour le variant original; la perte de neutralisation contre Delta était 4 à 6 fois plus élevée pour ChAdOx-1 (Astrazeneca) et 3 à 11 fois plus élevée pour BNT162b2 (Pfizer) (19, 32). Une autre étude a montré qu'après deux doses de ChAdOx-1 (Astrazeneca), la neutralisation contre Delta était réduite de 2,5 fois (IC à 95 % de 1,4 à 2,7) par rapport à BNT162b2 (Pfizer) (33). Deux autres études n'ont révélé qu'une faible réduction de la neutralisation pour les sérums provenant de personnes vaccinées, 2 à 4 semaines après la seconde dose du vaccin BNT162b2 (Pfizer) (24, 34). La neutralisation était 2,7 fois plus faible que celle des variants originaux contre les sérums de personnes vaccinées au BBV152 (Covaxin) (22). • La neutralisation des sérums (8 semaines après la vaccination par BNT162b2 (Pfizer)) était 3 fois plus faible pour Delta que pour Alpha (21). La plupart des sérums provenant de personnes vaccinées avec BNT162b2 (Pfizer) ont neutralisé Delta (94 %); en revanche, seuls 8 % des sérums provenant de personnes vaccinées avec ChAdOx-1	7 études *in vitro*. Très faible niveau de preuve.

	(Astrazeneca) ont été capables de neutraliser Delta (21).	
Études *in vitro* sur les thérapies par rapport au variant original	• Le bamlanivimab a perdu son activité antivirale contre Delta, ce qui démontre que L452R est une mutation d'échappement pour cet anticorps monoclonal (mAb) (21, 24, 35). • L'etesivimab, le casirivimab et l'imdevimab sont demeurés actifs contre le variant Delta (21). • Une combinaison de meplazumab et de l'anticorps C anti-CD147 a inhibé efficacement le pseudovirus Delta *in vitro* (36).	4 études *in vitro*. Très faible niveau de preuve.
Échec du test de diagnostic/détection		
Test et détection par rapport au variant original	• Il n'y a pas eu d'indication de problèmes de test (c'est-à-dire de changements de sensibilité/spécificité) avec Delta. Cependant, une étude a identifié 16 mutations de sites d'amorces dans des spécimens de la lignée B.1.617 qui ont un impact sur les sites d'amorces qui perturbent le séquençage du génome entier par deux protocoles de laboratoire largement utilisés (3 affectent le protocole de Freed et col. et 13 affectent le protocole ARTIC, version 3) (37). • L'amorce cible P681R a été introduite dans le test PCR de génotypage de Public Health England pour détecter le variant B.1.617 qui est principalement le variant Delta (13). • Un document propose des amorces PCR conçues pour identifier les VP, incluant Delta (38).	2 études sur la précision des tests de diagnostic et 1 rapport. Faible niveau de preuve.
Autre épidémiologie		
Mesures/interventions de santé publique	• Les projections de modèles visant à examiner l'impact potentiel du variant Delta en Inde au cours des six prochains mois montrent qu'alors que le pays entre dans la saison de la mousson à partir de juin, les infections pourraient ressurgir si les mesures	1 modèle prédictif. Faible niveau de preuve.

	d'intervention sont levées prématurément (12). Les projections indiquent qu'une accélération du déploiement de la vaccination de masse (jusqu'à 4 fois le rythme actuel) pourrait réduire le pic de charge, mais n'empêcherait probablement pas la résurgence. La combinaison d'un délai de 4 semaines avec un déploiement de la vaccination beaucoup plus rapide (par exemple, 4 fois le rythme actuel) et une couverture vaccinale très élevée pourrait permettre de maintenir les taux d'infection à des niveaux similaires à ceux observés fin mai 2021. Toutefois, sans une diffusion plus rapide de la vaccination, un report de la réouverture de 8 semaines pourrait être nécessaire pour empêcher la résurgence des taux d'infection.	
Émergence des VP au fil du temps	• Selon le GISAID (consulté le 10/06/2021), un total de 31 997 séquences (Europe = 24 606, Asie = 4 974, Amérique du Nord = 2 210, Océanie = 163, Afrique = 36, Amérique du Sud = 8) ont été assignées à la lignée B.1.617.2 (Delta) (32). • Le séquençage du génome à l'échelle de l'Ontario des échantillons N501Y-/E484K– (qui représente le variant Delta ou le variant original de type sauvage) a démontré le remplacement du type sauvage par le variant Delta (la proportion est passée de 2,2 % début avril à 83 % fin mai) (16). • Un rapport britannique indique qu'au 14 juin 2021, la proportion de cas Delta était de 98,2 % de tous les cas séquencés et génotypés au Royaume-Uni (14). • De nouvelles données datant de la fin du mois de juin indiquent que les temps de doublement Delta ont atteint un plateau ou ont commencé à diminuer dans toute l'Angleterre (14). Delta a été introduit à plusieurs reprises et a augmenté rapidement via la transmission	14 études de surveillance et deux rapports. Faible niveau de preuve.

	communautaire d'avril à la mi-mai 2021. Le taux de croissance a été estimé à environ 37 % (IC à 95 % de 26 à 49) au-dessus d'Alpha et le temps de doublement estimé à 5 à 14 jours, mais pouvant atteindre 21 jours dans certaines communautés (5, 9, 39, 40). L'indice de reproduction de mai/juin 2021 était de 1,44 en Angleterre (9). • L'étude REACT-1 menée en Angleterre a permis de détecter le variant Delta pour la première fois (2 sur 115) dans la ronde 11 de l'étude (15 avril au 3 mai) (6). Depuis lors, on a assisté à un remplacement rapide du variant Alpha par le variant Delta (9). Au cours de la ronde 12 (entre le 20 mai et le 7 juin), la proportion d'échantillons positifs qui étaient Delta est passée d'environ 60 % à environ 90 %. • En Inde, les lignées du B.1.617 sont passées de 5 % en février 2021 à 10 % en mars et à 60 % en avril. Delta est passé de moins de 10 % à 80 % des cas de B.1.617 (7, 12, 19, 41) et l'analyse phylogénétique a montré la propagation du B.1.617 et l'émergence de sous-lignées (8). • Une étude effectuée au Texas (É. -U.) entre janvier et avril 2021 a montré que 7 sur 2 543 échantillons étaient associés au variant B.1.617 (sous-lignée non confirmée) (42). • Aux États-Unis, P.1 (Gamma) et Delta étaient les principaux variants remplaçant Alpha. Ils ont représenté au moins 16 % et 14 % des cas pour la semaine du 9 au 15 juin, respectivement. Le taux de croissance de Delta était plus rapide que celui de Gamma (k = 0,61 contre 0,22), en particulier dans les comtés où les taux de vaccination sont plus faibles (10). • Au Japon, la fréquence de Delta devrait prendre le relais d'Alpha vers le 12 juillet 2021 (IC à 95 % du 8 au 16 juillet 2021) et	

	avant le début officiel des Jeux olympiques de Tokyo le 23 juillet 2021(11). • Public Health England a signalé qu'un petit nombre de séquences Delta ont été détectées qui ont acquis la mutation K417N de la protéine du spicule (13, 14). Au 22 juin 2021, 161 génomes de ce variant, désigné comme B.1.617.2.1, Delta-AY.1 ou Delta+, ont été identifiés dans GISAID : Canada (1), Inde (8), Japon (15), Népal (3), Pologne (9), Portugal (22), Russie (1), Suisse (18), Turquie (1), États-Unis (83) et Angleterre (41).	

TL = taux de létalité, IC = intervalle de confiance, Ct = seuil du cycle, USI = unité des soins intensifs, RC = rapport de cotes, PCR = réaction en chaîne de la polymérase, EV = efficacité du vaccin, RCa = rapport de cotes ajusté, GISAID = Global Initiative on Sharing Avian Influenza Data (Initiative mondiale sur le partage des données sur l'influenza aviaire)

Méthodes :

Une analyse quotidienne de la littérature (publiée et prépubliée) est effectuée par le groupe des sciences émergentes de l'ASPC. L'analyse a permis de compiler la littérature sur la COVID-19 depuis le début de l'épidémie et est mise à jour quotidiennement. Les recherches visant à extraire les ouvrages pertinents sur la COVID-19 sont menées dans Pubmed, Scopus, BioRxiv, MedRxiv, ArXiv, SSRN et Research Square, et les résultats sont recoupés avec les ouvrages figurant sur la liste de la documentation sur la COVID de l'Organisation mondiale de la Santé et des centres d'information sur la COVID-19 gérés par Lancet, BMJ, Elsevier, Nature et Wiley. Le résumé quotidien et les résultats complets de l'analyse sont conservés dans une base de données Refworks et une liste Excel consultable. L'un des objectifs vise à déterminer si les études portent sur des variants préoccupants ou des variants d'intérêt. Les études correspondantes ont été présentées plus en détail dans notre base de données sur les VP et VI alors que les résultats associés aux VP ont été inclus dans le présent résumé. Une contre-vérification afin de trouver des articles pertinents a également été effectuée dans les bases de données en utilisant pour ce faire des recherches ciblées par mot clé (B.1.617 OU Delta).
Cette revue contient des recherches publiées jusqu'au 30 juin 2021.
Chaque référence potentiellement pertinente a été examinée pour confirmer qu'elle comportait des données pertinentes, qui ont été extraites dans la revue.

Revue

Le Bureau de la Conseillère scientifique en chef a facilité la revue de ce document, qui comprenait des suggestions d'un rédacteur scientifique, un examen par les pairs d'un expert en la matière et la contribution d'un conseiller principal en politiques ayant une perspective de la science à la politique.

Préparé par : Lisa Waddell, LNM et Kaitlin Young, CMIOAEZ, Groupe des sciences émergentes, ASPC.

Connaissances mobilisées par le Bureau de la Conseillère scientifique en chef : phac.ocsoevidence-bcscdonneesprobantes.aspc@canada.ca

Emerging Evidence on COVID-19

Living Summary of SARS-CoV-2 Variants of Concern: The Delta variant (B.1.617.2) profile

Highlights up to July 29, 2021

Introduction

SARS-CoV-2 **variants of concern** (VOCs) are circulating variants that have been flagged by national or global public health organizations. VOCs are of concern when compared to the original SARS-CoV-2 variants, as their complement of mutations lead to increased transmissibility, increased virulence (morbidity or mortality), changes in clinical disease presentation, immune evasion, reduced effectiveness of treatments, vaccines and/or public health measures and/or diagnostic detection failures (1-3). In May 2021 WHO released a naming system for VOCs and variants of interest (VOIs) using Greek letters to improve the ease of communication on variants and reduce potential stigma related to places where variants were first identified, which has been adopted in this report (4).

TABLE 1: CURRENT VARIANTS OF CONCERN (VOCs)*

WHO name (05-21)	Pango lineage	Nextstrain clade	GISAID clade	Alternate name	First detected in	Earliest samples	Characteristic spike mutations
Alpha	B.1.1.7	20I/501Y.V1	GR/501Y.V1	VOC 202012/01	United Kingdom	Sep 2020	69/70del, 144del, N501Y, A570D, D614G, P681H, T716I, S982A, D1118H

							del157/158, T478K, D950N)

* A VOC/VOI lexicon and other resources are available in the appendix.

The goal of this living summary on the SARS-CoV-2 VOC literature is to highlight new data on the VOC B.1.617.2 (Delta), its epidemiology and how the attributes of this variant may impact the management of the pandemic. This living evidence profile on Delta is part of a larger project that summarizes the data on each VOC as well as captures data on VOIs. The focus will be on changes to epidemiological parameters (e.g., transmission rates, clinical outcomes of severity and mortality, shifts in age groups affected or asymptomatic proportions), impacts on diagnostic tests, immune evasion/vaccine effectiveness and impacts on other public health measures. The full dataset in Excel can be accessed here and filtered by the VOCs and VOIs of interest. The recent living evidence review on other VOCs (Alpha, Beta, Gamma) can be requested here.

In this summary, "original variant" refers to any variant that was not designated as a VOC or VOI.

What's New in July 2021

- A UK report indicates that Delta accounted for approximately 99% of sequenced and 96% genotyped cases from 27 June to 10 July 2021 (5, 6).
- A study including data on VOCs in Canada reported that Delta accounted for 0.82% of the cumulative VOC cases sequenced in Canada up to June 15th, 2021 with the highest prevalence in Alberta and British Columbia (7). The overall proportion of Delta cases for the week of June 13th was 37% and Delta was at the point of overtaking Alpha (41%) (8). Since late June, Delta has been the dominant VOC in Canada (8).
- A global surveillance study showed increased transmissibility of Delta compared to the original variant, Alpha, Beta, and Gamma was 97% (95%CI: 76-117), 55% (43-68), 60% (48-73), and 34% (26-43), respectively (9).
- Three new modelling studies investigated the level of public health interventions, including vaccination, restrictive measures and masking, that are needed to prevent or reduce resurgence in the context of Delta variant in France, Germany, and Australia (10-12) and a fourth model cautions lifting restrictive public health measures and masking for fully vaccinated people in Europe (13).
- A study from China reported a shorter time interval between exposure and first PCR positive test in quarantined cases involved in an outbreak of Delta across the province of Guangdong (n=34) compared to cases caused by 19A/19B genetic strains during the early 2020 epidemic (n=29): 4 days (IQR 3-5) vs. 6 days (IQR 5-8) (14). This finding is based on a small sample size and lacks statistical significance; additional research is needed to confirm this finding.
- A retrospective cohort study from Canada reported higher risk of hospitalization 120% (95%CI 93-153%), ICU admission 287% (198-399%), and death 137% (50-230%) associated with Delta compared to non-VOCs (15).

- In Canada, protection against symptomatic Delta infection after two doses of BNT162b2 (Pfizer) (87%; 95% CI, 64–95%) was comparable to that of Alpha and a combined Beta and Gamma VE (analysed together due to low sample size) (16). After one dose, vaccine effectiveness (VE) against symptomatic infection with Delta tended to be lower compared to Alpha for BNT162b2 (Pfizer) (56% vs. 66%) and mRNA-1273 (Moderna) (72% vs. 83%) but similar for ChAdOx1 (AstraZeneca) (67% vs. 64%) (16). In India, ChAdOx1 (AstraZeneca) demonstrated 63.1% (95%CI 51.5-72.1) vaccine effectiveness against infection with the Delta variant, with 81.5% (95%CI: 9.9, 99.0) protection against moderate/severe infection (17).

Key Points

As of July 29, 2021 there were 87 studies and 7 grey literature reports (6 from UK and 1 from Canada) that report on the Delta variant of concern (45 of which have been added/updated since the last update of this summary on June 30, 2021) and were considered for inclusion. The included grey literature reports provide data on Delta not yet reported in the primary literature. In total, 67 studies/reports were summarized in this profile, including studies describing transmission efficiency (n=19), clinical severity (n=8), immune escape (n=32), testing and diagnostics (n=5), and spread epidemiology (n=24). Twenty-seven are not included in this summary as two were case reports/case series, three were an animal model, three were *in silico* studies, seven were deemed irrelevant (e.g., presented outdated models), and twelve did not specify the lineage studied (i.e., reported B.1.617). Individual study details of all studies for B.1.617 lineage (n=99) can be found in the Excel dataset accessed here.

Delta Spread

- Surveillance data from the UK and India on the introduction and growth rate of Delta from February to July 2021 indicate Delta now represents 91-99% of cases (5, 6, 18-24). Studies from the USA and Japan found that the Delta variant is replacing B.1.1.7 (Alpha) as the dominant variant (25, 26). As of June 15th, 2021, Delta accounted for 0.82% of the cumulative VOC cases sequenced in Canada (7). The overall proportion of Delta cases for the week of June 13th was 37% and Delta was at the point of overtaking Alpha (41%) (8). Since late June, Delta has been the dominant variant in Canada.
- Included within the Delta VOC classification by the World Health Organization are sub-lineages AY.1, AY.2 and AY.3 that have acquired additional mutations (3, 27). Many countries have reported a relatively small number of Delta sequences with the additional mutations of these sub-lineages (5, 6, 28, 29).

Transmissibility

- In Ontario, Canada, the N501Y-/E484K- mutation profile (which represents Delta or the original variant) went from having a 29% transmission deficit relative to Alpha on April 1st to having a 50% transmission advantage on June 12th. Whole genome sequencing of N501Y-/E484K-cases confirmed that this increase in transmissibility coincided with the replacement of the original variant with the Delta variant (30).

- Three studies from the UK, India, and Japan, as well as a global surveillance analysis, have shown that Delta has increased transmissibility over Alpha by 43-120% (9, 21, 26, 31).
- Four studies using Ct (cycle threshold) value as a proxy for viral load reported that Delta viral loads may be higher than Alpha and original variant (14, 21, 32, 33) while one found no significant difference between Delta and non-Delta infections among vaccinated healthcare workers (most of whom were fully vaccinated) (34).
- Public Health England estimated incubation period at median 4 days (28) and a study from China reported a shorter time interval between exposure and first PCR positive test in quarantined cases involved in an outbreak of Delta across the province of Guangdong compared to cases caused by the original variant during the early 2020 epidemic (4 days, IQR 3-5 vs. 6 days, IQR 5-8) (14).

Public Health Measures

- Four predictive models explored the impact of public health measures in India, France, Germany, and Australia to control the epidemic in the context of Delta. Higher risk of resurgence was shown when interventions such as masking and restrictive policies that limit contact rates were lifted prematurely or when vaccine rollout slowed down or did not speed up depending on the country (10-12, 35). The fifth model caution against allowing fully vaccinated people to stop adhering to public health measures in Europe (13).

Clinical Outcomes

- Four studies, including one from Canada, report a higher risk of severe outcomes such as hospitalization, ICU admission, and death associated with Delta compared to non-VOCs or Alpha (15, 28, 32, 36). Additional surveillance and research are needed to confirm these findings.

Immune Escape

- Immune escape from vaccination or previous *in vitro* neutralization data shows there may be a small to moderate reduction (1.2 – 6 fold) in neutralization of Delta compared to Alpha, Beta, Gamma and the original variants (17, 34, 37-42). Predictive models have estimated that Delta is able to evade approximately 16 to 55% of the immune protection provided by prior infection with non-Delta lineages (34, 35). An ongoing prospective cohort initiated June 2020 reported that reinfection rates in the UK are increasing and a national surveillance analysis found an increased risk of reinfection with Delta compared to Alpha (adjusted odds ratio 1.46, 95%CI 1.03-2.05) (6).
- Four studies on vaccine effectiveness report a reduction in protection against Delta infection (n=2) and symptomatic disease (n=2) compared to Alpha after the first dose, but comparable protection after the second (16, 17, 36, 43).

Overview of the Evidence

Study designs on VOC research range widely from observational studies with a high risk of bias to double blind randomized controlled trials (RCTs) with a lower risk of bias. One clinical trial was identified for this review on the Delta variant. There were observational studies, including analyses of surveillance data and case control studies that are considered low levels of evidence. Certainty in the evidence from these observational studies may be upgraded for a given outcome when multiple studies are in agreement and have prospective designs. There was only one prospective study in this review. Other studies identified were *in vitro* experiments that are considered a low to very low level of evidence. Generally these types of studies are used to generate hypotheses that are then tested with a more rigorous study design. For this review, study designs were identified, but no formal risk of bias assessment was conducted for each study. A summary indication of the level of confidence of the evidence was given for each category of study. The greatest amount of evidence was on transmissibility, the spread of Delta in some geographic areas, clinical outcomes of severity, and immune escape. In the current published evidence, there were gaps in knowledge on epidemiological parameters including infectious period, incubation period, impacts on the accuracy of diagnostic tests, and impacts on therapeutics.

Overall, the level of evidence on the Delta variant is low and there are knowledge gaps in the existing and evolving literature base. Thus additional studies are needed to improve confidence in the summary results, and to fill in current knowledge gaps regarding the Delta variant.

CONTENTS

DELTA

The excel dataset includes summaries of individual studies and can be accessed here. Below is the detailed evidence profile developed for Delta.

Categories of evidence in the table below include the following:

Transmissibility includes changes in transmissibility, secondary attack rates, serial interval (time interval between the onset of symptoms in the primary and secondary case), and estimates of selective advantage.

Clinical Severity includes proportion of infections that are symptomatic, proportion of severe disease and mortality as well as risk factors for severe disease or mortality, viral load (Ct value is often used as a proxy for viral load with lower Ct value indicative of higher viral load), infectious period, incubation period. Note risk factors for severe disease would include special populations, e.g., persons who are pregnant (when reported).

Immune Escape includes changes to vaccine efficacy/effectiveness, risk of re-infection in humans, animal models, *in vitro* or *in silico* experiments as well as impacts on therapeutics when reported.

Diagnostic / Detection Test Failure is captured in the table.

Other Epidemiology includes all studies that document the emergence and spread of VOCs in a geographic area, ecological studies that examine VOC spread and risk factors for hot spots, and studies on effective public health measures/interventions against VOCs, with genomic epidemiology as subcategories when reported.

Table 2: Evidence Profile of Delta VOC (n=67)

CATEGORY	KEY SUMMARY OUTCOMES	OVERVIEW OF THE EVIDENCE
Transmission Efficiency		
Transmissibility Compared to original variant and other VOCs	• A global surveillance study showed a 97% (95%CI: 76-117), 55% (43-68), 60% (48-73), and 34% (26-43) increase in the pooled mean effective reproduction number (transmissibility) for Delta compared to the original variant, Alpha, Beta, and Gamma, respectively (9). • In Ontario, Canada, the N501Y-/E484K- mutation profile (which represents Delta or the original wild-type variant) went from having a 29% transmission deficit relative to Alpha (relative Re = 0.71, 95%CI 0.64-0.77) on April 1st to having a 50% transmission advantage on June 12th (relative Re = 1.50, 95% CI: 1.31, 1.71). Whole genome sequencing of N501Y-/E484K-cases confirmed that this increase in transmissibility coincided with the replacement of wild-type with the Delta variant (30). • UK study estimates Delta was 43-115% more transmissible than Alpha across weekly time periods (April 3- May 22) (31). • Studies from India estimate that the transmissibility of Delta was 1.1-1.4 fold more transmissible than previously circulating lineages in Mumbai during Jan 2021 (34), 50% more transmissible than Alpha (21), and 60% more infectious than original variants (35). Another study also found significantly higher transmissibility for Delta compared to original variants and Kappa (Rt: 1.1 vs. ~1.0, p<0.001) (44). • Japan study estimates that Delta is 94.8% and Alpha is 43.7% more transmissible than the non-VOC variants.	7 surveillance data analysis and 2 predictive models, all preprints. Low level of evidence.

	This translates to a 1.4 times higher transmissibility for Delta compared to Alpha (26). • Based on a logistic growth model of three regions in France from May 31-Jun 21, 2021, Delta had a median transmission advantage over Alpha greater than 70% (10).	
Secondary Attack Rate Compared to B.1.1.7 (Alpha)	• 5.8% (95%CI 5.6% - 5.9%) for Delta vs. 5.6 (5.5% - 5.8%) for Alpha for non-travel related cases (6). • 11.0% (10.9%-11.1%) of non-travel related household contacts for Delta vs. 10.2% (10.1%-10.3%) (6). • Increased household transmission for Delta vs. Alpha was adjusted odds ratio (aOR 1.64 (95%CI 1.26-2.13, p<0.001) (45)	1 report summarizing surveillance data analysis from several studies (Mar 29- Jul 21). 1 national case-control study. Low level of evidence.
Serial Interval Compared to Original Variant	• A study from Singapore indicates the serial interval has not changed (Apr-May data) compared to pre-VOC serial intervals: Median 3 days (IQR 2-4) (46). •	1 surveillance data analysis. Low level of evidence.
***In vitro* studies of infectivity** Compared to Original Variant	• Increased transmissibility is thought to be at least partially due to a P618R mutation in the S protein that enhances the ability of furin to cleave the peptide (39, 47).	2 *in vitro* studies. Very low level of evidence.
Public health measures / interventions	• Model projections to examine the potential impact of Delta in India over the next 6 months demonstrate that as the country enters its monsoon season starting in June, infections could resurge if intervention measures are lifted prematurely (35). Projections indicate that accelerating the rollout of mass-vaccination (up to 4 times the current rate) could reduce the peak burden but likely would not prevent resurgence. Combining a delay of 4 weeks with a much faster vaccination rollout (e.g., 4x the current rate) and very high vaccination coverage could help to keep infection rates at levels similar to those observed during late May 2021. However, without a faster vaccination rollout, a delay of reopening by 8 weeks may be needed to keep infection rates from resurging. • Model projections from France find that the Delta variant has the potential to initiate an epidemic rebound by the	5 predictive models. Low level of evidence.

	end of the summer that can be amplified by a slowdown in vaccine rollout (60% fully vaccinated) and an increase in infectious contact rate in September (e.g. back to school) (10). • In Germany, models show that timely implementation of non-pharmaceutical interventions in combination with masks and testing would considerably reduce the chance of a further surge in infections (12). • In Australia, a high level of compliance with physical distancing (80%) is required to reduce new cases below 10 per day approximately a month after a peak in incidence peak (11). • A SIR (susceptible, infected, and recovered) model investigating Vaccine Passports (VP) in Europe found that while VP holders could initially allow more freedom, the incomplete protection afforded by vaccines against the highly transmissible Delta variant will likely lead to a resurgence in cases (13). The resurgence can be avoided in the short/long-term only when the restrictions are kept high for the rest of the population, and the reduction in restrictions for the VP holders is moderate or small.	
Clinical Severity		
Virulence / Severity or Duration of Disease Compared to B.1.1.7 (Alpha) or Original Variant	• Canada, analysis of over 200,000 COVID-19 cases showed the risk of hospitalization and ICU admission associated with Delta compared to non-VOCs increased by 120% (95%CI 93-153%) and 287% (198-399%), and compared to N501Y-positive VOCs (i.e., Alpha, Beta, and Gamma) increased by 55% (45-63%) and 101% (79-124%), respectively (15). • England, analysis indicates significantly increased risk of hospitalisation within 14 days of specimen date (HR 2.26, 95%CI 1.32-3.89, p<0.001), and emergency care attendance or hospitalisation within 14 days (HR 1.45, 95%CI 1.08-1.95, p<0.001), for Delta cases compared to Alpha cases after adjustment for confounders (age, sex, ethnicity, area of residence, index of multiple deprivation, week of diagnosis and vaccination status) (28). • Scotland, Delta cases were associated with an increased risk of COVID-19 hospital admission: hazard ratio (HR) 1.85 (95%CI 1.39–2.47) when compared to Alpha, after adjusting for age, sex, deprivation, temporal trend, and comorbidities reported (36).	4 surveillance data analyses, 1 retrospective cohort study. Low level of evidence.

	• Singapore, infection with Delta was associated with higher odds of disease severity that included cases who required supplemental oxygen, intensive care unit admission, or death (aOR 4.90, 95%CI 1.43-30.78) (32). The aOR for pneumonia was 1.88 times higher (95%CI 0.95-3.76) for those infected with Delta compared to infection from original variant although not significant (32). • A surveillance study conducted in Houston, Texas, reported no significant difference in admission rate, disease severity or hospital length of stay for Delta cases compared to all other COVID-19 patients diagnosed in the city health system (33).	
Severity Risk Factors Compared to Original Variant	• Preliminary analysis from the EAVE II study in Scotland suggested that Delta cases were younger and from higher sociodemographic groups than other cases, however it is unclear if these observations are based on analyses controlling for confounding factors including vaccination. Further research is needed to draw any conclusions (36).	1 surveillance data analysis. Very low level of evidence.
Mortality Compared to Original Variant	• Canada, analysis of over 200,000 COVID-19 cases showed the risk of death associated with Delta compared to non-VOCs increased 137% (95%CI 50-230%) and 59% (39-85%) higher than N501Y-positive VOC (15).	1 retrospective cohort study. Low level of evidence.
Mortality Risk Factors Compared to Original Variant	• No studies	
Viral Load Compared to B.1.1.7 (Alpha) or Original Variant	• India, viral load may be higher for Delta than for Alpha based on analysis of Ct values (a proxy for viral load), which were stable at baseline from Dec 2020 to Feb 2021, dropped in March when Alpha was dominant and fell further in April when B.1.617 took over (mainly Delta) (21). The change in Ct values (-6) corresponds to a 50-fold increase in viral load. A study of vaccinated healthcare workers at three Delhi hospitals that tested positive for SARS-CoV-2, the median Ct value of Delta infections was not significantly different than non-Delta infections (34). • Singapore, the Delta variant was associated with significantly lower Ct values and a longer duration of sustained low Ct values (≤30) (median duration of 18	3 surveillance data analyses and 2 outbreak investigation study using Ct values as a proxy for viral load. Low level of evidence.

	days) compared to non-VOC lineages of SARS-CoV-2 (13 days) (32). • Houston, TX, Delta cases had significantly lower PCR cycle threshold (Ct) values on initial diagnosis than other cases (~21 vs. 26) (33). • In a Chinese sample, the viral loads in the Delta infections (n=62) were ~1000 times higher than those in the earlier 19A/19B strain infections (n=63) when they first tested positive by PCR during quarantine (Ct 24 vs. 34) (14).	
Infectious Period	• No studies	
Incubation / Latent Period	• Public Health England reports the incubation period to be a median of 4 days for both household and non-household contacts and was the same as Alpha (28). • A study from China reported a shorter time interval between exposure and first PCR positive test in quarantined cases involved in an outbreak of Delta across the province of Guangdong (n=34) compared to cases caused by 19A/19B genetic strains during the early 2020 epidemic (n=29): 4 days (IQR 3-5) vs. 6 days (IQR 5-8) (14).	1 outbreak report and 1 surveillance data analysis Low level of evidence.
Immune Escape - Re-infection and Impact on Vaccine Efficacy		
Re-infection after Infection Compared to Original Variant	• The SIREN cohort study is reporting an increase in the rate of PCR positive cases from 0.1/1000 (April/May) to 5.4/1000 (June); reinfections have increased from 7 cases (April/May) to 44 cases (June/July) (6). • Preliminary analysis of surveillance data from the UK found an increased risk of reinfection with Delta compared to Alpha (adjusted odds ratio 1.46, 95%CI 1.03-2.05), particularly when the primary infection was ≥180 days earlier (aOR 2.37, 95%CI 1.43-3.93) (6). • Two predictive models estimate that Delta is able to evade approximately 16 to 55% of the immune protection provided by prior infection with non-Delta lineages (34, 35).	1 prospective cohort study and 2 predictive models. Low level of evidence.
Breakthrough Infection After Vaccination / Vaccine Efficacy or Effectiveness Compared to B.1.1.7 (Alpha),	Breakthrough Infections: • In a study from India conducted between Nov 2020 and May 2021, 19/27 vaccine breakthrough cases were Delta. This is higher than would be expected given the variants in circulation and consistent with a higher vaccination breakthrough risk of Delta compared to Alpha (21). Analysis of ChadOx1 vaccine (AstraZeneca) vaccine	5 surveillance data analyses, 1 outbreak investigation study, 1 randomized controlled trial, and 3 test negative case control studies.

B.1.617.1 (Kappa) or Original Variant	breakthrough infections in over 100 healthcare workers in India concluded that there was a higher risk of Delta breakthrough infections as compared to Alpha or B.1.617.1 (Kappa) (Odds Ratio: 5.14, 95%CI 1.32-20.0, p=0.018), after adjusting for age, sex, and hospital (34). • UK, sequenced cases detected after 1 or 2 doses of vaccination had higher odds of infection with Delta compared to unvaccinated cases (OR 1.33, 95%CI 1.17-1.53) (43). • In Houston, Texas, Delta variants caused a significantly higher rate of vaccine breakthrough cases (19.7% compared to 5.8% for all other variants) (33). Vaccine effectiveness one dose: • BNT162b2 (Pfizer): A Canadian study reported a 56% vaccine effectiveness (VE) against symptomatic disease caused by Delta (VE was higher against Alpha at 66%) (16), and a UK study reported a VE of 94% (95%CI 46-99) against hospitalisation after one dose (48). • mRNA-1273 (Moderna): A Canadian study reported a VE of 72% against symptomatic disease caused by Delta (VE was higher against Alpha at 83%) following one dose (16). • ChAdOx1 (AstraZeneca): A Canadian study reported a VE of 67% against symptomatic disease caused by Delta, similar to that of Alpha (64%) (16). An Indian study reported a VE of 46.2% (95%CI 31.6-57.7) against infection, and 79.2% (95%CI 46.1-94.0) in preventing moderate-severe COVID-19 (17), and a UK study reported a VE of 92% (95%CI 75-97) against hospitalisation after 1 dose (48). General Vaccination: In the UK, BNT162b2 (Pfizer) or ChAdOx1 (AstraZeneca) VE against symptomatic disease was ~30.7% (95%CI: 25.2 35.7%) effective, an 18% reduction compared to Alpha (43). Another study found that, after one dose there was a 14% absolute reduction in VE against symptomatic disease with Delta compared to Alpha (29). In Scotland, vaccination (>28d post first dose) was associated with a decreased risk of hospitalization for Delta cases HR= 0.38 (95% CI 0·24–0·58), but was slightly diminished compared to Alpha (36) and the hazard ratio among vaccinated Delta patients was HR 0.37 (95%CI 0.22-0.63) after one dose and HR 0.29 (95%CI 0.11-0.72) after two doses of any vaccine compared to unvaccinated (48).	Low level of evidence.

	Vaccine effectiveness two doses: • BNT162b2 (Pfizer): In Scotland, VE in preventing confirmed infection was 79% (95%CI: 75–82) (36). Canadian and UK studies found that protection against symptomatic Delta infection was ~88%, which was comparable to that of Alpha and Beta/Gamma (16, 43). Protection against hospitalization/death was higher (96%, 95%CI 86-99) (16, 48). • ChAdOx1 (AstraZeneca): Studies from the UK and India found that VE against infection, symptomatic disease, moderate/severe disease, and hospitalization was 63% (95%CI 51-72) (17)/ 60% (95%CI: 53–66) (36), 67% (95%CI 61-72) (43), 81.5% (95%CI 10-99)(17) and 92% (95%CI 75-97) (48), respectively. • BBV152 (Covaxin, Bharat Biotech): In India, VE against Delta infection was 65.2% (95% CI: 33·1–83·0) (49). This vaccine was effective in preventing severe disease and mortality caused by the Delta variant in completely vaccinated hospitalized patients in India (50). • General Vaccination: In the UK, VE following 2 doses of BNT162b2 (Pfizer) or ChAdOx1 (AstraZeneca) was 7.5-10% lower for Delta compared to Alpha (29, 43).	
***In vitro* studies Convalescent Sera** Compared to other VOCs or Original Variant	• Convalescent sera from cases had a reduced neutralization of 1.2-6.8 fold for Delta compared to other VOCs or the original variant across studies (17, 34, 37-41, 41, 42). However, T-cell responses have been shown to be preserved against the recombinant mutant receptor binding domain antigens suggesting cell-mediated immune protection (17).	8 *in vitro* studies. Very low level of evidence.
***In vitro* studies Vaccinated Sera** Compared to B.1.1.7 (Alpha) or Original Variant	• There was a 1.4-11.3-fold reduction of neutralization of the Delta variant by BNT162b2 (Pfizer) relative to the original variant (34, 40, 41, 41, 51-55) and 3-fold reduction relative to Alpha (37). • Studies evaluating ChAdOx-1 (AstraZeneca) report a 3-6-fold reduction of the Delta variant compared to original variant (34, 41, 41, 54, 56). • After two doses of ChAdOx-1 (AstraZeneca), neutralization against Delta was reduced by 2.5-fold (95%CI 1.4-2.7) relative to BNT162b2 (Pfizer) (57). • A single dose of BNT162b2 (Pfizer) or ChAdOx-1 (AstraZeneca) was either poorly or not at all efficient against Delta variant (37), while two doses of either	16 *in vitro* studies. Very low level of evidence.

	vaccine generated a sufficient neutralizing response in most individuals (37, 41). • A study evaluating BBV152 (Covaxin) reported a 2.7-fold reduction of Delta compared to the original variant (38). • A study evaluating Ad26.COV2.S (Janssen) reported a 1.6-fold reduction of Delta compared to the original variant (58). • A study evaluating mRNA-1273 (Moderna) reported a 2.1-fold reduction of Delta compared to the original variant (59). • A study evaluating ZF2001 vaccine reported a non-significant 1.2-fold reduction of Delta compared to the original variant (60). • Convalescent cases following the first dose of vaccine had significantly higher neutralizing antibody (Nab) titers compared to COVID-19 negative people post first dose, (56).	
***In vitro* studies Therapeutics** Compared to Original Variant	• Bamlanivimab lost antiviral activity against Delta, demonstrating that L452R is an escape mutation for this monoclonal antibody (mAb) (34, 37, 40, 61). • Etesivimab, Casirivimab and Imdevimab remained active against Delta (37). • A combination of Meplazumab and anti-CD147 antibody C effectively inhibited Delta pseudovirus *in vitro* (62). • Remdseivir and B12 compounds were effective at inhibiting replication of Delta *in vitro* (63). • mAbs being developed for clinical use, including those by AstraZeneca, Regeneron, Lilly, and Adagio, generally demonstrated potent neutralizing activity against Delta, with small (up to 5-fold) reductions in neutralization for some antibodies (41). The exception was LY-CoV555, which was severely reduced for Delta.	7 *in vitro* studies. Very low level of evidence.
Diagnostic / Detection Test Failure		
Testing and Detection Compared to Original Variant	• There has been no indication of test issues (i.e. changes in sensitivity/specificity) with Delta. However, one study identified 16 primer site mutations in B.1.617 lineage specimens that impact the primer sites which disrupt whole genome sequencing by two widely used laboratory protocols (3 affect the Freed et al. protocol and 13 affect the ARTIC version 3 protocol) (64).	4 diagnostic test accuracy studies and 1 report. Low level of evidence.

	• The P681R target primer was introduced to Public Health England's genotyping PCR test to detect B.1.617 which are mainly Delta (28). • One paper proposes PCR primers designed to identify the VOCs including Delta (65). • A deep learning model for genetic sequencing demonstrated test accuracy scores for Delta (B.1.617.2) of 75.75% (66). • A sensitive RT-qPCR assay for the direct detection of Delta in wastewater samples has also been proposed (67).	
Other Epidemiology		
VOC Emergence Over Time	• According to GISAID (accessed on 10/06/2021), a total of 31,997 sequences (Europe = 24,606, Asia = 4,974, North America = 2,210, Oceania = 163, Africa = 36, South America = 8) have been assigned to lineage B.1.617.2 (Delta) (54). • Ontario-wide genome sequencing of N501Y-/E484K- samples (which represents Delta or the original wild-type variant) demonstrated the replacement of wild-type with Delta variant (proportion increased from 2.2% in early April, to 83% in late May) (30). A study including data on VOCs in Canada reported that Delta accounted for 0.82% of the cumulative VOC cases sequenced in Canada up to June 15th, 2021 (7). The variant specific prevalence of Delta was highest in Alberta, British Columbia, Manitoba, Ontario and Saskatchewan at 73 per 1 million population and lowest in the eastern provinces at 2 per 1 million population (7). The overall proportion of Delta cases for the week of June 13th in Canada was 37% and Delta was at the point of overtaking Alpha (41%) (8). Since late June, Delta has been the dominant variant in Canada. • A UK report indicates that the Delta variant accounted for approximately 99% of sequenced and ~96% genotyped cases from 27 June to 10 July 2021 (5). New data from the end of June indicate that Delta doubling times have plateaued or started to decline across England (29). Delta was repeatedly introduced and rapidly increased via community transmission from April to mid-May 2021. The growth rate was estimated to be around 37% (95%CI 26-49) above Alpha and doubling	18 surveillance studies and six reports. Low level of evidence.

	time estimated to be 5-14 days but as long as 21 days in some communities (19, 23, 68, 69).The May/Jun 2021 reproduction number was 1.44 in England (23). • REACT-1 study in England detected Delta for the first time (2/115) in round 11 (Apr 15-May 3) (20). Since then, there was rapid replacement of the Alpha variant with the Delta variant (23). During round 12 (between May 20-Jun 7), the proportion of positive samples that were Delta rose from ~60% to ~90%. Within round 13 (Jun 24-Jul 5, 2021), prevalence amongst those reporting they were unvaccinated was over three-fold higher at 1.15% (95%CI: 0.92%, 1.43%) compared with those reporting two doses of vaccine at 0.35% (0.26%, 0.45%) (70). • In India, B.1.617 lineages increased from 5% in Feb 2021 to 10% in March and 60% in April. Delta rose from less than 10% to >80% of B.1.617 cases (21, 24, 34, 35, 71) and phylogenetic analysis showed the spread of B.1.617 and the emergence of sub-lineages (22). • USA, P.1 (Gamma) and Delta were the main variants replacing Alpha. They represented at least 16% and 14% of the cases for the week of June 9 to June 15, respectively. The growth rate of Delta was faster than Gamma (k = 0.61 vs. 0.22), particularly in counties with lower vaccination rates (25). Between March 15 to July 3, 2021, Delta variants increased to cause 58% of all COVID-19 cases and spread throughout the metropolitan Houston area (33). • In Japan, the frequency of Delta is expected to take over Alpha around July 12, 2021 (95%CI from July 8 to July 16, 2021) and before the Tokyo Olympic Games official start on July 23, 2021(26). • VOCs including Delta have been increasing in Australia. Out of 17,694 SARS-CoV-2 sequences in Australia from Jan 23, 2020 to May 23, 2021, 122 (0.7%) were Delta (72). • Public Health England reported that a small number of Delta sequences have been detected which have acquired the spike protein mutation K417N (5, 6, 28, 29). As of July 16, 2021, 873 genomes of this variant, designated as B.1.617.2.1, Delta-AY.1, or Delta+, have been identified in GISAID: US (n=592), Portugal (56), Japan (47), England (45), Switzerland (41), Poland (27), India (23), France (11), Nepal (11), Germany (3), Netherlands (2), Spain (2), Qatar (2), Australia (2), Mexico	

	(2), Canada (1), Kuwait (1), Ecuador (1), Romania (1), Russia (1), Denmark (1), and Czech Republic (1)(6).	

CFR = case fatality rate, CI = confidence interval, Ct = cycle threshold, ICU = intensive care unit, OR = odds ratio, PCR = polymerase chain reaction, VE = vaccine effectiveness, OR= odds ratio, aOR= adjusted odds ratio, GISAID = global initiative on sharing avian influenza data

Methods:

A daily scan of the literature (published and pre-published) is conducted by the Emerging Science Group, PHAC. The scan has compiled COVID-19 literature since the beginning of the outbreak and is updated daily. Searches to retrieve relevant COVID-19 literature are conducted in Pubmed, Scopus, BioRxiv, MedRxiv, ArXiv, SSRN, Research Square and cross-referenced with the COVID-19 information centers run by Lancet, BMJ, Elsevier, Nature and Wiley. The daily summary and full scan results are maintained in a Refworks database and an excel list that can be searched. One of the foci is to identify studies as variants of concern or under investigation. Studies identified under this foci were further characterized in our VOC/VOI database and Delta results were extracted into this review. A cross check for relevant articles was also conducted within the databases using targeted keyword searching (B.1.617 OR Delta).
This review contains research published up to July 29, 2021.
Each potentially relevant reference was examined to confirm it had relevant data and relevant data was extracted into the review.

Review
The Office of the Chief Science Officer facilitated the review of this document, which included suggestions from a scientific editor, peer-review by a subject matter expert, and input from a senior policy advisor with a science-to-policy perspective.

Prepared by: Kaitlin Young, CFEZID & Lisa Waddell, NML, Emerging Science Group, PHAC.

Emerging Evidence on COVID-19

Living Summary of SARS-CoV-2 Variants of Concern: The Gamma variant (P.1) profile

Highlights up to July 1, 2021

Introduction

SARS-CoV-2 **variants of concern** (VOCs) are circulating variants that have been flagged by national or global public health organizations. VOCs are of concern when compared to the original SARS-CoV-2 variants, as their complement of mutations lead to increased transmissibility, increased virulence (morbidity or mortality), changes in clinical disease presentation, immune evasion, reduced effectiveness of treatments, vaccines and/or public health measures and/or diagnostic detection failures (1-3). Canada has established a national definition (2). In May 2021 WHO released naming system for VOCs and variants of interest (VOIs) using Greek letters to improve the ease of communication on variants and potential stigma related to places where variants were first identified, which has been adopted in this report (1, 4).

TABLE 1: CURRENT VARIANTS OF CONCERN (VOCS)*

WHO name (05-21)	Pango lineage	Nextstrain clade	GISAID clade	Alternate name	First detected in	Earliest samples	Characteristic spike mutations
Alpha	B.1.1.7	20I/501Y.V1	GR/501Y.V1	VOC 202012/01	United Kingdom	Sep 2020	69/70del, 144del, N501Y, A570D, D614G, P681H, T716I, S982A, D1118H
Beta	B.1.351 B.1.351.2 B.1.351.3	20H/501Y.V2	GH/501Y.V2	VOC 202012/02	South Africa	May 2020	D80A, D215G, 241/243del, K417N, E484K, N501Y, D614G, A701V
Gamma	P.1, P.1.1 P.1.2	20J/501Y.V3	GR/501Y.V3	VOC 202101/02	Brazil and Japan	Nov 2020	L18F, T20N, P26S, D138Y, R190S, K417T, E484K, N501Y, D614G H655Y, T1027I, V1176F
Delta	B.1.617.2 AY.1 AY.2 AY.3	21A	G/478K.V1		India	Oct 2020	L452R, D614G, P681R, ± (E484Q, Q107H, T19R, del157/158, T478K, D950N)

* A VOC/VOI lexicon and other resources are available in the appendix.

The goal of this living summary on the SARS-CoV-2 VOC literature is to highlight new data on the VOC P.1 (Gamma), its epidemiology and how the attributes of this variant may impact the management of the

pandemic. This living evidence profile on Gamma is part of a larger project that summarizes the data on each VOC as well as captures data on VOIs. The focus will be on changes to epidemiological parameters (e.g., transmission rates, clinical outcomes of severity and mortality, shifts in age groups affected or asymptomatic proportions), impacts on diagnostic tests, immune evasion/vaccine effectiveness and impacts on other public health measures. The full dataset in Excel can be accessed here and filtered by the VOCs and VOIs of interest. The recent living evidence review on other VOCs (Alpha, Beta, Delta) and a high level contrasting table of VOC evidence can be requested here.

In this summary, "original variant" refers to any variant that was not designated as a VOC or VOI.

Key Points

As of July 1, 2021 there were 187 studies that report on the Gamma variant of concern. 39 studies were summarized in the profile, including studies describing transmission efficiency (n=9), clinical severity (n=16), immune escape (n=16), testing and diagnostics (n=5), and spread epidemiology (n=10).

148 studies were not summarized in the profile, including: case reports and case series (n=10); point prevalence or period prevalence estimates (n=25); studies reporting detection of Gamma or phylogenetic analysis only (n=9); studies reporting outcomes related to cell infectivity, binding affinity, or genomic characterization and no outcomes related to therapeutics (n=30); studies on therapeutics that are not commercialized, e.g., individual monoclonal antibodies (n=17); predictive models in which the time period for projections has already passed (n=4); *in vitro* studies with no relevant extractable outcomes and neutralization experiments on convalescent or vaccinated sera (n=35); diagnostic test accuracy studies evaluating a new test/method (not commercially available) to detect VOCs (n=15); vaccine breakthrough data with no control group to compare the VOC proportion of breakthrough cases vs. VOC proportion of all COVID-19 cases (n=3).

However, details for all 187 studies that report on Gamma can be found in the Excel dataset accessed here.

Transmissibility:

- Studies from several countries showed increased transmissibility for Gamma compared to the original variant, although the magnitude of increased transmissibility ranged widely (12%-160%). One Canadian study of household transmission reported Gamma had 62% increased transmissibility and 8% higher secondary attack rates compared to the original variant (5).

Clinical Severity:

- One European study reported a higher proportion of hospitalized cases for Gamma compared to the original variant (20% vs. 7.5%), and higher odds of Gamma cases being admitted to hospital or ICU (6). For severity indicators, this study also reported:
    - Higher odds of hospitalization in the 20-79 age group and admission to ICU in the 40-80 age group compared to the original variant.
    - A significantly lower proportion of pre-existing conditions among Gamma cases compared to the original variant (27.8% vs. 89%).
- There was conflicting evidence on mortality risk for Gamma compared to the original variant, with most studies indicating higher mortality risk for Gamma.

- Three studies using Ct values as a proxy for viral load reported that Gamma viral load was higher compared to the original variant. One study reported Gamma viral load was lower than Alpha (7).
- One study using data from France reported no significant difference in the infectious period for combined Gamma and Beta case data compared to original variant (95% CI of the HR: 0.79-1.06) (8).
- There were no studies on incubation period for Gamma.

Immune Escape:

- Two studies from Brazil suggest there may be substantial reinfections with Gamma, however this is based on ecological analyses and needs further study.
- One Canadian vaccine effectiveness (VE) study reported the BNT162b2 (Pfizer) and mRNA-1273 (Moderna) vaccines have reduced protection against symptomatic infection with Gamma compared to the original variant after the first (VE = 43% vs. 61%) and second dose (VE= 88% vs. 93%), although the confidence intervals overlap in both comparisons (9).

Testing and Diagnostics:

- No studies evaluating diagnostic tests for SARS-CoV-2 described failure or performance issues for detecting Gamma.
- One study found that mutations in Gamma disrupted genomic sequencing in the Freed *et al.* primer scheme (10).

Spread Epidemiology:

- Three studies from Brazil reported on the rapid spread of Gamma over time. Gamma first emerged in November 2020 and became the dominant lineage in Brazil by February 2021 (11).

Overview of the Evidence

Study designs on VOC research range widely from observational studies with a high risk of bias to double blind randomized controlled trials (RCTs) with a lower risk of bias. No clinical trials were identified for this review on the Gamma variant. There were observational studies, including surveillance data analyses, retrospective cohort studies, and case-control studies, which are considered low levels of evidence. Certainty in the evidence from these observational studies may be upgraded for a given outcome when multiple studies are in agreement and have prospective designs. Other studies identified in this profile were predictive models, ecological studies, animal models and *in vitro* studies, which are considered a low to very low level of evidence. Generally these types of studies are used to generate hypotheses that are then tested with a more rigorous study design. For this profile, study designs were identified, but no formal risk of bias assessment was conducted for each study. A summary indication of the level of confidence of the evidence was given for each category of study. The greatest amount of evidence was on transmissibility and the spread of Gamma over time. There were gaps in knowledge on epidemiological parameters including infectious period and incubation period, impact of public health measures, and vaccine effectiveness.

Overall, the level of evidence on the Gamma variant is low and there are several knowledge gaps. Thus additional research is needed to improve confidence in the summary results, and to fill in current knowledge gaps regarding the Gamma variant.

CONTENTS

GAMMA

The excel dataset includes summaries of individual studies and can be accessed here. Below is the detailed evidence profile developed for Gamma.
Categories of evidence in the tables below include the following:

Transmissibility includes changes in transmissibility, secondary attack rates, and estimates of selective advantage.

Clinical Severity includes proportion of infections that are symptomatic, proportion of severe disease and mortality as well as risk factors for severe disease or mortality, viral load, infectious period, incubation period. Note risk factors for severe disease would include special populations e.g., persons who are pregnant (when reported).

Immune Escape includes changes to vaccine efficacy, risk of re-infection in humans, animal models, *in vitro* or *in silico* experiments as well as impacts on therapeutics when reported.

Diagnostic / Detection Test Failure is captured in the table.

Other Epidemiology includes all studies that document the emergence and spread of VOCs in a geographic area, ecological studies that examine VOC spread and risk factors for hot spots, and studies on effective public health interventions against VOCs, with genomic epidemiology as subcategories when reported.

Table 2: Evidence Profile of Gamma VOC (n=187)

CATEGORY	KEY SUMMARY OUTCOMES	OVERVIEW OF THE EVIDENCE
Transmission Efficiency		
Transmissibility Compared to Original Variant	Increased transmissibility above the original variant: • Brazil: 2.6 (95%CI 2.4-2.8) (12) and 2.0 (50%CrI 1.7-2.4) times more transmissible than the original variant with median cross-immunity estimated at 68% (50%CrI 54-79) (13). • Italy: 1.12 (95%CI 1.03-1.23) times more transmissible assuming complete immune evasion to	Seven studies provided estimates of Gamma transmissibility including: 6 surveillance data analyses from Brazil (2) / France (2) / global (2), and 1 cross-sectional study from Italy.

	1.39 (95%CI 1.26-1.56) assuming complete cross protection (14). • Global: Combined Gamma and Beta case data showed a higher transmission advantage over the original variants ranging between 18-26% in Japan, France, Brazil, USA and Niger (8). • France: 27% higher transmissibility for combined Gamma and Beta (7). Between May-Jun 2021, the transmission advantage of combined Gamma, Beta, and Eta over Alpha was 17.2% (95% CI 15.6-18.9) in Ile-de-France, 16.1% (95% CI 4.63-28.5) in Hauts-de-France, and 9.12% (95% CI 7.34-10.9) in Normandie (15). • Other studies place Gamma transmissibility between that of the original variant and Alpha and show the transmissibility of Gamma has slightly decreased over time from Jan 2021 to Apr 2021 worldwide (16).	Across studies there is little consistency. Heterogeneity in increased transmissibility estimates may be due to factors such as geographic location and time points in which estimates were taken. Low level of evidence.
Secondary Attack Rate Compared to Original Variant	• In a Canadian study of household transmission, the secondary attack rate for Gamma index cases was 28.2%, which was higher than the rate for the original variant cases at 20.2%. This equated to Gamma index cases had higher odds of transmitting infection to household members, compared to wild-type cases (aOR 1.62, 95% CI 1.21-2.16) (5).	1 surveillance data analysis from Canada. Low level of evidence.
Public Health Measures/ Interventions Compared to Original Variant	• Gamma emerged in Manaus Brazil in late Nov 2020 and showed a high effective reproductive number (Re) of 2.6 (95% Highest Posterior Density [HPD]: 1.5-4.5) during Dec 2020. After increased social distancing restrictions, the Re was estimated to have decreased to 1.2 (95% HPD: 0.9-1.6) in late Dec 2020 and Jan 2021 In comparison, a previous variant also had a Re of 2.6 (HPD 1.6-3.8) in Mar 2020 that decreased to 1.0 (HPD 0.8-1.2) in Apr 2020 after social distancing increased by more than 50% in Manaus (due to implementation of non-pharmaceutical interventions) (17).	1 surveillance data analysis from Brazil. Low level of evidence.
Clinical Severity		
Virulence / Severity or Duration of Disease Compared to Original Variant	• Europe: A higher proportion of hospitalized Gamma cases were reported compared to the original variant (20% vs. 7.5% p<0.001) (6). o Higher adjusted odds ratio (aOR 2.6, 95%CI 1.4-4.8) of Gamma cases being admitted to hospital	2 surveillance data analyses from Europe and Brazil. Low level of evidence.

	or to ICU (aOR 2.2, 95%CI 1.8-2.9) compared to original variant (6). • Brazil: From Feb 2021-Mar 2021, hospitalized cases in one state exhibited exponential growth, with an average doubling time of 13.4 days and a daily growth rate of 5.3% (18). ○ Similar exponential growth (doubling time 13.3 days, daily growth rate 5.4%) for hospitalizations was reported in one city (18).	
Severity Risk Factors Compared to Original Variant	• Europe: In an age-stratified analysis, Gamma cases had 3.0-13.1 times higher odds of hospitalization in the age groups 20–39, 40–59 and 60–79 (6). • Odds of admission to ICU were 2.9–13.9 times higher in 40–59, 60–79 and ≥ 80 age groups (6). • Pre-existing conditions were lower in Gamma cases (27.8%) vs original variant (89%), p<0.001 (6). No whole genome sequencing: • Brazil: Among severe cases, people under 60 years old increased from 39% in the first wave (Nov-Dec 2020) to 47% in the second wave (Feb 2021) when Gamma was predominant (19). • Brazil: There was no increase in the proportion hospitalized in any age group before (Feb-Oct 2020) and after (Oct 2020-Feb 2021) Gamma emerged (20). • In Sao Paulo, Brazil, there was no significant difference in the mean age of infected hospitalized patients before and after Mar 2021 when Gamma became dominant (21).	2 surveillance data analyses from European countries and Brazil, 1 ecological study in Brazil, and 1 retrospective cohort study in Brazil. In three studies, whole genome sequencing was not conducted so the lineage was not determined. Low level of evidence.
Mortality Compared to Original Variant	• Brazil: the risk ratio of Gamma case fatality risk (CFR) vs. non-Gamma variant CFR is 1.54 (95% CI: 1.13-2.02), which indicates increased mortality risk for Gamma (11). • Brazil: A differentiated increase in COVID-19 mortality among adults aged 18-50 after Gamma emerged suggests the possibility of greater severity of Gamma in this population. Young adults had high hospital mortality rates >10% (20). • Predictive model estimated Gamma infections in Manaus Brazil are a median 1.5 (50%CrI 1.2–1.9) times more likely to result in mortality in the period following the emergence of Gamma in Nov 2020, compared to before (13). However, it cannot be	1 surveillance data analysis from European countries, and 2 ecological studies and 1 predictive model from Brazil. Low level of evidence.

	determined whether the estimated increase in relative mortality risk is due to Gamma infection, stresses on the Manaus healthcare system, or both. • Europe: Lower odds of mortality due to Gamma compared to original variant in multivariable analysis (aOR 0.6, 95%CI 0.3-1.0) (6). This result conflicts with the other three studies reporting a higher mortality risk for Gamma, which may be due to the fact that this analysis used data from European countries and is based on a few observations while the other studies were from Brazil, where Gamma first emerged and has had a large impact.	
Mortality Risk Factors Compared to Original Variant	• Brazil: mortality in COVID-19 cases <60 years old increased from 18% in Nov 2020 to 28% in Feb 2021 when Gamma was predominant (19). • The case fatality ratio increased the most in 20-59 year olds and among patients without pre-existing risk conditions. Among severe cases, the proportion of patients without pre-existing risk conditions was higher in Feb 2021 (33% vs. 25% in Nov 2020) (19). • Compared with Nov/Dec 2020, females 20-39 years old, with no pre-existing risk conditions, were at 5.65 (95%CI 2.9-11.03; p <0.0001) times higher risk of death in Feb 2021 and 40-59 year olds were at 7.7 (95%CI 5.01-11.83; p <0.0001) times higher risk of death (19).	1 surveillance data analysis from Brazil. Whole genome sequencing was not conducted so the lineage was not determined. Very low level of evidence.
Viral Load Compared to Original Variant	• France: Viral load (measured by Ct values) of Gamma samples was lower than Alpha samples and higher than original variant samples (7). Similarly, Ct values for combined Gamma and Beta were significantly lower compared to the original variant, Ct difference was 0.754 (p=0.0072), which indicates higher viral load for combined Gamma and Beta (8). • Brazil: Approximately 10-fold higher viral load in Gamma infections compared to non-Gamma infections (other variants circulating in Brazil up to Jan 2021). Regression analysis found Gamma infections were significantly higher than non-Gamma infections in adult (18-59 years) men (P=0.0005), adult women (P<0.0001), and elderly (>59 years) women (P=0.0149), but not significantly different in elderly men (P=0.4624) (17). No whole genome sequencing:	3 surveillance data analyses from France / Brazil / global, and 1 retrospective cohort study in Brazil. In one study, whole genome sequencing was not conducted so the lineage was not determined. Low level of evidence.

	• Brazil: There was no significant difference in mean Ct values among infected hospitalized patients and healthcare workers before and after Mar 2021 when Gamma became dominant (21).	
Infectious Period	• France: There was no indication that the infectious period (data in graphs only) was significantly different for combined Gamma and Beta compared to the original variant (95% CI of the HR: 0.79-1.06), measured by the duration of decline in viral load (8).	1 surveillance data analysis using data from France. Low level of evidence.
Incubation Period	No studies	
Immune Escape - Re-infection and Impact on Vaccine Efficacy		
Re-infection After Infection Compared to Original Variant	• 28% of the cases in Manaus Brazil from Nov 2020 to Jan 2021 were estimated to be re-infections considering 78% of the population was previously infected in an ecological analysis of syndromic surveillance data (12). • 16.9% of Gamma cases (95%CI 9.48-28.5) in Manaus from Jan 2021 to Mar 2021 were estimated to be re-infections in an analysis of blood donor data. If probable reinfections are also included, then 25.8% were reinfections (95%CI 16.7-37.4). If possible reinfections are also included, then 31.0% were reinfections (95%CI 21.4-42.5) (22).	2 surveillance data analyses from Brazil. Low level of evidence.
Breakthrough Infection After Vaccination / Vaccine Efficacy or Effectiveness Compared to Original Variant	• In Manaus Brazil where >75% of the cases were Gamma during the study period, vaccination with at least one CoronaVac (Sinopharm) dose was associated with a 0.50-fold reduction (adjusted VE 49.6%, 95% CI 11.3-71.4) in the odds of symptomatic SARS-CoV-2 infection during the period 14 days or more after receiving the first dose. Female sex (OR 0.50, 95% CI 0.38-0.81) and a positive SARS-CoV-2 RT-PCR or antigen test in the prestudy period (OR 0.38, 95% CI 0.17-0.87) were associated with a reduced odds of symptomatic SARS-CoV-2 infection (23). • In Sao Paulo state Brazil where >75% of the cases were Gamma during the study period, CoronaVac (Sinopharm) 14 or more days after the second dose among individuals ≥70 years old had an adjusted VE against symptomatic SARS-CoV-2 infection of 41.6% (95% CI 26.9-53.3), against hospitalization 59.0% (95% CI 44.2-69.8), and against deaths 71.4% (95% CI 53.7-82.3) (24).	3 case-control studies from Brazil (2) and Canada (1), and 1 surveillance data analysis from USA. Low level of evidence.

	• Canada: mRNA-1273 (Moderna) or BNT162b2 (Pfizer) vaccine >7 days after the second dose had an adjusted VE against symptomatic Gamma infection of 88% (95%CI 61-96) versus symptomatic original variant infection of 93%, (95%CI 87-96). Adjusted VE against symptomatic Gamma infection for one dose was 43% (95%CI 22-59) versus symptomatic wild-type infection (61%, 95% CI 53-67) (9). • In an underpowered study (n=20 breakthrough cases) from Washington State USA, Gamma was not over represented in breakthrough infections compared to its representation in COVID-19 cases during Feb-Apr 2021 (25).	
***In Vitro* Studies of Therapeutics** Compared to Original Variant	• Multiple therapeutics have been shown to have reduced effectiveness against Gamma, including Casirivimab (26-29), Bamlanivimab (28, 30), Etsevimab and Imdevimab (26). • The combination of Imdevimab and Casirivimab was shown to efficiently inhibit Gamma (28).	5 *in vitro* experiments have been identified with results specific to commercialized therapeutics against Gamma. *In vitro* studies are a low level of evidence that offer preliminary insights into what we may expect *in vivo*.
***In Vitro* Studies of Convalescent and Vaccinated Sera** Compared to Original Variant	• Most studies have shown that convalescent sera and fully vaccinated sera (BNT162b2 (Pfizer), CoronaVac (Sinopharm), mRNA-1273 (Moderna), Ad26.COV2.S (Janssen)) have reduced neutralizing activity for Gamma. *Note: Many in vitro studies have been identified, please see the Excel dataset for details on each study.*	31 *in vitro* experiments have been identified with results specific to Gamma neutralization. Very low level of evidence. The immune response is complex, and lack of or reduced neutralizing antibodies does not mean a lack of immune protection. Further research is needed (see the PHAC Emerging Science review on protective immunity.)
Testing and Diagnostics		
Testing and Detection	• No testing failures have been reported for Gamma PCR, antigen tests, or serological assays (31, 32).	4 diagnostic test accuracy studies and 1 surveillance data analysis that described

Compared to Original Variant	• Mutations in Gamma were shown to disrupt genomic sequencing of Gamma clinical specimens in the Freed *et al.* primer scheme, resulting in significantly reduced depth of coverage at three primer sites compared to non-Gamma specimens (p-values <0.00001) (10). • Studies report reliable sequencing methods for detection of Gamma from wastewater samples (33, 34). In Missouri USA, the daily wastewater load of Gamma (in genome copies/day) was significantly correlated with clinical case counts of Gamma during the same time period (R^2=0.89) (34).	a new method for analyzing sequencing data from wastewater. Low level of evidence.
Spread Epidemiology		
VOC Emergence Over Time	• The prevalence of Gamma grew from 0% in Nov 2020 to 73.8% in Amazonas, Brazil (17) and almost 30% in Amazonas, Columbia by Jan 2021 (35). • Brazil: The weekly prevalence of Gamma increased rapidly since Dec 2020 and reached more than 50% in Feb 2021 (11). • Brazil: The frequency of Gamma among asymptomatic and mild symptomatic cases at a university was 9.1% on Jan. 21, 2021, and increased to 42.9% two weeks later. By the start of Apr 2021, 100% of cases were Gamma, completely displacing P.2 and original variants (36). • Italy: The prevalence of Gamma remained relatively stable from Feb 2021 (5.0%, 95%CI 3.9-6.4) to Mar 2021 (4.8%, 95%CI 3.9-5.9) compared to Alpha, which grew from 53.1% (95%CI 50.3-55.9) to 85.7% (95%CI 84.1-87.3) (14). • USA: From Apr-Jun 2021, the main variants replacing Alpha were Delta and Gamma. Delta was shown to have a faster growth rate than Gamma (k=0.66 vs. 0.34) (37).	4 surveillance data analyses from Brazil (2) / Colombia (1) / USA (1), 1 cross-sectional study from Italy, and 1 ecological study from Brazil. Low level of evidence.
Predictions of Spread	Two scenarios were explored in a model of VOCs in North America based on data collected until the end of April 2021: • If vaccination does not affect the proportion of VOCs, the frequency of Gamma is predicted to be at just over 15% by Mar 2022. Meanwhile, Alpha would be dominant at more than 60%, Beta would be at just under 5%, and Delta would be at 20% (38).	3 predictive models from North America. Low level of evidence.

	• If 75% of the population in North America is fully vaccinated in Jul 2021, the frequency of Gamma is predicted to be at 5% by Mar 2022. Meanwhile, Alpha would be at 0%, and Beta and Delta would each be at 5%. The model assumes 100% vaccine efficacy (38). Two predictive models that do not take Delta into account: • Based on data from March 2021, an SIR (susceptible-infected-recovered) model was developed to evaluate the impact of a full return to pre-pandemic levels of contacts once 50% of the USA population is vaccinated in Jul 2021. Gamma was predicted to outcompete Alpha and Beta and become the dominant strain in 2-3 months The model assumes Gamma reduces the protection from vaccine or previous infection immunity by 32% (39). • In a simulation of May 2021-Aug 2021 where Gamma and Beta become established in the New York City population simultaneously, Gamma is predicted to outcompete Alpha and become co-dominant with Beta by Aug 2021. However, if Gamma becomes established in the population before Beta, Gamma would suppress Beta and become dominant. The model assumes Gamma has the same VE for symptomatic infection and hospitalizations as the original variant (40).	
Evolution of Variant	• The most recent common ancestor of Gamma emerged in mid-Aug 2020 in the state of Amazonas, Brazil. Gamma then emerged around late Nov 2020 (41). • Analysis of Gamma sequences in Brazil suggests that lineage-defining mutations of Gamma did not accumulate within one infected individual over a period of time, but were sequentially added during transmission between hosts (41).	1 surveillance data analysis from Brazil. Low level of evidence.

CFR = case fatality rate, CI = confidence interval, CrI = Credible Interval, Ct = cycle threshold, ICU = intensive care unit, OR = odds ratio, PCR = polymerase chain reaction, VE = vaccine effectiveness, OR= odds ratio, aOR= adjusted odds ratio

Methods:

A daily scan of the literature (published and pre-published) is conducted by the Emerging Science Group, PHAC. The scan has compiled COVID-19 literature since the beginning of the outbreak and is updated daily. Searches to retrieve relevant COVID-19 literature are conducted in Pubmed, Scopus, BioRxiv, MedRxiv, ArXiv, SSRN, Research Square and cross-referenced with the COVID-19 information centers run by Lancet, BMJ, Elsevier, Nature and Wiley. The daily summary and full scan results are maintained in a Refworks database and an excel list that can be searched. One of the foci is to identify studies as variants of concern or under investigation. Studies identified under this foci were further characterized in our VOC/VOI database and Gamma results were extracted into this review. A cross check for relevant articles was also conducted within the databases using targeted keyword searching (P.1 OR B.1.1.28 OR 501Y.V3 OR Gamma).
This review contains research published up to July 1, 2021.
Each potentially relevant reference was examined to confirm it had relevant data and relevant data was extracted into the review.

Review

The Office of the Chief Science Officer facilitated the review of this document, which included suggestions from a scientific editor, peer-review by a subject matter expert, and input from a senior policy advisor with a science-to-policy perspective.

Prepared by: Melanie Katz, NML, Emerging Science Group, PHAC.

Emerging Evidence on COVID-19

Living Summary of SARS-CoV-2 Variants of Interest: The C.37 (Lambda) Variant Profile

Highlights up to August 10, 2021

Introduction

SARS-CoV-2 **variants of concern** (VOCs) are circulating variants that have been flagged by national or global public health organizations. VOCs are of concern when compared to the original SARS-CoV-2 variants, as their complement of mutations lead to increased transmissibility, increased virulence (morbidity or mortality), changes in clinical disease presentation, immune evasion, reduced effectiveness of treatments, vaccines and/or public health measures and/or diagnostic detection failures (1-3). Canada has established a national VOC definition (2). **Variant of interest** (VOI), also referred to as variant under investigation (VUI), is a designation used to flag a variant that has the potential to be a VOC, but requires further investigation or evidence. Indicators for a VOI designation include; phenotypic change or acquisition of mutations with established phenotypic implication AND has been the cause of community transmission/clusters or is detected in multiple countries OR is assessed to be a VOI by an authority such as WHO (1, 2). Canada, has established a national VOI definition (2). In May 2021 WHO released a naming system for VOCs and VOIs using Greek letters to improve the ease of communication on variants and reduce potential stigma related to places where variants were first identified, which has been adopted in this report (4).

TABLE 1: CURRENT VARIANTS OF CONCERN (VOCS) AND VARIANTS OF INTEREST (VOIS)

WHO name (05-21) VOC	Pango lineage	Nextstrain clade	GISAID clade	Alternate name	First detected in	Earliest samples	Characteristic spike mutations

On June 14, 2021, the C.37 variant was assigned a global VOI by WHO and was given the label “Lambda” (14). Lambda was subsequently identified as a VOI in Canada on July 20, 2021 (2). The goal of this living summary on the SARS-CoV-2 VOC and VOI literature is to highlight the existing data on the VOI C.37 (Lambda), its epidemiology and how the attributes of this variant may impact the management of the pandemic. This living

evidence profile on Lambda is part of a larger project that summarizes the data on each VOC, captures data on VOIs and develops summaries for the VOIs as needed. The focus will be on changes to epidemiological parameters (e.g., transmission rates, clinical outcomes of severity and mortality, shifts in age groups affected or asymptomatic proportions), impacts on diagnostic tests, immune evasion/vaccine effectiveness and impacts on other public health measures. The full dataset in Excel can be accessed here and filtered by the VOCs and VOIs of interest. The recent living evidence review on VOCs (Alpha, Beta, Gamma, Delta) can be requested here.

In this summary, "original variant" refers to any variant that was not designated as a VOC or VOI.

Key Points

As of August 10, 2021 there were 9 studies that report on the Lambda VOI. No studies were excluded due to the limited evidence available on the Lambda variant. Individual study details of all studies for the C.37 lineage (n=9) can be found in the Excel dataset accessed here.

Currently in Canada, the larger provinces, British Columbia, Alberta, Ontario, and Quebec have reported cases of the Lambda variant (2).

Lambda Spread/ Epidemiology

- The earliest record of Lambda on the Global Initiative on Sharing Avian Influenza Data (GISAID) is from Argentina on November 8, 2020 (5, 6), however Bayesian tip-dating analysis estimates its emergence in July 2020 (January-October 2020) (6).
- Analysis of Lambda sequences revealed that it emerged in July 2020 and the earliest sequenced sample was from August 2020 in Peru and November 2020 in Argentina. Despite sequence analyses revealing emergence and sample sequencing as early as July 2020, Lambda was first officially reported in Lima, Peru in December 2020 and was present in 1/192 (0.5%) of genomes (5, 6, 14). It expanded to 20.5%, 36.4%, 79.2%, and 96.6% of genomes in January, February, March, and April 2021, respectively (5).
- Across South America the percentage of the Lambda sequence was increasing in Peru, Chile, and Argentina starting as early as November 2020 until June 2021, by which time the variant was also identified globally (5-10). By the end of June 2021, there were 1,908 Lambda sequences identified from 26 countries where sequencing could detect Lambda (6).

Lambda Mutations

- The spike protein of the consensus sequence of the Lambda variant bears six substitution mutations (G75V, T76I, L452Q, F490S, D614G and T859N) which are relatively highly (> 90%) conserved and a 7-amino-acid deletion in the N-Terminal Domain (NTD) (RSYLTPGD246-253N), which is also highly

conserved (15% do not harbour the mutation), the latter mutation is reported to be responsible for the infection spread in South America (6).

Transmissibility

- A pseudotyped virus (a virus consisting of a surrogate viral core that is surrounded by an envelope of surface glycoproteins of another virus of interest) carrying the Lambda spike was found to have significantly increased infectivity by up to 2-fold compared to Alpha, Gamma, and original variants (6, 8, 11). The T76I and L452Q mutations were found to be responsible for the higher infectivity of the Lambda variant, while insertion of the RSYLTPGD246-253N mutation was not found to affect viral infectivity (6).

Clinical severity and risk factors

- There have been no studies to date documenting its virulence, severity, duration of the disease or severity risk factors.

Immune Escape

- *In vitro* studies showed a reduction (1.5 – 6.1 fold) in neutralization of Lambda with convalescent and vaccinated sera compared to the original variants (6, 8, 11-13).
- Resistance of the Lambda variant to BNT162b2 (Pfizer) and mRNA-1273 (Moderna) vaccines was attributed to both the L452Q and F490S mutations. (6, 12). Further, the RSYLTPGD246-253N mutant exhibited a significant resistance to the vaccine-induced neutralization and the G75V, T76I, GT75-76VI and T852N mutations did not affect the vaccine-induced neutralization (6).
- Lambda had 3.6-fold increased resistance to neutralization by monoclonal antibody REGN10987 (Imdevimab) compared to the original variant (11), but Lambda was neutralized by REGN10933 (Casirivimab) alone and by a REGN10933 (Casirivimab) and REGN10987 (Imdevimab) cocktail with no significant decrease in neutralizing titers (11, 12).

Overview of the Evidence

Study designs on VOC/VOI research range widely from observational studies with a high risk of bias to double blind randomized controlled trials (RCTs) with a lower risk of bias. All studies included in the review of the Lambda variant were considered a very low level of evidence. While certainty in the evidence from observational studies may be upgraded for a given outcome when multiple studies are in agreement and have prospective designs, there were only two retrospective analyses of surveillance data available. Two case reports are also included (despite the fact that they are considered to be a very low level of evidence) due to the limited evidence currently available on the Lambda variant. Lastly, five *in vitro* experiments were identified. These experiments are generally used to generate hypotheses that are then tested with more rigorous study design. For this review, study designs were identified, but no formal risk of bias assessment was conducted for each study. A summary indication of the level of confidence of the evidence was given for each category of study. The greatest amount of evidence was available on infectivity, *in vitro* resistance to

vaccination, and VOI emergence over time. Given the currently very limited published evidence base, there are substantial gaps in knowledge for transmissibility, secondary attack rate, serial interval, public health measures/interventions, clinical severity parameters, and immune escape parameters re-infection after infection and breakthrough infection after vaccination/vaccine efficacy or effectiveness. Thus, additional studies are needed to improve confidence in the current summary results, and to fill in existing knowledge gaps regarding the Lambda variant.

CONTENTS

LAMBDA

The excel dataset includes summaries of individual studies and can be accessed here. Below is the detailed evidence profile developed for Lambda.

Categories of evidence in the table below include the following:

Transmissibility includes changes in transmissibility, secondary attack rates, serial interval (time interval between the onset of symptoms in the primary and secondary case), and estimates of selective advantage.

Clinical Severity includes proportion of infections that are symptomatic, proportion of severe disease and mortality as well as risk factors for severe disease or mortality, viral load (Ct value is often used as a proxy for viral load with lower Ct value indicative of higher viral load), infectious period, incubation period. Note risk factors for severe disease would include special populations, e.g., persons who are pregnant (when reported).

Immune Escape includes changes to vaccine efficacy/effectiveness, risk of re-infection in humans, animal models, *in vitro* or *in silico* experiments as well as impacts on therapeutics when reported.

Diagnostic / Detection Test Failure is captured in the table.

Other Epidemiology includes all studies that document the emergence and spread of VOCs in a geographic area, ecological studies that examine VOC spread and risk factors for hot spots, and studies on effective public health measures/interventions against VOCs, with genomic epidemiology as subcategories when reported.

Table 2: Evidence Profile of Lambda VOI (n=9)

CATEGORY	KEY SUMMARY OUTCOMES	OVERVIEW OF THE EVIDENCE
Transmission Efficiency		
Transmissibility	No studies	
Secondary Attack Rate	No studies	
Serial Interval	No studies	
***In vitro* studies of infectivity** Compared to VOCs and original variant	• A pseudotyped virus carrying the Lambda spike was found to have significantly increased infectivity compared to pseudotyped viruses carrying the D614G mutation, Alpha, and Gamma spikes(6, 8). • A pseudotyped virus carrying the Lambda spike had significantly increased infectivity by 2-fold compared to wild-type due to a L452Q mutation (11). • Lambda spikes had a 3-fold increase in soluble ACE2 binding compared to wild-type (11, 12). • T76I and L452Q mutations are responsible for the higher infectivity of Lambda, while insertion of the RSYLTPGD246-253N mutation was not found to affect viral infectivity (6).	4 *in vitro* studies. Very low level of evidence.
Public health measures / interventions	No studies	
Clinical Severity		
Virulence / Severity or Duration of Disease	No studies	
Severity Risk Factors	No studies	
Mortality	No studies	
Mortality Risk Factors	No studies	
Viral Load	No studies	

Infectious Period	No studies	
Incubation / Latent Period	No studies	
Immune Escape - Potential Impact on Vaccine Efficacy/Effectiveness, Possibility of Re-infection		
Re-infection after Infection	No studies	
Breakthrough Infection After Vaccination / Vaccine Efficacy or Effectiveness	No studies	
***In vitro* studies Convalescent Sera** Compared to original variant	• Lambda had 3.3-fold higher resistance to neutralization by convalescent sera compared to the wild-type (11). • Neutralizing titers from individuals infected prior to the emergence of Lambda were decreased 3.2-fold relative to D614G (12).	2 *in vitro* studies. Very low level of evidence.
***In vitro* studies Vaccinated Sera** Compared to Original Variant	• Lambda had 3.0-fold higher resistance to neutralization by sera from BNT162b2 (Pfizer)-vaccinated individuals compared to wild-type (P≤0.001) (11). Lambda was 1.5-fold, on average (2.63-fold at a maximum), more resistant to neutralization by BNT162b2-induced antisera than the parental D614G S antisera (6). Antibodies from fully vaccinated BNT162b2 (Pfizer) sera cross-reacted on Lambda with a 3.2 fold decreased titer compared to D614G (12). At 90-days post injection with BNT162b2 (Pfizer), the neutralizing titer against Lambda was decreased 4.2-fold (12). • Lambda had 2.3-fold higher resistance to neutralization by sera from mRNA-1273 (Moderna)-vaccinated individuals compared to wild-type (P≤0.05) (11). Antibodies from sera collected 7-days post second injection with mRNA-1273 (Moderna) cross-reacted on Lambda with a 2.6 fold decrease in titer. At 80-days post injection, the neutralizing titer against Lambda was decreased 3.6-fold (12). • Resistance of the Lambda variant to BNT162b2 (Pfizer) and mRNA-1273 (Moderna) vaccines was attributed to both the L452Q and F490S mutations (6, 12). Further, the RSYLTPGD246-253N (7-amino-acid deletion in the NTD) mutant exhibited a significant resistance to the BNT162b2 (Pfizer) vaccine-induced neutralization) and	5 *in vitro* studies. Very low level of evidence.

	the G75V, T76I, GT75-76VI and T852N mutations did not affect the BNT162b2 (Pfizer) vaccine-induced neutralization (6). • At 82 days post injection with Ad26.COV2.S (Janssen), compared to D614G, the neutralizing titer against Lambda was decreased 6.1-fold (12). • A study evaluating plasma samples from CoronaVac-vaccinated individuals showed that the ID50 neutralization titer decreased by a factor of 3.05 (95% CI: 2.57 – 3.61) for Lambda compared to the wild-type (8). • The geometric mean titer (GMT) of neutralization of Lambda was reduced by 4.6 fold compared to WA1 by sera from mRNA-vaccinated participants (13).	
***In vitro* studies Therapeutics** Compared to Original Variant	• Lambda had 3.6-fold increased resistance to neutralization by monoclonal antibody REGN10987 (Imdevimab) compared to wild-type (11). • Lambda was neutralized by REGN10933 (Casirivimab) with no decrease in neutralizing titers compared to wild-type (11). • Lambda was neutralized by a Regeneron monoclonal antibody therapeutic consisting of both REGN10933 and REGN10987 with no significant decrease in neutralizing titers compared to wild-type (11, 12).	2 *in vitro* studies. Very low level of evidence.
Diagnostic / Detection Test Failure		
Testing and Detection	No studies	
Other Epidemiology		
VOC Emergence Over Time	• Analysis of Lambda sequences revealed that it emerged on July 12, 2020 and the earliest sequenced sample was from August 2020 in Peru and then Argentina November 2020 (5, 6, 14). The percentage of the Lambda sequence was increasing in South American countries including Peru, Chile, and Argentina from November 2020 until June 2021. By the end of June 2021 there were 1,908 Lambda sequences identified from more than 26 countries including Chile, USA, Peru, Argentina, Germany, Mexico, Spain, and Ecuador (5, 6, 14). The RSYLTPGD246-253N (7-amino-acid deletion in the NTD) mutant of the Lambda variant is shown to have emerged and quickly became the dominant version at the beginning of 2021 while Lambda cases were rapidly increasing (6).	2 surveillance studies, 2 *in vitro* studies and 2 case reports. Very low level of evidence.

	○ Lambda was first officially reported in Lima, Peru in December 2020 and was present in 1/192 (0.5%) of genomes. It expanded to 20.5%, 36.4%, 79.2%, and 96.6% of genomes in January, February, March, and April 2021, respectively (5). ○ Lambda has expanded rapidly in Chile and Argentina, reaching 33% and 12% of all sequenced genomes on GISAID by April 2021, respectively (5). • Molecular surveillance from Argentina revealed that the Lambda variant showed a continuous increase since epidemiological week 20 of 2021 (EW 20/2021) in the city of Buenos Aires (CABA) and Great Buenos Aires (GBA), reaching frequencies of 48.4% (95% CI = 36.6-60.4) in the EW 20/2021. The proportion of cases associated with Alpha, Gamma, and Lambda among individuals with no travel history or contact with travelers in CABA and GBA surpassed 98% of the total samples in EW 20/2021. Between EW 9/2021 and EW 20/2021, north GBA presented 9/39 cases of Lambda (23.1%), west GBA presented Lambda in 58/176 cases (33.0%), CABA presented Lambda in 150/508 cases (29.5%), south GBA presented a predominance of Lambda (127/253 cases, 50.2%) (7). • In Chile, up to June 24, 2021 there was a dominance of Gamma and Lambda variants, together accounting for 79% of 3695 sequences analyzed (8). • A surveillance study reported two cases of possible coinfection between Alpha and Lambda in the city of Buenos Aires (CABA) and these cases will be further analyzed (7). • The spread of the Lambda variant to Brazil and Italy are documented in case reports. One described the first case of the Lambda variant in southern Brazil, who had travelled to Argentina (9). The second described a 53-year old female Peruvian immigrant who entered Italy on June 2, 2021 after an indirect flight Lima-Madrid-Milan, who initially tested negative leaving Peru on June 1, but tested positive on follow-up in Italy on June 11. She was confirmed to be infected with the Lambda variant (10). • The S protein of the consensus sequence of the Lambda variant bears six substitution mutations (G75V, T76I, L452Q, F490S, D614G and T859N) which are relatively highly (> 90%) conserved and a 7-amino-acid deletion in	

	the NTD (RSYLTPGD246-253N), which is also highly conserved (15% do not harbour the mutation). The data suggest that there are at least two virological features on the Lambda variant: increasing viral infectivity (by the T76I and L452Q mutations) and exhibiting resistance to antiviral immunity (by the RSYLTPGD246-253N, L452Q and F490S mutations) (6).	

CFR = case fatality rate, CI = confidence interval, Ct = cycle threshold, ICU = intensive care unit, OR = odds ratio, PCR = polymerase chain reaction, VE = vaccine effectiveness, OR= odds ratio, aOR= adjusted odds ratio, GISAID = global initiative on sharing avian influenza data

Methods:

A daily scan of the literature (published and pre-published) is conducted by the Emerging Science Group, PHAC. The scan has compiled COVID-19 literature since the beginning of the outbreak and is updated daily. Searches to retrieve relevant COVID-19 literature are conducted in Pubmed, Scopus, BioRxiv, MedRxiv, ArXiv, SSRN, Research Square and cross-referenced with the COVID-19 information centers run by Lancet, BMJ, Elsevier, Nature and Wiley. The daily summary and full scan results are maintained in a Refworks database and an Excel list that can be searched. One of the foci is to identify studies as variants of concern or under investigation. Studies identified under this foci were further characterized in our VOC/VOI database and Lambda results were extracted into this review. A cross check for relevant articles was also conducted within the databases using targeted keyword searching (C.37 OR Lambda).
This review contains research published up to July 29, 2021.
Each potentially relevant reference was examined to confirm it had relevant data and relevant data was extracted into the review.

Review
The Office of the Chief Science Officer facilitated the review of this document, which included suggestions from a scientific editor, peer-review by a subject matter expert, and input from a senior policy advisor with a science-to-policy perspective.

Prepared by: Alexandra Romanski, CFEZID & Lisa Waddell, NML, Emerging Science Group, PHAC.

Research and analysis reports on Investigation of SARS-CoV-2 variants of concern technical briefings. 2020 Dec to present	Technical reports compile information from various studies and surveillance across the UK on the VOC and VOIs that are circulating. There is a lot of overlap from these reports and research publications.

VOC Comparison Table of Alpha, Beta, Gamma, and Delta

Context

SARS-CoV-2 **variants of concern** (VOCs) are circulating variants that have been flagged by national or global public health organizations. VOCs are of concern when compared to the original SARS-CoV-2 variants, as their complement of mutations lead to increased transmissibility, increased virulence (morbidity or mortality), changes in clinical disease presentation, immune evasion, reduced effectiveness of treatments, vaccines and/or public health measures and/or diagnostic detection failures (1-3). Canada has established a national definition (2). This summary table highlights the key data from individual VOC risk profiles (available upon request) on B.1.1.7 (Alpha), B.1.351 (Beta), P.1 (Gamma) and B.1.617.2 (Delta).

Overview of the Risk Profiles

A total of 543 Alpha, 341 Beta, 187 Gamma and 94 Delta studies were identified and the full dataset can be accessed here. Data were summarized on 293 Alpha, 65 Beta, 39 Gamma up to July 1 and 67 Delta up to July 29, 2021 studies on the following key categories of evidence and were compared to the original variants (non-VOC variants) in circulation at the time of the study unless otherwise stated:

Transmissibility includes changes in transmissibility, secondary attack rates, and estimates of selective advantage.

Clinical Severity includes proportion of infections that are symptomatic, proportion of severe disease and mortality as well as risk factors for severe disease or mortality, viral load, infectious period, incubation period. Note risk factors for severe disease would include special populations e.g., persons who are pregnant if they are reported.

Immune Escape includes changes to vaccine efficacy, risk of re-infection in humans, animal models, *in vitro* or *in silico* experiments as well as impacts on therapeutics if reported.

Other Epidemiology includes all studies that document the emergence and spread of VOCs in a geographic area, ecological studies that examine VOC spread and risk factors for hot spots, and studies on effective public health interventions against VOCs, genomic epidemiology as subcategories.

Studies not summarized in the evidence profiles include case reports or case series, point prevalence estimates, animal studies, zoonotic investigations, predictive models in which the time period has already passed, cell infectivity, binding affinity, or genomic characterization studies, and most *in vitro* studies looking at neutralization by convalescent and/or vaccinated sera, and therapeutic products. An excel dataset with summaries of all the studies on the Alpha, Beta, Gamma, Delta VOCs as well as all variants of interest can be accessed here. Overall, the level of evidence was low to moderate.

TABLE 1: SUMMARY OF KEY EVIDENCE FROM THE ALPHA (N=543), BETA (N=341), GAMMA (N=187) AND DELTA (N=94) RISK PROFILES.

CATEGORY	P.1 (GAMMA) UPDATED JUL 1, 2021	B.1.351 (Beta) UPDATED JUL 1, 2021	B.1.1.7 (ALPHA) UPDATED JUL 1, 2021	B.1.617.2 (DELTA) UPDATED JUL 29, 2021
TRANSMISSION EFFICACY				
Transmissibility Compared to Original Variant unless otherwise stated	6 surveillance data analyses and 1 cross-sectional study: • Increased transmission ranging from 12%-160% has been reported in countries from South America, North America, Europe and Africa. • One Canadian study of household transmission reported Gamma had 62% increased transmissibility and 8% higher secondary attack rates. Low level of evidence.	6 surveillance studies and 1 predictive model: • Studies from multiple countries report an increased transmissibility of 20% to 175%. • One Canadian study of household transmission reported Beta has 58% increased transmissibility and a 31% higher secondary attack rate. Low level of evidence.	54 surveillance and observational studies: • 91% of studies reported increased relative transmissibility of Alpha (1-$R_{voc}/R_{original\ variant}$) ranging between 34-118% higher across studies from North America, Europe, Middle East, and Asia. • Canadian studies (n=3) reported higher transmissibility of 34%-63% and a 20%-31% higher secondary attack rate for Alpha. • Other secondary attack rates among household transmission studies were 30-88% higher in Norway, Denmark, Germany, Israel, and UK. Low to moderate level of evidence.	13 surveillance and observational studies: • Delta's estimated higher transmissibility over Alpha ranges from 43-120% in North America, Europe and Asia. • A global study estimated higher transmissibility of 97% (95%CI: 76-117), 55% (43-68), 60% (48-73), and 34% (26-43) compared to original variant, Alpha, Beta, and Gamma, respectively. • Recently revised surveillance data from the UK reported 3.5-8% higher secondary attack rates for Delta vs. Alpha, however a UK case control study estimated this to be 64%. Low level of evidence.
CLINICAL SEVERITY				
Virulence / Severity or Duration of Disease	2 surveillance data analyses: • In Europe, a higher proportion of cases were	2 surveillance studies and 2 observational studies: • Studies from several European countries	25 surveillance and observational studies: • Conflicting evidence on whether there are fewer	5 surveillance and observational studies: • Three studies reported a higher risk of

CATEGORY	P.1 (GAMMA) UPDATED JUL 1, 2021	B.1.351 (Beta) UPDATED JUL 1, 2021	B.1.1.7 (ALPHA) UPDATED JUL 1, 2021	B.1.617.2 (DELTA) UPDATED JUL 29, 2021
Compared to Original Variant unless otherwise stated	hospitalized vs. original variant (20% vs. 7.5%: aOR 2.6, 95%CI 1.4-4.8). • In Europe, higher odds of being admitted to ICU (aOR 2.2, 95%CI 1.8-2.9). • Exponential growth of hospitalized cases was reported in Brazil during predominance of Gamma. Low level of evidence.	reported higher odds of hospitalization for Beta compared to the original variant (OR=3.6) and Alpha (OR= 1.6). • Conflicting evidence for ICU admissions due to Beta has been reported across different settings, including increased odds (OR=3.3) across several European countries, and a lower risk in South Africa and no association in France. Low level of evidence.	symptomatic cases among Alpha infections. • Six studies found higher odds of hospitalization (OR 1.25–2.25) and one reported no difference. • Four studies found higher odds of ICU admission (OR 2.15-3.31) and one study reported no difference. • Two studies reported Alpha cases had higher rates of hypoxia on admission to hospital. • Longer symptom duration (≥7 days), fewer loss of smell and taste symptoms, and more sore throat symptoms occurred in Alpha cases in two studies. Moderate level of evidence.	hospitalization; OR= 2.2 Canada compared to original variant and OR=1.5, aHR= 1.45-2.26 England, HR= 1.85 Scotland compared to Alpha, while no difference was reported in Houston, Texas. • Two studies reported a higher risk of ICU admission; OR= 3.9 Canada and aOR 4.9 Singapore compared to original variant and OR=2.01 Canada compared to Alpha. Low level of evidence.
Severity Risk Factors Compared to Original Variant unless otherwise stated	1 surveillance data analysis from Europe: • Odds of hospitalization in 20-79 age groups were 3.0 - 13.1 times higher.	1 surveillance study and 2 observational studies: • Odds of hospitalization among adults aged 40-79 were 3.5-3.6 times higher in several European countries and hospitalized Beta cases in	13 observational studies: • Indicators of changes in severity with the Alpha variant were not consistent, some reported age-stratified risk of hospitalization and increased odds in adult age groups between 20-59 years old, while	1 surveillance study: • Analysis suggested there may be higher risk of severe outcomes in some younger age groups. More data is needed.

CATEGORY	P.1 (GAMMA) UPDATED JUL 1, 2021	B.1.351 (Beta) UPDATED JUL 1, 2021	B.1.1.7 (ALPHA) UPDATED JUL 1, 2021	B.1.617.2 (DELTA) UPDATED JUL 29, 2021
	• Odds of ICU admission for ≥40 year olds was 2.9–13.9 times higher. • Pre-existing conditions were lower in Gamma cases vs. original variant cases (27.8% vs 89%, p<0.001). Low level of evidence.	South Africa were significantly older (57 vs. 54 years, p=0.03). • Odds of ICU admission for adults aged 40-59 years were 8 times higher in several European countries, but not different in a study from France. • Beta cases were less likely to have comorbidities in studies from Europe and South Africa. Low level of evidence.	others reported no associations. Higher risk in males and those with comorbidities were also reported. • ICU admission due to Alpha was associated with being male, higher age, and comorbidities in two studies. Low to moderate level of evidence.	Very low level of evidence.
Mortality Compared to Original Variant unless otherwise stated	1 surveillance data analysis, 1 ecological study, and 1 predictive model: • There was conflicting evidence on mortality risk for Gamma in studies from Brazil indicating a higher mortality risk (RR = 1.5) and a study from Europe reporting a borderline lower risk (RR=0.6).	1 surveillance study and 2 observational studies: • Beta cases were not associated with a change in mortality in one surveillance study in European countries. • Two retrospective cohort studies from South Africa and France reported increased ICU mortality among Beta cases	19 surveillance and observational studies: • Associations with mortality were conflicting across studies (11 indicated increased mortality, 7 found no change, 2 lower mortality) for Alpha infections.	1 retrospective cohort: • In this Canadian study Delta mortality risk was increased by 137% over the original variants and 59% over other VOCs.

CATEGORY	P.1 (GAMMA) UPDATED JUL 1, 2021	B.1.351 (Beta) UPDATED JUL 1, 2021	B.1.1.7 (ALPHA) UPDATED JUL 1, 2021	B.1.617.2 (DELTA) UPDATED JUL 29, 2021
	Low level of evidence.	compared to original variant and Alpha cases. Low level of evidence.	Moderate level of evidence.	Low level of evidence.
Mortality Risk Factors Compared to Original Variant unless otherwise stated	1 surveillance data analysis: • Brazil data not confirmed by whole genome sequencing, reported an increase in mortality for cases<60 years (from 18% to 28%) and higher risk of mortality among women aged 20-59 with no pre-existing conditions (RR 5.6-7.7). Very low level of evidence.	No studies. No evidence.	2 surveillance data analyses and 1 retrospective cohort study: There was no agreement across studies on whether any risk factors were associated with Alpha mortality risk including age, and sex, and ethnicity, but one study did report that Alpha infections with comorbidities were higher risk. Low level of evidence.	No studies. No evidence.
Viral Load Compared to Original Variant unless otherwise stated Ct (cycle threshold) value was used as a	3 surveillance data analyses: • Viral load from Gamma cases were lower than Alpha but higher than the original variant. • Viral load from Gamma cases was ~10-fold	2 surveillance studies and 1 cross sectional study: • Studies from France report a higher viral load of Beta compared to the original variant, but is lower compared to Alpha.	28 observational studies and surveillance analyses: • With the exception of one study, most reported lower Ct values or higher estimated viral loads. The median order of magnitude higher varies across studies and target	5 surveillance and observational studies: • Four studies reported that Delta viral loads may be higher than Alpha and the original variant. • One study reported no significant difference in viral loads for Delta

CATEGORY	P.1 (GAMMA) UPDATED JUL 1, 2021	B.1.351 (Beta) UPDATED JUL 1, 2021	B.1.1.7 (ALPHA) UPDATED JUL 1, 2021	B.1.617.2 (DELTA) UPDATED JUL 29, 2021
proxy for viral load (where lower Ct values indicate higher viral load).	higher than original variants in Brazil. Low level of evidence.	 Low level of evidence.	protein from 2 to 10 fold differences. Low to moderate level of evidence.	compared to non-Delta infections among vaccinated healthcare workers (most of whom were fully vaccinated). Low level of evidence.
Infectious Period Compared to Original Variant unless otherwise stated	1 surveillance study from European countries: • No significant difference in infectious period for combined Gamma and Beta data vs. original variant (95% CI of the HR: 0.79-1.06), measured by the duration of decline in viral load. Low level of evidence.	1 surveillance study from European countries: • No significant difference in infectious period for combined Gamma and Beta data vs. original variant (95% CI of the HR: 0.79-1.06), measured by the duration of decline in viral load. Low level of evidence.	1 prospective study , 1 longitudinal study and 1 surveillance analysis: • Alpha was reported to have a longer infectious period in all studies, although the magnitude of the increase was highly variable across studies ranging from 0.86 days to 5.1 days. Low level of evidence.	No studies. No evidence.
Incubation Period Compared to Original Variant unless otherwise stated	No studies.	No studies.	1 retrospective cohort and 1 surveillance report: • Mean incubation period was 3.53 vs. 5.71 for original variant in a small study (n=60). • Public Health England also estimated incubation period at median 4 days.	1 contact tracing study and 1 surveillance report: • Small study from China reported a shorter time interval between exposure and first PCR positive test in quarantined cases was reported for Delta (4 days,

CATEGORY	P.1 (GAMMA) UPDATED JUL 1, 2021	B.1.351 (Beta) UPDATED JUL 1, 2021	B.1.1.7 (ALPHA) UPDATED JUL 1, 2021	B.1.617.2 (DELTA) UPDATED JUL 29, 2021
				IQR 3-5) compared to cases from the early 2020 epidemic (6 days, IQR 5-8). • Public Health England also estimated incubation period at median 4 days. Very low level of evidence.
	No evidence.	No evidence.	Very low level of evidence.	
IMMUNE ESCAPE – Re-infection and Impact on Vaccine Efficacy				
Re-infection after Infection Compared to Original Variant unless otherwise stated	2 surveillance data analyses: • Two studies from Brazil suggest there may be substantial reinfections with Gamma, however this is based on ecological analyses and needs further study. Very low level of evidence.	• Only case reports have been reported and are not summarized. Very low level of evidence.	3 surveillance, cohort and ecological studies: • There is no change in the re-infection rate (0.7-0.9%) with Alpha based on data from the UK and USA. Low-moderate level of evidence.	1 prospective cohort study and 2 predictive models: • In the UK there have been more reinfections with Delta (aOR 1.46) compared to Alpha • Predictive models estimate Delta can evade 16-55% of immune protection from prior infections. Low level of evidence.
Breakthrough Infection After Vaccination / Vaccine Efficacy or Effectiveness Compared to Original Variant	3 case-control studies and 1 surveillance data analysis: Among vaccinated: • One Canadian vaccine effectiveness (VE) study reported the BNT162b2 (Pfizer) and mRNA-1273 (Moderna) vaccines have	10 studies including RCTs, cohorts, case-control studies, a surveillance study, and an outbreak investigation: Among fully vaccinated: • VE against Beta infection was 50%-93.48% for	27 studies that included RCTs, cohorts and surveillance studies: • Most VE studies comparing the Alpha variant with the original variants have reported reduced protection after the first dose of mRNA (BNT162b2 (Pfizer), mRNA-1273 (Moderna)) and ChAdOx1 (AstraZeneca)	5 surveillance data analyses, 1 outbreak investigation, 1 RCT, and 3 test negative case control studies: • Four studies on VE report a reduction in protection against Delta infection (n=2) and symptomatic disease (n=2) compared to

CATEGORY	P.1 (GAMMA) UPDATED JUL 1, 2021	B.1.351 (Beta) UPDATED JUL 1, 2021	B.1.1.7 (ALPHA) UPDATED JUL 1, 2021	B.1.617.2 (DELTA) UPDATED JUL 29, 2021
unless otherwise stated	reduced protection against symptomatic infection with Gamma after the first (VE = 43% vs. 61%) and second dose (VE= 88% vs. 93%), although the confidence intervals overlap in both comparisons. • Two studies on CoronaVac (Sinopharm) reported VEs 42-50% against infection, 59% hospitalizations and 71% mortality. • One underpowered study (n=20) indicated Gamma was not over represented in breakthrough infections. Low level of evidence.	BNT162b2 (Pfizer-BioNTech). • VE against symptomatic infection was ≥ 88% for BNT162b2 (Pfizer) or mRNA-1273 (Moderna), 10.4% for ChAdOx1 (AstraZeneca), and 51% for NVX-CoV2373 (Novavax). • VE against moderate disease caused by Beta was 52%-64% after Ad26.COV2.5 (Janssen) vaccine. • VE against severe disease or mortality due to Beta was 97.4%-100% after second dose of BNT162b2 (Pfizer) and 73-82% for Ad26.COV2.5 (Janssen). • Breakthrough infections in long-term care facilities in France and Canada show no indication that the Beta breakthrough rate is higher than expected, however one underpowered study (n=20) in the USA indicated	vaccines, but equivalent protection after the second dose of vaccine. • Many studies report breakthrough infections of Alpha, however there is conflicting evidence on whether they are more common among Alpha VOCs than would be expected. • Breakthrough Alpha infections compared to unvaccinated Alpha cases had a shorter infectious (7.1 vs. 31 days) period and viral load (6.45 vs. 8.15 log10 copies/mL) in one study and no difference in viral load in another, and less severe outcomes were reported in vaccinated cases. Low to moderate level of evidence.	Alpha after the first dose (e.g., 56% Delta vs. 66% Alpha for BNT162b2/ 72% vs. 83% for mRNA-1273 and 67% vs. 64% for ChAdOx1). • Protection following two doses reported a 7.5-10% reduction in protection in one study and comparable protection after the second (>88% for BNT162b2 and mRNA-1273 and 63% for ChAdOx1) in another compared to Alpha. • Four studies on breakthrough infections from UK, USA and India indicated a higher than expected rate of Delta breakthrough cases was observed. Low to moderate level of evidence.

CATEGORY	P.1 (GAMMA) UPDATED JUL 1, 2021	B.1.351 (Beta) UPDATED JUL 1, 2021	B.1.1.7 (ALPHA) UPDATED JUL 1, 2021	B.1.617.2 (DELTA) UPDATED JUL 29, 2021
		Beta was overrepresented in breakthrough infections. Low to moderate level of evidence.		
VARIANT SPREAD AND PUBLIC HEALTH MEASURES				
Spread of the Variant Globally compared to Original Variant unless otherwise specified.	4 surveillance analyses 1 cross-sectional, 1 ecological study and 1 predictive model in Brazil (3) / Colombia (1) / USA (1)/ Italy (1)/ North America (1): • Rapid spread of Gamma in Brazil and Columbia is reported in 4 studies from Nov 2020 onward. • In countries e.g., USA and Italy, Gamma cases remained stable while Alpha was dominant and growing and a similar trend is reported in a predictive model that included Delta where Gamma is predicted to remain at 5% by Mar 2022 assuming 75% vaccine coverage in North America.	6 surveillance analyses and 2 predictive models from South Africa (2) / Canada (1) / Comoros Islands (1) / Bangladesh (1) / multiple countries (2)/ North America (1): • Beta emerged in South Africa around Aug 2020 and was first detected in Oct 2020. First detection of Beta in other countries started in Dec 2020. • A predictive model of North America that included Delta predicts Beta remains stable (<5%) of cases from July 2021 gradually increasing to 5% in Mar 2022 assuming 75% of the population is vaccinated in July 2021. • In a predictive model, Beta outgrows Alpha in regions	147 studies report on emergence and spread of Alpha: • Many countries including Canada are reporting that the proportion of new cases attributed to Alpha has declined and was surpassed by Delta in June/July 2021. • A predictive model forecasting variants in North America estimates Alpha will reach close to 0% of the cases by Oct 2021.	18 surveillance studies and 6 reports: • Delta has become the dominant variant in Canada overtaking Alpha in late June. • Surveillance data from the UK and India on the introduction and growth rate of Delta from February to July 2021 indicate Delta now represents 91-99% of cases. • Studies from the USA and Japan found that the Delta variant is replacing Alpha as the dominant variant. • The Delta VOC classification includes sub-lineages AY.1, AY.2 and AY.3 for which small numbers of cases for these sub-lineages have

Rapid Review on Protective Immunity

Context

Understanding the extent and limits of protective immunity has important implications for the COVID-19 pandemic. An evidence review was conducted to address whether antibodies to SARS-CoV-2 confer immunity against reinfection; to determine if protective immunity lasts more than 6 months; and to identify if past infection with wild-type SARS-CoV-2 protects against variants of concern (VOC).

Key Findings

There were 49 studies identified:15 cohort studies on risk of reinfection, 21 studies on antibody kinetics and other immunity markers >6 months post initial infection, 10 studies on immunity and the new VOCs and three systematic reviews. The appendix summarizes 21 case reports of confirmed reinfection.

Documented cases of confirmed reinfection of COVID-19, based on genomic data, are rare. In most cohort studies, reinfection was based on serology, documented proof of a non-infected phase between infections and PCR evidence of reinfection.

- Cohort studies on reinfection that targeted the general population or healthcare workers indicate a low risk of reinfection (0% - 3.4%) compared to the COVID-19 susceptible population (1.3 – 27.7%). Data on time to reinfection was highly variable, with a median of 52-172 days across studies and a range of 13-250 days.
- Older age, duration of symptoms, and number of symptoms were correlated with higher IgG antibody levels after primary infection. Higher and prolonged serum IgG antibody levels were correlated with milder symptoms and a lower risk of reinfection.

Protective immunity lasts at least 6 months:

- Immunity following an infection arises from both B-cell and T-cell responses. Memory B-cell and T-cell activity was elevated and expanded beyond 6 months post infection in 8 studies, which may be better measures of long term protective immunity than circulating antibodies. CD4+ T-cell activity continued to be detected in 92% of individuals between 6-8 months following infection.
- Twenty studies reported on circulating antibodies, 11 of which reported >86% of people remained positive for SARS-CoV-2 specific neutralizing antibodies (NAbs) ≥6 months after infection.

There is preliminary evidence that the extent of cross-protection of the original wild type SARS-CoV-2 for VOCs depends on the variant, with better cross-protection for B.1.1.7 than B.1.351.

Considerations

Greater access to sequencing data is needed to confirm reinfection and the extent of cross-protection between the original wild-type virus and VOCs.

Aperçu des éléments de preuve :

Revue rapide de l'immunité protectrice, mise à jour 1

Contexte

Comprendre la portée et les limites de l'immunité protectrice a d'importantes répercussions sur la pandémie de COVID-19. Une revue rapide a été effectuée afin de résumer les éléments de preuve récents sur la question de savoir si les anticorps provenant d'une infection naturelle ou d'une vaccination contre le SRAS-CoV-2 peuvent protéger contre les infections et si l'immunité contre le SRAS-CoV-2 peut durer plus de six mois, ainsi que de déterminer si les preuves actuelles indiquent que la protection peut différer en ce qui concerne les variants préoccupants (VP).

Principales constatations

Cette revue comprend 30 études sur la réinfection après une infection naturelle, 7 études avec série complète sur l'infection sporadique après la vaccination, 36 études et 4 revues sur la cinétique des anticorps et les marqueurs immunitaires cellulaires plus de six mois après l'infection ou la vaccination disponibles, toutes disponibles au 9 avril 2021.

Risque de réinfection et infections sporadiques après la vaccination :

- Les cas documentés de réinfection confirmée à la COVID-19 fondée sur des données génomiques sont rares. Bon nombre des cohortes ont plutôt utilisé des données longitudinales associées au PCR et à la sérologie combinées à des données épidémiologiques pour identifier les infections initiales et de réinfection ou les infections sporadiques.
- On a pu voir que l'infection qui avait entraîné la présence d'anticorps détectables avait également assuré une protection de 96 à 99 % contre la réinfection pendant un maximum de 8 mois pour les cas initiaux confirmés et de 83 à 96 % pour les cas dont l'infection était soupçonnée. Même si le risque de réinfection était semblable, tant pour la souche originale que pour le variant B.1.1.7, une étude a indiqué que la réinfection ne protégeait pas contre le variant B.1.351.
- Un petit nombre d'infections sporadiques qui se sont produites plus de 14 jours après la vaccination complète ont cependant été signalées. L'incidence était plus faible de plus de 90 % après l'administration des vaccins PfizerBioNTech, Moderna ou Oxford-AstraZeneca alors qu'elle était de 85 % après l'infection naturelle.
- Les données préliminaires présentées dans une des études indiquent cependant que la protection contre les infections sporadiques était la même pour le variant B.1.1.7 (VP) que pour la souche originale.

Réactions immunitaires qui se sont produites plus de six mois après l'infection ou la vaccination :

- Onze des études ont indiqué qu'après six mois, les marqueurs immunitaires cellulaires et l'activité des cellules B et T étaient élevés et avaient même augmenté après l'infection, en plus d'être détectables même chez les personnes dont les anticorps circulants étaient devenus indétectables.
- Trente-cinq études ont fait état d'anticorps circulants spécifiques au SRAS-CoV-2 après l'infection naturelle (6 à 12 mois) alors qu'une seule étude a indiqué la même chose après la

vaccination (6 mois). Des anticorps neutralisants, des protéines de spicule ou des anticorps IgG contre le domaine de liaison du récepteur (RBD) ont été détectés chez 70 % à 99 % des personnes six mois après l'infection ou la vaccination.

Facteurs dont il faut tenir compte

On voit une grande variabilité dans les études incluses. Il faut un meilleur accès aux données de séquençage pour confirmer la réinfection et l'étendue de la protection croisée avec les variants du SRAS-CoV-2, ainsi qu'une meilleure compréhension de la corrélation entre les marqueurs immunitaires et l'immunité protectrice.

Emerging Evidence on COVID-19

Evidence Brief on SARS-CoV-2 antibodies in patients that retest RT-PCR positive

Introduction

Do hospitalized SARS-CoV-2 patients that successfully recover with no subsequently positive RT-PCR tests present with SARS-CoV-2 antibody levels or seropositivity rates that differ from those that do retest positive?

Confirmed cases of recovered COVID-19 patients retesting positive after discharge raise concerns of potential reinfection or reactivation of the virus. Research comparing immune response indicators from hospitalized patients that successfully recovered from SARS-CoV-2 with no subsequent positive RT-PCR test compared to those who retested RT-PCR positive were identified to investigate possible relationships between viral RNA test positive and immune response. This report summarizes the COVID-19 literature published up to September 9, 2020, on the differences in the immune response between patients that retest positive and those who do not, as well as SARS-CoV-2 antibody dynamics in relation to the possibility for virus reinfection or reactivation.

In this review, nine studies were identified as fitting the inclusion criteria (please see the Methods section). All nine studies occurred in China. As such, all patients that were discharged from hospital had at least two consecutive negative RT-PCR tests at least 24 hours apart. After discharge, all patients were moved to separate facilities for a mandatory 14 days monitored quarantine. It should be noted that patients that retest positive after discharge are referred to as 'RP patients', however, studies use slightly different terms - retest positive, re-detectable positive, re-positive, or recurrent positive. Patients that do not retest positive are referred to as NRP.

Key Points

- The rate of retesting positive (prevalence of RP) varied from 1.87% of discharged patients (Chen et al., 2020) to 52.7% (Hu et al., 2020) for an average of 16.5% from all studies (397/2412 patients). No study found a difference in sex distribution, but four of the nine studies found RP patients to be significantly younger than NRP patients. A wider review would be needed to explore this further (Chen et al., 2020, Lu et al., 2020, Huang et al., 2020, Yang et al., 2020).
- Of six studies that reported on the positivity rate of patients for IgG or IgM antibodies, RP patients exhibited positivity rates that did not differ from the positivity rates of NRP patients. This indicates that the presence of IgG or IgM antibodies is unlikely to be predictive of retesting positive (Yang et al., 2020, Liu et al., 2020., Yuan et al., 2020, Zou et al., 2020, Huang et al., 2020, Zhu et al., 2020).
- Of the four studies that reported on the level of IgG or IgM antibodies in serum, the results are mixed. One study found that the levels of IgM and IgG antibodies were significantly lower in RP patients than

NRP patients (Chen et al., 2020). A second found no difference (Liu et al., 2020). The third found IgG to be significantly lower in RP patients but no difference in IgM levels (Hu et al., 2020). The fourth found no difference in IgG, but that IgM levels varied over time – initially RP patients had higher IgM titers (week 3 post discharge), but the levels of IgM antibodies eventually became significantly lower for RP patients compared to NRP patients (week 6-8 post discharge) (Yang et al., 2020). This suggests that lower antibody levels might play a role in retesting positive after discharge, but the evidence is not conclusive at this point.

- It is still unclear why patients retest positive. All nine studies took place in China, which enforced a mandatory 14-day quarantine following hospital discharge at separate facilities with individual rooms. Three studies that only followed patients during this period found up to 52.7% of patients retested positive (Chen et al., 2020, Hu et al., 2020, Yuan et al., 2020). One plausible explanation for retesting positive within the two-week quarantine period is a 'reactivation' of the initial infection, following incomplete clearing of the virus. It is also possible that concentration of viral RNA in samples fluctuate during clearance of the virus resulting in two false negative results leading to discharge. In Zou et al., 2020, patients retested positive less often when required to have three negative PCR tests prior to hospital discharge, instead of the usual two.
- One study demonstrated that some patients will retest positive more than once. Upon retesting positive, patients were re-hospitalized until discharged again following two consecutive negative RT-PCR tests, only to retest positive a second, third and even fourth time (Yang et al., 2020).
- Another study found that requiring three consecutive negative tests prior to discharge significantly reduced the chance of retesting positive (Zou et al., 2020). This indicates that false-negatives may play a role in retesting positive after discharge, although an additional review would need to uncover any additional literature on this topic.

Overview of the Evidence

Nine papers were identified, eight of which were cohort studies and one of which was a case control study, scored using the Newcastle-Ottawa Scale Risk of Bias Tool. The maximum score is four for selection criteria, two for comparability between groups, and three for exposure or outcome criteria. Adequate follow-up was cut off at four weeks of follow-up.

- Three prospective cohort studies
  - Clinical, immunological and virological characterization of COVID-19 patients that test re-positive for SARS-CoV-2 by RT-PCR (Lu et al., 2020), score: 4, 0, 3.
  - Recurrence of positive SARS-CoV-2 viral RNA in recovered COVID-19 patients during medical isolation observation (Yuan et al., 2020), score: 4, 0, 1.
  - Viral RNA level, serum antibody responses, and transmission risk in discharged COVID-19 patients with recurrent positive SARS-CoV-2 RNA test results: a population-based observational cohort study (Yang et al., 2020), score: 4, 0, 2.

  - Three retrospective cohort studies
    - The production of antibodies for SARS-CoV-2 and its clinical implication (Hu et al., 2020), score: 4, 0, 1.
    - Clinical features of COVID-19 convalescent patients with re-positive nucleic acid detection (Zhu et al., 2020), score: 4, 0, 2.
    - The issue of recurrently positive patients who recovered from COVID-19 according to the current discharge criteria: investigation of patients from multiple medical institutions in Wuhan, China (Zou et al., 2020), score: 3, 0, 1.
  - Two cohort studies (unclear if prospective or retrospective)
    - Recurrent positive SARS-CoV-2 - immune certificate may not be valid (Liu et al., 2020), score: 4, 0, 1.
    - Kinetics of SARS-CoV-2 Positivity of Infected and Recovered Patients: A Single Center COVID-19 Experience and Potential Implications (Huang et al., 2020), score: 4, 0, 2.
  - One case-control study
    - Clinical Characteristics of Recurrent-positive Coronavirus Disease 2019 after Curative Discharge: a retrospective analysis of 15 cases in Wuhan China (Chen et al., 2020), score: 2, 0, 3.

- Limitations
  - All nine studies occurred in China, with no other jurisdictions producing similar studies.
  - The sample size in some of the studies was small; two studies had fewer than 100 patients (Hu et al., 2020, Zhu et al., 2020) and three studies had fewer than 200 patients (Chen et al., 2020, Liu et al., 2020, Yuan et al., 2020).
  - The duration of follow-up varied greatly. Many studies only followed patients during the mandatory, centralized two-week quarantine that follows discharge from hospital in China, while others followed patients for many weeks afterward. There were also a wide range of RT-PCR testing intervals, spanning from a single test near the end of the 14-day quarantine period, to testing every three to five days. In combination, these limitations casts some doubt on the prevalence of retesting positive and average time to retest positive following discharge.
- Data Gaps
  - All studies that met the inclusion criteria were from China where all cases were hospitalized, caution in extrapolation of these results to other settings is recommended.
  - This review does not consider other factors that may be predictive or contribute to retesting positive following hospital discharge, including immune cell counts, comorbidities, severity of disease upon initial hospitalization, and more. These are topics for potential future reviews.
  - In this series of studies, 'reactivation' or a series of false negatives are both plausible reasons for patients retesting PCR positive shortly after discharge. A separate review and more research is needed to explore the reason and mechanism by which patients are retesting positive.

TABLE 1: SEROLOGICAL CHARACTERISTICS OF DISCHARGED HOSPITALIZED COVID-19 CASES WHO RETESTED RT-PCR POSITIVE COMPARED TO THOSE THAT DID NOT

Reference	Report Details	Key Findings
Lu et al., 2020 Prospective cohort study Guangdong, China. Jan 23 - Feb 19, 2020	This followed 619 discharged patients and serology was the main outcome of this study. 288 patients had serological testing a median of 35 days post symptom onset (range = 23 to 47 days). Patients were followed for up to 66 days.	- Neutralizing antibody titers for RP and NRP patients were not significantly different 14 days post hospital discharge. - This study had the largest cohort that was followed for the longest period of time, recording a RP incidence rate of 14% (87/619 patients). - RP patients in this study were significantly younger than NRP patients. Sex distribution did not differ between groups. - Patients were followed for 66 days post discharge, and experience reactivation on day 10 on average (tested on day 7 and 14 only).
Yang et al., 2020 (Preprint) Prospective cohort study Shenzhen, China Feb 1 – May 5, 2020	This study followed 479 discharged patients. Serology is main outcome of this study, with serum specimens collected on the 1st, 3rd, 7th, and 14th days of each of the post-discharge 14-day quarantine period. Patients were followed up to 90 days.	- RP and NRP patients did not differ in rates of testing positive for IgG antibodies (99% and 98%, respectively). Serum levels of IgG antibodies also did not differ between groups at any point after disease onset. -RP and NRP patients did not differ in rates of testing positive for IgM antibodies (37% and 50%, respectively). Serum levels of IgM antibodies differed between groups at different points post-disease onset: In week 3, RP patients had significantly higher levels of IgM, while in weeks 6 through 8, RP patients had significantly lower IgM levels. -The incident rate of RP in this study was 19% (93/479 patients). In addition, 45 (9%) experience multiple RP events: two (n=32, 7%), three (n=9, 2%), or four (n=4, 1%) RP events. - RP patients in this study were significantly younger than NRP patients (34 years compared to 45 years). Sex distribution did not differ between groups. - Patients were followed for 90 days post discharge, and experience reactivation on day 8 on average. An average of 46 days elapsed between disease onset and the final RP event for each patient.

Yuan et al., 2020 Prospective cohort study Shenzhen, China Before Apr 21, 2020	This prospective cohort study followed 182 discharged patients. Serology is one of the main outcomes of this study, with 147 patients submitting for serological testing at some point after discharge. Patients were followed for 14 days.	- RP and NRP patients did not differ in rates of testing positive for IgG antibodies (100% and 99.2%, respectively). - RP and NRP patients did not differ in rates of testing positive for IgM antibodies (71.4% for both). -The incident rate of RP in this study was 11% (20/182 patients). However, only a subset had serology results (14 RP patients and 133 NRP patients). - RP patients were not significantly younger in this study, however, patients under 18 years of age were overrepresented in the RP group. Sex distribution did not differ between groups. - Patients were followed during the mandatory 14-day quarantine following hospital discharge, and retested on day 7 and 14 of quarantine.
Zhu et al., 2020 Retrospective cohort study Zhejiang, China Before Apr 2, 2020	This retrospective cohort study followed 98 discharged patients. Serology was part of a wide range of factors examined, with testing measuring temporal changes in antibody levels. The exact timing of tests is not stated. The follow-up period is at least 17 days.	- In this study, 35.5% of RP patients tested positive for both IgG and IgM antibodies, compared to 8.6% of NRP patients. 58.8% of RP patients tested positive for IgG and negative for IgM antibodies, compared to 44.4% of NRP patients. Two RP and one NRP patients tested negative for both IgG and IgM antibodies. The groups were not determined to be significantly different. - The incident rate of RP in this study was 17% (17/98 patients). - Neither age nor sex was found to differ between RP and NRP patients. - Patients were followed for at least 17 days following discharge, with the average time to RP being 7 days.
Hu et al., 2020 (Preprint) Retrospective cohort study Chongquin, China Jan 23 - Mar 3, 2020	This study followed 221 hospitalized patients. Serology was the main outcome, with serum samples taken every 3 days post-symptom onset. Only 74 patients were discharged and followed for	- Patients that experienced RP had post-discharge IgG levels of 8.94 on average, compared to 20.19 in NRP patients, which is significantly different. Levels are expressed as a ratio of the chemiluminescence signal to the cutoff value (S/CO). - RP and NRP patients did not have significantly different post-discharge IgM levels (0.90 compared to 1.39, respectively). - Reports the highest RP incidence rate of the ten studies (39/74, or 52.7%). No average time to reactivation was stated. - No age/sex differences between RP and NRP patients. - Patients were followed for up for 14 days.

	the 14-day quarantine period.	
Zou et al., 2020 Retrospective cohort study Wuhan, China Jan 1 – Mar 10, 2020	This study followed 257 hospitalized patients. Serology was not main outcome of the study. It is unclear how long patients were followed for or when they underwent serological testing.	- RP and NRP patients did not differ in rates of testing positive for IgG antibodies (94.4% and 85.1%, respectively). - RP and NRP patients did not differ in rates of testing positive for IgM antibodies (52.8% and 58.8%, respectively). - The incident rate of RP in this study was 20.6% (53/257 patients). However, only a subset had serology results (36 RP patients and 114 NRP patients). - Neither age nor sex was found to differ between RP and NRP patients. - It is unclear how long patients were followed for, but were said to retest positive an average of 4.6 days post-discharge. - The goal of this study was to compare RP rates for patients with two subsequent negative PCR tests compared to three subsequent negatives to qualify for discharge. 20.6% of patients with two negative tests experience RP, compared to only 5.4% of patients with three negative tests.
Huang et al., 2020 (Preprint) Cohort study - unclear if prospective or retrospective Shenzhen, China Jan 11 - Apr 23, 2020	This study followed 414 hospitalized patients. Serology was part of a wide range of factors examined. 154 patients had serological testing at discharge from hospital. Patients were followed for four weeks.	- RP and NRP patients did not differ in rates of testing positive for IgG antibodies (100% and 99.1%, respectively). - RP and NRP patients did not differ in rates of testing positive for IgM antibodies (75.0% and 48.2%, respectively). - The incident rate of RP in this study was 16.7% (69/414 patients). - RP patients in this study were significantly younger than NRP patients. Sex distribution did not differ between groups. - Patients were followed for four weeks following discharge. Reactivation occurred on the day 10 on average, with RT-PCR testing done every 3-5 days.
Liu et al., 2020 Cohort study- unclear if prospective or retrospective Wuhan, China Mar 1 - 13, 2020	This study followed 150 discharged patients. Serology was main outcome measure, but neither timing of serology nor the duration of follow-up was noted.	- RP and NRP patients did not differ in rates of testing positive for IgG antibodies (100% and 90.6%, respectively). Serum levels of IgG antibodies also did not differ between groups (243 AU/mL and 185 AU/mL, respectively). -RP and NRP patients did not differ in rates of testing positive for IgM antibodies (45.5% and 47.5%, respectively). Serum levels of IgM antibodies also did not differ between groups (9.6 AU/mL and 8.9 AU/mL, respectively). - The incident rate of RP in this study was 7.3% (11/150 patients). - Neither age nor sex was found to differ between RP and NRP patients. - Testing at different points following discharge may have affected the results.

Chen et al., 2020 Case-control study Wuhan, China Feb 10 - Mar 31, 2020	This study examined the serology of 15 RP cases and 107 controls admitted to a single hospital. Serology was part of a wide range of factors examined. The timing of the serological testing is not clear.	- Patients experiencing RP had IgG levels of 78.53 AU/mL on average, compared to 147.85 AU/mL in NRP patients, which is significantly different. - Patients experiencing RP had IgM levels of 13.69 AU/mL on average, compared to 68.10 AU/mL in NRP patients, which is significantly different. - Reports the lowest RP incidence rate of the ten studies (2/107, or 1.9%) from the cohort in a single hospital. 15 cases from multiple sites were compared to 107 controls. - Age and sex were not matched between cases and controls. RP patients were found to be significantly younger than NRP patients (43 years compared to 60 years). There was no significant difference in sex of RP versus NRP patients. - Patients were followed up for 14 days. Reactivation occurred at day 12 post-discharge on average. However, patients were only tested near the end of the 14-day quarantine.

Methods:

A daily scan of the literature (published and pre-published) is conducted by the Emerging Sciences Group, PHAC. The scan has compiled COVID-19 literature since the beginning of the outbreak and is updated daily. Searches to retrieve relevant COVID-19 literature are conducted in Pubmed, Scopus, BioRxiv, MedRxiv, ArXiv, SSRN, Research Square and cross-referenced with the literature on the WHO COVID literature list, and COVID-19 information centers run by Lancet, BMJ, Elsevier and Wiley. The daily summary and full scan results are maintained in a refworks database and an excel list that can be searched. Targeted keyword searching is conducted within these databases to identify relevant citations on COVID-19 and SARS-CoV-2. Search terms used included: Reactivation, reinfection, reoccurrence, recurrent, in conjunction with hospitalization, discharge, antibody and immunity (including terms with similar endings and alternative spelling).

This review contains research published up to September 9, 2020.

Each potentially relevant reference was examined to confirm it had relevant data and relevant data is extracted into the review.

All studies included in this review focus on characteristics of hospitalized patients who retested positive (RP) compared to those who did not retest positive (NRP) after discharge, and also included serology data for both RP and NRP groups. Papers included in this review were either case-control or cohort studies. Review articles were excluded to avoid double counting. Case-series or case reports were also excluded as they do not present a comparison between patients that retested positive versus those that did not.

Nouveaux éléments de preuve sur la COVID-19

Synthèse en bref sur la présence des anticorps dirigés contre le SRAS-CoV-2 chez les patients ayant obtenu un nouveau résultat positif au test RT-PCR

Introduction

Une fois rétablis, est-ce que les patients hospitalisés en raison du SRAS-CoV-2 qui n'ont pas obtenu de résultat positif subséquent au test RT-PCR présentent des niveaux d'anticorps contre le SRAS-CoV-2ou des taux de séropositivité différents de ceux qui ont reçu un résultat positif à un nouveau test?

Les cas confirmés de patients qui ont eu la COVID-19 et ont reçu un nouveau résultat positif après avoir obtenu leur congé de l'hôpital soulèvent des préoccupations quant à une possible réinfection ou réactivation du virus. Les recherches visant à comparer les indicateurs de réponse immunitaire des patients rétablis après avoir été hospitalisés en raison du SRAS-CoV-2 et qui n'ont pas reçu de résultat positif lors d'un test RT-PCR subséquent à ceux des patients qui ont obtenu un résultat positif au test RT-PCR test ont été sélectionnées afin d'étudier les liens possibles entre les résultats positifs au test d'ARN viral et la réponse immunitaire. Cette revue résume la documentation sur la COVID-19 publiée jusqu'au 9 septembre 2020 portant sur les différences entre les réponses immunitaires des patients qui ont obtenu un résultat positif à un nouveau test et ceux qui ont obtenu un résultat négatif. Elle porte également sur le lien entre la dynamique des anticorps du SRAS-CoV-2 et la possibilité de réinfection ou de réactivation du virus.

Cette synthèse comprend neuf études qui correspondaient aux critères d'inclusion (veuillez consulter la section Méthodologies pour plus de détails). Ces neuf études ont toutes été réalisées en Chine. Dans le cadre de ces études, tous les patients qui ont obtenu leur congé de l'hôpital avaient reçu au moins deux résultats négatifs consécutifs à des tests RT-PCR effectués à au moins 24 heures d'intervalle. Après leur congé, tous les patients ont été transférés dans des établissements distincts pour une quarantaine obligatoire surveillée d'une durée de 14 jours. Il est à noter que les es patients qui ont reçu un nouveau résultat positif après avoir obtenu leur congé sont généralement appelés « patients RP », mais certaines études utilisent des termes légèrement différents, par ex., nouveau résultat positif, positif de nouveau détectable, positif à nouveau ou positif récurrent. Les patients dont le résultat n'était pas positif sont, quant à eux, appelés patients NRP.

Points clés

- Le taux de résultat positif (prévalence de résultats positifs (RP)) variait de 1,87 % chez les patients ayant reçu leur congé (Chen et coll., 2020) à 52,7 % (Hu et coll., 2020) avec une moyenne de 16,5 % pour l'ensemble des études (397 patients sur 2 412). Aucune étude n'a relevé de différence dans la répartition selon le sexe, mais quatre des neuf études ont mentionné que les patients RP étaient

beaucoup plus jeunes que les patients NRP. Un plus vaste examen serait cependant nécessaire pour explorer cette question en profondeur (Chen et coll., 2020, Lu et coll., 2020, Huang et coll., 2020, Yang et coll., 2020).

- Parmi les six études ayant indiqué une proportion de cas positifs pour les anticorps IgG ou IgM chez les patients, aucune n'a mentionné de différence quelconque entre les taux des patients RP et ceux des patients NRP. Il est donc peu probable que la présence d'anticorps IgG ou IgM permette de prédire le résultat positif d'un nouveau test (Yang et coll., 2020, Liu et coll., 2020, Yuan et coll., 2020, Zou et coll., 2020, Huang et coll., 2020, Zhu et coll., 2020).
- Les résultats des quatre études qui ont mentionné la concentration d'anticorps IgG ou IgM dans le sérum sont cependant mitigés. Ainsi, la première étude a révélé que les taux d'anticorps IgM et IgG étaient beaucoup plus faibles chez les patients RP que chez les patients NRP (Chen et coll., 2020). La seconde n'a trouvé aucune différence à cet égard (Liu et coll., 2020). La troisième a, quant à elle, indiqué que le taux d'anticorps IgG était significativement plus faible chez les patients RP, mais qu'aucune différence n'avait été observée pour le taux d'anticorps IgM (Hu et coll., 2020). La quatrième n'a relevé aucune différence entre les taux d'anticorps IgG, mais a cependant indiqué que les niveaux d'IgM variaient avec le temps. Ainsi, au départ, les patients RP avaient des titres d'IgM plus élevés (troisième semaine après le congé), mais ces niveaux sont finalement devenus beaucoup plus faibles chez les patients RP que chez les patients NRP (entre six et huit semaines après le congé; Yang et coll., 2020). Ces observations suggèrent que des niveaux d'anticorps plus faibles pourraient jouer un rôle dans le nouveau résultat positif obtenu après le congé. Les preuves à cet égard ne sont cependant pas concluantes pour le moment.
- On ne sait toujours pas précisément pourquoi les patients ont de nouveau reçu un résultat positif. Comme cela a été indiqué ci-dessus, les neuf études ont été réalisées en Chine qui imposait une quarantaine obligatoire de 14 jours après tout congé d'hôpital. Cette quarantaine a été effectuée dans des établissements distincts avec des chambres individuelles. Trois études qui n'ont suivi les patients que pendant cette période ont révélé qu'un maximum de 52,7 % des patients avait reçu un nouveau résultat positif (Chen et coll., 2020, Hu et coll., 2020, Yuan et coll., 2020). Une « réactivation » de l'infection initiale en raison de l'élimination incomplète du virus pourrait expliquer de façon plausible pourquoi ces patients ont reçu un résultat positif au test effectué pendant la période de quarantaine de deux semaines. Il est également possible que la concentration d'ARN viral dans les échantillons ait fluctué pendant l'élimination du virus, ce qui a entraîné deux faux négatifs qui ont permis au patient d'obtenir son congé. L'étude réalisée par Zou et coll., 2020 indique que les patients ont reçu des résultats positifs moins souvent lorsqu'ils devaient obtenir trois résultats négatifs au test PCR plutôt que les deux tests habituels avant d'obtenir leur congé de l'hôpital.
- Une étude a démontré que certains patients obtenaient des résultats positifs à plus d'une reprise. Lorsque les patients ont reçu un nouveau résultat positif au test, ils ont alors été hospitalisés de nouveau et ne se sont vus accorder de congé que lorsqu'ils ont eu deux résultats négatifs à deux tests

RT-PCR consécutifs, pour finalement subir d'autres tests et recevoir un résultat positif au deuxième, au troisième et même au quatrième test (Yang et coll., 2020).

- Une autre étude a révélé que le fait d'exiger trois résultats négatifs consécutifs avant d'accorder un congé aux patients réduisait significativement le risque de nouveaux résultats positifs (Zou et coll., 2020), ce qui indique que les faux négatifs peuvent jouer un rôle dans l'obtention d'un nouveau résultat positif chez un patient ayant obtenu son congé. Un examen supplémentaire sera cependant requis pour obtenir plus de précisions à cet égard.

Vue d'ensemble des éléments de preuve

Neuf documents ont été recensés, dont huit étaient des études de cohorte et un, une étude cas-témoins. Tous ont été évalués à l'aide de l'outil de mesure du risque de partialité dans l'échelle Newcastle-Ottawa (NOS). Pour les critères de sélection, le score maximal est de quatre, alors qu'il est de deux pour la comparabilité entre les groupes et de trois pour les critères d'exposition ou de résultat. Le suivi approprié a cependant été interrompu après quatre semaines de suivi.

- Trois études de cohorte prospectives
  - Clinical, immunological and virological characterization of COVID-19 patients that test re-positive for SARS-CoV-2 by RT-PCR (Lu et coll., 2020), score : 4, 0, 3.
  - Recurrence of positive SARS-CoV-2 viral RNA in recovered COVID-19 patients during medical isolation observation (Yuan et coll., 2020), score : 4, 0, 1.
  - Viral RNA level, serum antibody responses, and transmission risk in discharged COVID-19 patients with recurrent positive SARS-CoV-2 RNA test results: a population-based observational cohort study (Yang et coll., 2020), score : 4, 0, 2.
- Trois études de cohortes rétrospectives
  - The production of antibodies for SARS-CoV-2 and its clinical implication (Hu et coll., 2020), score : 4, 0, 1.
  - Clinical features of COVID-19 convalescent patients with re-positive nucleic acid detection (Zhu et coll., 2020), score : 4, 0, 2.
  - The issue of recurrently positive patients who recovered from COVID-19 according to the current discharge criteria: investigation of patients from multiple medical institutions in Wuhan, China (Zou et coll., 2020), score : 3, 0, 1.
- Deux études de cohorte (aucune indication à savoir si elles étaient prospectives ou rétrospectives)
  - Recurrent positive SARS-CoV-2 - immune certificate may not be valid (Liu et coll., 2020), score : 4, 0, 1.

        - Kinetics of SARS-CoV-2 Positivity of Infected and Recovered Patients: A Single Center COVID-19 Experience and Potential Implications (Huang et coll., 2020), score : 4, 0, 2.
    - Une étude cas/témoins
        - Clinical Characteristics of Recurrent-positive Coronavirus Disease 2019 after Curative Discharge: a retrospective analysis of 15 cases in Wuhan China (Chen et coll., 2020), score : 2, 0, 3.
    - Limites Les neuf études ont été réalisées en Chine, et aucune autre administration n'a produit d'études semblables.
    - La taille de l'échantillon dans certaines études était petite. Ainsi, deux études comptaient moins de 100 patients (Hu et coll., 2020, Zhu et coll., 2020) alors que trois autres comptaient moins de 200 patients (Chen et coll., 2020, Liu et coll., 2020, Yuan et coll., 2020).
    - La durée du suivi variait considérablement. De nombreuses études n'ont suivi les patients que pendant les deux semaines de quarantaine obligatoire et centralisée qui a suivi l'obtention du congé de l'hôpital, tandis que d'autres ont plutôt suivi les patients pendant de nombreuses semaines par la suite. L'éventail était également assez large en ce qui concerne l'intervalle des tests RT-PCR puisqu'il variait d'un seul test vers la fin de la quarantaine de 14 jours à des tests effectués tous les trois à cinq jours. Cumulativement, ces limites, laissent planer un doute sur la prévalence des résultats positifs répétés et sur le temps moyen requis pour qu'ils soient de nouveau positifs après qu'un patient ait obtenu son congé.
- Lacunes dans les données
    - Toutes les études qui répondaient aux critères d'inclusion provenaient de la Chine où tous les cas ont été hospitalisés. Il faut donc faire preuve de prudence au moment d'extrapoler ces résultats à d'autres contextes.
    - Cette synthèse ne tient pas compte d'autres facteurs pouvant être prédictifs ou contribuer à un nouveau diagnostic positif une fois qu'un patient a reçu son congé de l'hôpital, ce qui inclut la numération des cellules immunitaires, les comorbidités, la gravité de la maladie au moment de l'hospitalisation initiale, et plus encore. Ces sujets pourraient faire l'objet de synthèses à venir.
    - Dans cette série d'études, la « réactivation » ou une série de faux négatifs sont deux raisons plausibles pour lesquelles les patients obtiennent un nouveau résultat positif au test PCR peu de temps après avoir obtenu leur congé. Une synthèse distincte et des recherches supplémentaires sont nécessaires pour examiner la raison et le mécanisme par lequel les patients reçoivent de nouveaux résultats positifs aux tests.

TABLEAU 1 : CARACTÉRISTIQUES SÉROLOGIQUES DES PATIENTS AYANT OBTENU LEUR CONGÉ APRÈS UNE HOSPITALISATION EN RAISON DE LA COVID-19 ET DONT LE RÉSULTAT DU TEST RT-PCR EST POSITIF, COMPARATIVEMENT À CEUX DONT LE RÉSULTAT EST NÉGATIF

Référence	Détails du rapport	Principales conclusions
Lu et coll., 2020 Étude de cohorte prospective Guangdong, en Chine. Du 23 janvier au 19 février 2020	Cette étude, qui a suivi 619 patients ayant reçu leur congé, a permis d'en établir la sérologie. Ainsi, 288 patients ont subi des tests sérologiques pendant une période médiane de 35 jours après l'apparition des symptômes (intervalle variant entre 23 et 47 jours). Ils ont ensuite été suivis pendant une période pouvant aller jusqu'à 66 jours.	- Les titres des anticorps neutralisants pour les patients RP et NRP ne différaient pas significativement 14 jours après qu'ils aient reçu leur congé de l'hôpital. - Cette étude comportait la plus grosse cohorte suivie pendant la plus longue période de temps avec un taux d'incidence de RP de 14 % (87 patients sur 619). - Dans cette étude, les patients RP étaient beaucoup plus jeunes que les patients NRP. La répartition selon le sexe ne différait cependant pas entre les groupes. - Les patients ont été suivis pendant une période de 66 jours après qu'ils aient obtenu leur congé et la réactivation s'est produite en moyenne le jour 10 (tests effectués les jours 7 et 14 seulement).
Yang et coll., 2020 (prépublication) Étude de cohorte prospective Shenzhen, en Chine Du 1er février au 5 mai 2020	Cette étude a suivi 479 patients ayant reçu leur congé. Elle portait principalement sur la sérologie, puisque des spécimens de sérum ont été prélevés les 1er, 3e, 7e et 14e jours de chacune des périodes de quarantaine de 14 jours, après le congé de l'hôpital. Les patients ont ensuite été suivis	- Aucune différence n'a été observée en ce qui concerne les taux de résultats positifs aux tests d'anticorps IgG des patients RP et NRP (99 % et 98 %, respectivement). Quant aux niveaux sériques des anticorps IgG, ils ne différaient pas non plus d'un groupe à l'autre en tout temps après l'apparition de la maladie. - Aucune différence n'a été observée en ce qui concerne les taux de résultats positifs aux tests d'anticorps IgM pour les patients RP et NRP (37 % et 50 %, respectivement). Les niveaux sériques des anticorps IgG variaient entre les groupes à différents moments après l'apparition de la maladie : ainsi, pendant la troisième semaine, les patients RP présentaient des taux d'IgM beaucoup plus élevés, alors que les taux d'IgM étaient beaucoup plus faibles pendant les semaines 6 à 8 chez les patients RP. -Le taux d'incidence des résultats positifs (PR) dans cette étude était de 19 % (93 patients sur 479). De plus, 45 (9 %) d'entre eux ont été associés à plusieurs événements de résultat positif

	pendant une période pouvant aller jusqu'à 90 jours.	connexes, soit deux (n=32,7 %), trois (n=9,2 %) ou quatre (n=4,1 %) événements. - Dans cette étude, les patients RP étaient beaucoup plus jeunes que les patients NRP (34 ans comparativement à 45 ans). La répartition selon le sexe ne différait cependant pas entre les groupes. - Les patients ont été suivis pendant une période de 90 jours après qu'ils aient obtenu leur congé et la réactivation s'est produite en moyenne le jour 8. Il s'est donc écoulé en moyenne 46 jours entre l'apparition de la maladie et l'événement RP final pour chaque patient.
Yuan et coll., 2020 Étude de cohorte prospective Shenzhen, en Chine Avant le 21 avril 2020	Cette étude de cohorte prospective a suivi 182 patients ayant reçu leur congé. Elle portait principalement sur la sérologie avec 147 patients qui ont été soumis à des tests sérologiques à un moment donné après avoir obtenu leur congé. Ils ont ensuite été suivis pendant 14 jours.	- Aucune différence n'a été observée en ce qui concerne les taux de résultats positifs aux tests d'anticorps IgG des patients RP et NRP (100 % et 99,2 %, respectivement). - Aucune différence n'a été observée en ce qui concerne les taux de résultats positifs aux tests d'anticorps IgM des patients RP et NRP (71,4 % pour les deux). - Le taux d'incidence des RP dans cette étude atteignait 11 % (20 patients sur 182), mais des résultats de sérologie n'ont été obtenus que pour un seul sous-ensemble (14 patients RP et 133 patients NRP). - Bien que, dans cette étude, les patients RP n'étaient pas beaucoup plus jeunes, les patients de moins de 18 ans étaient cependant surreprésentés dans le groupe RP. La répartition selon le sexe ne différait cependant pas entre les groupes. - Les patients ont été suivis pendant leur quarantaine obligatoire de 14 jours qui a suivi l'obtention du congé de l'hôpital, avant d'être soumis à un nouveau test les jours 7 et 14 de la quarantaine.
Zhu et coll., 2020 Étude de cohorte rétrospective Zhejiang, en Chine Avant le 2 avril 2020	Cette étude de cohorte rétrospective a suivi 98 patients ayant reçu leur congé. La sérologie faisait partie d'une vaste gamme de facteurs examinés, puisque les tests ont mesuré les changements dans les niveaux d'anticorps en fonction du temps.	- Dans le cadre de cette étude, 35,5 % des patients RP ont reçu un résultat positif pour les anticorps IgG et IgM, comparativement à 8,6 % des patients NRP alors que 58,8 % des patients RP ont reçu un résultat positif pour l'IgG et un résultat négatif pour les anticorps IgM, comparativement à 44,4 % des patients NRP. Deux patients RP et un patient NRP ont obtenu des résultats négatifs pour les anticorps IgG et IgM. Il n'a pas été jugé que ces groupes sont significativement différents. - Le taux d'incidence des RP dans cette étude était de 17 % (17 patients sur 98). - Il a été jugé que ni l'âge ni le sexe ne différaient entre les patients RP et NRP. - Les patients ont été suivis pendant au moins 17 jours après avoir reçu leur congé, avec une durée moyenne de 7 jours pour les patients RP.

	Les dates exactes des tests ne sont pas précisées, mais le suivi a duré au moins 17 jours.	
Hu et coll., 2020 (prépublication) Étude de cohorte rétrospective Chongquin, en Chine Du 23 janvier au 3 mars 2020	Cette étude a suivi 221 patients hospitalisés. Elle portait principalement sur la sérologie puisque des échantillons de sérum ont été prélevés tous les trois jours après l'apparition des symptômes. Seuls 74 patients ont reçu leur congé et ont été suivis pendant la période de quarantaine de 14 jours.	- Les patients RP présentaient des taux d'IgG après leur congé de 8,94 en moyenne alors que les patients NRP ont obtenu des résultats significativement différents avec un taux de 20,19. Les niveaux sont exprimés sous forme de rapport entre le signal de chimiluminescence et la valeur seuil. - Les niveaux d'IgM des patients RP et NRP n'étaient pas significativement différents après leur congé (0,90 comparativement rapport à 1,39, respectivement). - Cette étude est celle qui comporte le taux d'incidence de RP le plus élevé parmi les dix études (39 sur 74 ou 52,7 %). Aucune durée moyenne de réactivation n'a été indiquée. - Aucune différence d'âge ou de sexe entre les patients RP et NRP n'a été mentionnée. - Les patients ont été suivis pendant une période pouvant aller jusqu'à 14 jours.
Zou et coll., 2020 Étude de cohorte rétrospective Wuhan, en Chine Du 1er janvier au 10 mars 2020	Cette étude a suivi 257 patients hospitalisés. L'étude ne portait pas principalement sur la sérologie. Ni la durée du suivi des patients ni la date à laquelle ils ont subi des tests sérologiques n'ont été indiquées.	- Aucune différence n'a été observée en ce qui concerne les taux de résultats positifs aux tests d'anticorps IgG des patients RP et NRP (94,4 % et 85,1 %, respectivement). - Aucune différence n'a été observée en ce qui concerne les taux de résultats positifs aux tests d'anticorps IgM des patients RP et NRP (52,8 % et 58,8 %, respectivement). - Le taux d'incidence des RP dans cette étude était de 20,6 % (53 patients sur 257). Cependant, un seul sous-ensemble incluait des résultats sérologiques (36 patients RP et 114 patients NRP). - Il a été jugé que ni l'âge ni le sexe ne différaient entre les patients RP et NRP. - L'étude n'indique pas précisément la durée du suivi, mais précise que le nouveau résultat positif au test s'est produit en moyenne 4,6 jours après que les patients aient obtenu leur congé. - Cette étude visait à comparer les taux de RP chez les patients qui ont reçu deux résultats négatifs subséquents à des tests PCR comparativement à trois résultats négatifs subséquents avant de pouvoir obtenir leur congé. Ainsi, 20,6 % des patients qui ont obtenu deux tests négatifs ont ensuite obtenu un RP

		comparativement à seulement 5,4 % des patients qui ont obtenu trois résultats négatifs.
Huang et coll., 2020 (prépublication) Étude de cohorte - aucune indication à savoir si elle était prospective ou rétrospective Shenzhen, en Chine Du 11 janvier au 23 avril 2020	Cette étude a suivi 414 patients hospitalisés. La sérologie faisait partie d'un large éventail de facteurs examinés. Dans cette étude, 154 patients ont passé des tests sérologiques avant d'obtenir leur congé de l'hôpital. Ces patients ont été suivis pendant quatre semaines.	- Aucune différence n'a été observée en ce qui concerne les taux de résultats positifs aux tests d'anticorps IgG des patients RP et NRP (100 % et 99,1 %, respectivement). - Aucune différence n'a été observée en ce qui concerne les taux de résultats positifs aux tests d'anticorps IgM des patients RP et NRP (75,0 % et 48,2 %, respectivement). - Le taux d'incidence des RP dans cette étude était de 16,7 % (69 patients sur 414). - Dans cette étude, les patients RP étaient beaucoup plus jeunes que les patients NRP. La répartition selon le sexe ne différait cependant pas entre les groupes. - Les patients ont été suivis pendant quatre semaines après avoir obtenu leur congé. La réactivation s'est produite en moyenne le dixième jour, avec des tests RT-PCR effectués tous les 3 à 5 jours.
Liu et coll., 2020 Étude de cohorte - aucune indication à savoir si elle était prospective ou rétrospective Wuhan, en Chine Du 1er mars au 13 avril 2020	Cette étude a suivi 150 patients ayant reçu leur congé. La sérologie était la principale mesure visée, mais ni la date à laquelle elle a eu lieu ni la durée du suivi n'ont été indiquées.	- Aucune différence n'a été observée en ce qui concerne les taux de résultats positifs aux tests d'anticorps IgG des patients RP et NRP (100 % et 90,6 %, respectivement). Les concentrations sériques d'anticorps IgG ne différaient pas non plus entre les groupes (243 AU/ml et 185 AU/ml, respectivement). - Aucune différence n'a été observée en ce qui concerne les taux de résultats positifs aux tests d'anticorps IgM des patients RP et NRP (45,5 % et 47,5 %, respectivement). Les concentrations sériques d'anticorps IgM ne différaient pas non plus d'un groupe à l'autre (9,6 AU/ml et 8,9 AU/ml, respectivement). - Le taux d'incidence des résultats positifs dans cette étude était de 7,3 % (11 patients sur 150). - Il a été jugé que ni l'âge ni le sexe ne différaient entre les patients RP et NRP. - Les tests effectués à différents moments après l'attribution du congé peuvent avoir eu une incidence sur les résultats.

Chen et coll., 2020 Étude cas/témoins Wuhan, en Chine Du 10 février au 31 mars 2020	Cette étude a examiné la sérologie de 15 patients RP et de 107 témoins admis dans un seul hôpital. La sérologie faisait partie d'un large éventail de facteurs examinés. La date à laquelle les tests sérologiques ont été effectués n'est pas indiquée de façon précise.	- Les patients RP avaient des taux moyens d'IgG de 78,53 AU/ml comparativement à 147,85 AU/ml chez les patients NRP, ce qui est significativement différent. - Les patients RP présentaient également des taux moyens d'IgM de 13,69 AU/ml comparativement à 68,10 AU/ml chez les patients NRP, ce qui est aussi significativement différent. - Cette étude a le taux d'incidence de RP le plus faible parmi les dix études évaluées (2 sur 107, ou 1,9 %) et ce taux provient d'une cohorte prise dans un seul hôpital. Elle a comparé 15 patients provenant de sites multiples à 107 cas témoins. - L'âge et le sexe ne correspondaient pas entre les patients et les témoins. L'étude a indiqué que les patients RP étaient beaucoup plus jeunes que les patients NRP (43 ans comparativement à 60 ans). Il n'y avait aucune différence significative entre le sexe des patients RP et celui des patients NRP. - Les patients ont été suivis pendant 14 jours. La réactivation s'est produite en moyenne au 12^{e} jour après qu'ils aient reçu leur congé. Toutefois, les patients n'ont été testés qu'à la fin de la quarantaine de 14 jours.

Méthodologies :

Une analyse documentaire quotidienne (ouvrages publiés et en prépublication) est effectuée par le Groupe des sciences émergentes de l'ASPC. L'analyse a compilé les ouvrages sur la COVID-19 depuis le début de l'éclosion et est mise à jour quotidiennement. Les recherches visant à extraire les ouvrages pertinents sur la COVID-19 sont menées dans Pubmed, Scopus, BioRxiv, MedRxiv, ArXiv, SSRN et Research Square, et les résultats sont recoupés avec les ouvrages figurant sur la liste de la documentation sur la COVID de l'Organisation mondiale de la Santé et des centres d'information sur la COVID-19 gérés par Lancet, BMJ, Elsevier et Wiley. Le résumé quotidien et les résultats complets de l'analyse sont conservés dans une base de données RefWorks et dans une liste Excel consultable. Une recherche ciblée par mot-clé a été effectuée dans ces bases de données pour recenser les citations pertinentes sur la COVID-19 et le SRAS-CoV-2. Les termes de recherche utilisés comprenaient : Réactivation, réinfection, récurrence, récidive, en liaison avec l'hospitalisation, le congé de l'hôpital, les anticorps et l'immunité (y compris les termes ayant une terminaison similaire et une orthographe différente).

La présente revue contient des recherches publiées jusqu'au 9 septembre 2020.

Chaque référence potentiellement pertinente a été examinée pour confirmer qu'elle comportait des données pertinentes, qui ont été extraites dans la revue.

Toutes les études incluses dans cette revue portent sur les caractéristiques de patients hospitalisés qui ont reçu un nouveau résultat positif (RP) par rapport à ceux qui n'ont pas eu de résultat positif (NRP) après leur congé de l'hôpital, et comprennent également des données sérologiques pour les groupes RP et NRP. Les articles inclus dans cette revue étaient soit des études cas-témoins, soit des études de cohorte. Les articles de synthèse ont été exclus pour éviter tout double comptage. Les séries de cas ou les rapports de cas ont également été exclus, car ils ne présentent aucune comparaison entre les patients dont les résultats de test sont positifs comparativement à ceux dont le résultat est négatif.

Nouveaux éléments de preuve sur la COVID-19

Résumé des éléments de preuve sur les procédures pouvant générer des aérosols dans le milieu des soins dentaires

Introduction

Quelles sont les preuves existantes de la transmission du SRAS-CoV-2 en milieu dentaire et de la transmission de l'infection dans le cadre de procédures pouvant générer des aérosols (PGA) utilisées dans les soins dentaires?

Les PGA peuvent augmenter le risque de transmission de l'infection d'un patient infecté à un travailleur de la santé en raison de la proximité et de la production de forts volumes d'aérosols. Le présent résumé des éléments de preuve résume la littérature et les conseils disponibles sur les procédures pouvant générer des aérosols (PGA) dans le milieu des soins dentaires en ce qui concerne la transmission du SRAS-CoV-2 et peut être utilisée avec le résumé des éléments de preuve sur l'analyse aérodynamique du SRAS-CoV-2 datée du 28 mai 2020, qui résume les preuves sur l'aérosolisation du SRAS-CoV-2, qui est disponible par l'intermédiaire du Secrétariat des sciences émergentes de l'ASPC.

Points clés

- Aucun rapport publié sur la transmission de la COVID-19, les grappes ou les éclosions dans le milieu des soins dentaires n'a pu être recensé.
- Aérosolisation du SRAS-CoV-2 :
    - Des échantillons d'air prélevés dans le milieu des soins hospitaliers traitant des cas de COVID-19 ont démontré une contamination par l'ARN du SRAS-CoV-2, probablement par des aérosols et de petites gouttelettes respiratoires (Guo *et al.*, 2020; Liu *et al.*, 2020; Santarpia *et al.*, 2020). On a constaté que le SRAS-CoV-2 restait viable sous forme d'aérosol pendant une période pouvant aller jusqu'à 4 heures, mais ni le caractère infectieux ni la dose infectieuse de ces particules n'ont été établis (van Doremalen *et al.*, 2020).
    - Les procédures dentaires peuvent induire des réflexes nauséeux entraînant une augmentation de la sécrétion de salive et de la toux chez les patients. Les instruments dentaires à grande vitesse peuvent créer de grands volumes d'aérosols contenant de l'eau, de la salive, du sang, des micro-organismes et d'autres débris (Ather, Patel, Ruparel, Diogenes, et Hargreaves, 2020; Jamal *et al.*, 2020; Sales, Sales et Da Hora Sales, 2020).

- Une publication récente de Workman *et al.* fait état de simulations à l'aide de cadavres au cours desquelles les risques d'aérosolisation liés aux procédures endonasales ont été évalués (Workman *et al.*, 2020). L'étude conclut que les procédures de forage chirurgical à grande vitesse ont entraîné une contamination substantielle par des aérosols dans toutes les conditions testées. Ces résultats peuvent être étendus aux forages et aux procédures dentaires, qui sont considérés comme des procédures générant des aérosols.

- Documents d'orientation :
  - Les directives publiées indiquent que les patients chez qui la COVID-19 est confirmée ou suspectée ne doivent PAS être traités dans un environnement de soins dentaires de routine et ne doivent être pris en charge que dans des chambres d'isolement des infections aéroportées (CIIA) (Ather *et al.*, 2020; Jamal *et al.*, 2020).
  - L'examen de plusieurs documents d'orientation sur les soins dentaires et la COVID-19 révèle que certaines procédures et certains équipements utilisés sont associés à un risque accru de production d'aérosols et devraient être soit évités soit modifiés pendant la pandémie de COVID-19 (tableau 1). Les orientations spécifiques liées aux procédures et aux instruments qui génèrent des aérosols tirées de ces publications sont résumées ci-dessous.
    - Les radiographies intra-orales doivent être évitées et remplacées par l'imagerie extra-orale telle que la radiographie panoramique ou la tomographie assistée par ordinateur à faisceau conique lorsque l'imagerie intra-orale est inévitable (Ather *et al.*, 2020; Jamal *et al.*, 2020; Meng, Hua et Bian, 2020).
    - L'utilisation d'une digue en caoutchouc pour minimiser la génération d'éclaboussures est la norme de soins pour les traitements endodontiques non chirurgicaux. Les recommandations suggèrent qu'il peut être avantageux de placer la digue en caoutchouc de manière à ce qu'elle couvre le nez (Ather *et al.*, 2020; Jamal *et al.*, 2020; Sales, Sales et Da Hora Sales, 2020). En outre, lorsque la digue en caoutchouc est utilisée, il est recommandé d'aspirer à très haut volume les aérosols et les éclaboussures, en plus de l'aspiration régulière (Peng *et al.*, 2020).
    - Il a été établi que les instruments à ultrasons tels que les seringues à triples voies, les fraises dentaires à haute vitesse, les détartreurs à ultrasons, les dispositifs d'abrasion à l'air et les sableuses intra-orales sont associés à un risque accru d'aérosolisation qu'il convient d'éviter ou de réduire au minimum (Ather *et al.*, 2020; Jamal *et al.*, 2020; Meng *et al.*, 2020; Sales *et al.*, 220). Si l'utilisation d'un tel équipement est inévitable, l'application de pompes à salive à grand volume est recommandée en plus des instruments applicables (Ather *et al.*, 2020; Jamal *et al.*, 2020; Meng *et al.*, 2020).
    - Pour réduire au minimum le risque d'aérosols dentaires, il est recommandé d'utiliser, dans la mesure du possible, des instruments à main, des fraises dentaires à faible vitesse, des

instruments sans jet d'eau et des instruments à main équipés d'une valve anti-retrait ou d'une autre technologie anti-reflux (Ather *et al.*, 2020; Jamal *et al.*, 2020).

- Peng *et al.* suggèrent que l'utilisation d'instruments à main dentaires sans fonction anti-retrait devrait être interdite durant l'épidémie de COVID-19. Un instrument à main dentaire doté de valves anti-retrait spécialement conçues ou d'autres conceptions anti-reflux sont fortement recommandés comme mesure préventive supplémentaire des infections croisées. Il est important de noter que ces recommandations sont basées sur des preuves antérieures de la transmission de l'hépatite B dans le milieu des soins dentaires (Peng *et al.*, 2020).

Vue d'ensemble des éléments de preuve

Actuellement, il n'existe aucun rapport publié sur les grappes ou les éclosions de COVID-19 liées aux soins dentaires. Aucune étude de simulation publiée n'a évalué spécifiquement la dispersion des gouttelettes ou la génération d'aérosols associées aux procédures dentaires depuis l'apparition de la COVID-19. La désignation de PGA en milieu dentaire est largement fondée sur des preuves issues de simulations d'interventions médicales ou sur les conseils de diverses associations dentaires à l'échelle nationale. Les éléments de preuve disponibles établis à la lumière d'interventions médicales sont peu nombreux, largement théoriques, et ne prennent pas explicitement en compte l'infectiosité des aérosols du SRAS-CoV-2; toutefois, ils ne semblent pas être de mauvaise qualité.

Les procédures pouvant générer des aérosols (PGA) et la transmission de la COVID-19 dans les soins dentaires sont des sujets peu étudiés qui présentent des lacunes importantes en matière de connaissances. Ces domaines pourraient tirer des avantages de recherches et de rapports supplémentaires axés sur les expériences en dentisterie pendant la pandémie de COVID-19.

TABLE DES MATIÈRES

DIRECTIVES SUR LA COVID-19 POUR LE MILIEU DES SOINS DENTAIRES

Tableau 1 : Cinq examens décrivent les procédures dentaires générant des aérosols, les données probantes sous-jacentes et les conseils disponibles pour réduire les aérosols générés au cours des procédures dentaires.

Référence	Principales caractéristiques
(Ather *et al.*, 2020)	Fournit un aperçu de l'épidémiologie, des symptômes et des voies de transmission de la COVID-19, ainsi que des recommandations spécifiques pour la pratique dentaire pendant la pandémie actuelle. Ces recommandations s'appuient sur les nouvelles données probantes concernant le SRAS-CoV-2 et sur les expériences de transmission passées du SRAS-CoV-2 dans les établissements de santé.
(Jamal *et al.*, 2020)	Examine et résume les directives sur la COVID-19 publiées par plusieurs associations dentaires nationales, notamment les directives de l'American Dental Association, du Scottish Dental Clinical Effectiveness Programme, de la déclaration conjointe de la New Zealand Dental Association et de l'International federation of Endodontic Association - Indian Endodontic Society et de l'American Association of Endodontics.
(Meng *et al.*, 2020)	Décrit les procédures et les techniques générant des aérosols qui ont été évitées dans un hôpital de stomatologie à Wuhan, en Chine, lors de l'émergence de la pandémie COVID-19 au début de l'année 2020.
(Peng *et al.*, 2020)	Fournit un aperçu des données probantes disponibles sur les voies de transmission de l'infection par la COVID-19 et décrit les mesures de prévention de l'infection par la COVID-19 et les conseils pour les milieux dentaires. Les auteurs plaident fortement pour l'interdiction de l'utilisation d'instruments à main dentaires sans fonction anti-retrait pendant la pandémie. Les preuves contre l'utilisation d'instruments à main sans fonction anti-retrait proviennent d'études sur le risque d'infection croisée par le virus de l'hépatite B (qui n'est pas un virus respiratoire).

(Sales *et al.*, 2020)	Examine la documentation disponible et fournit des recommandations pour les soins dentaires à la lumière de la pandémie de COVID-19. Recommande d'éviter les instruments à grande vitesse et d'utiliser des barrages en caoutchouc pour atténuer les risques liés aux aérosols.

Méthodologies

Une analyse documentaire quotidienne (ouvrages publiés et en prépublication) est effectuée par le Groupe des science émergentes de l'ASPC. L'analyse a compilé les ouvrages sur la COVID-19 depuis le début de l'éclosion et est mise à jour quotidiennement. Les recherches visant à extraire les ouvrages pertinents sur la COVID-19 sont menées dans Pubmed, Scopus, BioRxiv, MedRxiv, ArXiv, SSRN et Research Square, et les résultats sont recoupés avec les ouvrages figurant sur la liste de la documentation sur la COVID de l'Organisation mondiale de la Santé et des centres d'information sur la COVID-19 gérés par Lancet, BMJ, Elsevier et Wiley. Le résumé quotidien et les résultats complets de l'analyse sont conservés dans une base de données RefWorks et dans une liste Excel consultable. Une recherche ciblée par mot-clé est effectuée dans ces bases de données pour recenser les citations pertinentes sur la COVID-19 et le SRAS-CoV-2. Les termes de recherche utilisés comprenaient les suivants : aérosol, dentaire

La présente revue contient des recherches publiées jusqu'au 9 juin 2020.

Chaque référence potentiellement pertinente a été examinée pour confirmer qu'elle comportait des données pertinentes, qui ont été extraites dans la revue.

Emerging Evidence on COVID-19

Rapid Review on SARS-CoV-2 Aerosol Transmission, Update 2

Introduction

What is the emerging cluster/outbreak, experimental and biological evidence implicating aerosol transmission of SARS-CoV-2?

The scientific evidence and understanding of SARS-CoV-2 modes of transmission has rapidly evolved over the past year. Expelled respiratory particles containing infectious pathogens can occur in a continuum of sizes, and smaller respiratory particles (often termed aerosols) can remain suspended in air and disperse further distances than large respiratory droplets. Other pathogens that are known to primarily transmit through large droplets (e.g., Influenza, SARS-CoV-1, streptococcus pneumonia, and *Legionella*) can also spread by aerosols in some settings and conditions (1-6). As such, a range of evidence has been produced to describe the characteristics and relative importance of aerosols in SARS-CoV-2 transmission in different settings and conditions.

This evidence brief summarizes the scientific literature providing evidence on SARS-CoV-2 aerosol transmission published up to March 12, 2021 and is organized into the follow evidence sections:

1) SARS-CoV-2 cluster or outbreak investigations that have implicated aerosol transmission;
2) Experiments on indirect transmission of SARS-CoV-2 virus using animal models;
3) Experimental evidence on SARS-CoV-2 virus stability and viability in aerosols;
4) Biological monitoring studies on SARS-CoV-2 RNA in exhaled breath; and
5) Biological monitoring studies on SARS-CoV-2 RNA and viability in environmental air samples in patient care and in community (i.e., non-hospital/patient care) settings.

The evidence section on fluid dynamic simulations and *in-silico* analyses has been omitted from this update given the increasing amount of empirical evidence supporting the potential for SARS-CoV-2 aerosol transmission.

What's New

- This update identified 46 new studies, pre-published and published, between November 6, 2020 (the last update date) and March 12, 2021 on SARS-CoV-2 aerosol transmission potential. These studies are summarized below and identified as *new* throughout the evidence tables.
- The update includes twelve new reports of SARS-CoV-2 outbreaks/cluster investigations in real-world settings (Table 1). These aerosol implicated transmission events were reported to have occurred inside a post-travel quarantine hotel, nursing home, hospital hematology unit,

passenger bus, a restaurant, fitness facilities, department store, and apartments arranged in a vertical line in an apartment building (7-16). In these reports, most reported mask use was infrequent or improper at the time of assumed aerosol transmission, and index cases were reported to be at pre-symptomatic or early symptomatic stages of infection.

- Two new animal model-based experiments reported on multiple modes of SARS-CoV-2 transmission, including aerosols, between infected and susceptible hamster pairs (17, 18). One study suggested aerosol exposure led to earlier virus replication, shedding in respiratory tissue, and more acute disease manifestation in hamsters, when compared to fomite and intranasal exposures (17). The other study found aerosols from naïve infected hamsters can infect previously infected hamsters, which suggests recovery from a primary SARS-CoV-2 infection does not eliminate subsequent infection risk by aerosols (18).
- A newly included experimental study investigating the viability and decay rates of SARS-CoV-2 virus in aerosols reported the infectiousness of virus in aerosols to be highly dependent on environmental conditions in the following order of influence: simulated sunlight exposure levels (midday summer, spring midday, indoor/night tested) >temperature (10-40 °C tested)> humidity (20-70% tested) (19). A 90% reduction in infectious virus was estimated to take 4.8 minutes (at 40^0C, 20% relative humidity) with midday summer sunlight exposure, with similar reductions estimated to take more than 2 hours (at 40^0C, 20% relative humidity) under no sunlight exposure conditions (i.e., indoors or at night). Sunlight had the largest influence on decay rate, however higher decay was also noted at 30°C with high (70%) humidity or at 40°C regardless of humidity.
- One new biological monitoring study on exhaled breath samples from five patients found viral RNA to only be detected in exhaled air samples of COVID-19 patients with positive oropharyngeal, nasopharyngeal, and/or salivary swabs at the time of sampling (20).
- Twenty-eight new biological monitoring studies that investigated SARS-CoV-2 virus contamination in environmental air samples in patient care (includes hospitals and long-term care studies) and in community (i.e., non- patient care) settings are included in this update.
    - Two Canadian studies suggested viral RNA contamination in environmental air samples from a hospital (~ 3 meters from COVID-19 patients) and on no touch surfaces from long-term care home settings (21, 22) to indicate SARS-CoV-2 can spread through aerosols.
    - A new study confirmed the presence of viable virus in air samples collected from a car driven by a mildly symptomatic individual (23). This highlights SARS-CoV-2 virus can be expelled in to the surrounding air, even by a mild case over a short period of time (23).
    - Another study compares environmental air samples collected from inpatient hospital rooms and quarantine households with active cases (24). The household environmental air samples were estimated to be approximately eight times (OR 8.75 [95% CI 1.21-63.43; p=0.058]) more likely to be contaminated with viral RNA than hospital air samples. Based on these study findings the investigators suggest differences in air exchanges and

ventilation to be a key difference that is more important than disease acuity, with respect to environmental air contamination.

Key Points

- In total, 84 studies on the potential for aerosol transmission have now been identified in the published and pre-published literature. Multiple outbreak and cluster investigations suggest aerosol transmission of SARS-CoV-2 may have occurred in some settings. Emerging experimental evidence in separated animals indicates infection can spread from aerosol exposure, and infectious virus can remain stable and viable within suspended aerosols. Biological monitoring studies confirm the presence of viral RNA in exhaled breath and environmental air samples. Clinical evidence informed systematic review and meta-analysis estimates of viable respiratory virus emission of SARS-CoV-2.
- Twenty-six investigations of twenty different COVID-19 outbreaks/clusters in different real-world settings (e.g., nursing home, hospital hematology unit, post-travel quarantine hotel/facility, meat processing plants, indoor choir practice, restaurant, cruise ship, passenger bus, fitness facilities, high-rise apartment building and shopping mall), have implicated aerosol transmission among cases (Table 1). The outbreak investigations suggest aerosol transmission is amplified and/or more likely to occur in some settings and under some conditions such as poorly ventilated or crowded indoor spaces, presence of early symptomatic or pre-symptomatic cases, or when individuals are engaged in physically exertive activities (e.g., singing, fitness classes).
- A systematic review and meta-analysis of clinical estimates found the likelihood of viable virus in respiratory aerosols expelled by an individual at peak viral load to be 61.1% (95% CI: 51.8-70.4%), and the likelihood estimates to be substantially lower at ≤ 0.69% (95% CI: 0.43-0.95%) for an individual with a mean viral load Peak viral load was estimated to happen between 1 day before symptom onset to 5 days post symptom onset (Table 7). This is consistent with the findings across outbreaks where the index case was usually pre-symptomatic or very early in their symptomatic illness when transmission occurred.
- Animal studies provide evidence on infection by aerosols, and infection transmission even when infected and susceptible animals are separated by cage setup or barriers. This indirect infection transmission is at least partially attributed to aerosols and air flow by the study investigators (Table 2).
- Three studies report on aerosol virus stability and viability, as well as the influence of environmental factors (e.g., temperature, humidity and sunlight exposure) on virus persistence in aerosols (Table 3). Experimental evidence has demonstrated prolonged viability of SARS-CoV-2 virus within laboratory aerosols for up to several hours (range 2 to 16 hours).
- Biomonitoring studies measure viral RNA in exhaled breath samples of infected individuals (Table 4) and environmental air from patient care and community settings (Table 5 and Table 6). The increasing number of studies that confirm the presence of SARS-CoV-2 in environmental air provide

additional evidence to support aerosol transmission in community settings. The few studies that confirmed virus viability in cell culture reported collecting environmental air samples near (<2 meters) infected individuals (Table 5 and Table 6).

Overview of the Evidence

The available body of evidence on the potential transmission of SARS-CoV-2 by aerosols in the published and pre-published literature is rapidly evolving. This review includes studies (n=84) accessed up to March 12, 2021 and deemed relevant by a single reviewer. The overall quality of the evidence reviewed is broadly described below for each section of presented evidence based on study design, quantity, and consistency of the presented data. Briefly, the hierarchy of evidence and general quality ratings consider well-conducted randomized controlled trials to be high quality due to their low risk of bias. Other experimental designs may be considered moderate quality, but may also be downgraded due to power or conduct issues. Experiments using animal models are considered low quality evidence. Observational studies are generally considered to be at high risk of bias and thus low quality, however some large, well-conducted, prospective cohort studies may be assessed to be of moderate or low risk of bias, and thus may be considered moderate to high quality.

There are 26 outbreak/cluster investigation studies focusing on 20 different human outbreaks that suggest aerosol transmission of SARS-CoV-2 (Table 1). These are retrospective observational studies that are at risk of numerous biases. The retrospective nature of these investigations and the lack of genotyping data on the majority of identified cases mean that inferences about aerosol transmission are limited to epidemiological linkages. Multiple cluster investigations include both a description of the investigation as well as *in silico* simulations that explore the potential for aerosol transmission in real world settings.

Animal models provide experimental evidence on infection by aerosol exposure, by assessing indirect transmission from infected to susceptible animals by either passive or directed air flow, when separated using a variety of cage and barrier setups (Table 2). These studies did not provide sufficient details about the symptoms and behaviors of the infected animals (e.g., sneezing and respiratory fluid transfer by sniffing/licking barriers) or the experimental setup to rule out infection transmission by contact with respiratory and oral fluids in most experiments. Overall, animal models of transmission offer the lowest quality of evidence for aerosol transmission.

Three experimental studies provide evidence confirming the stability and viability of infectious virus in artificially generated and suspended aerosols (Table 3). Although these studies provide robust evidence that supports the longevity of infectious virus in laboratory environments for as much as 16 hours, the extension of these findings to real-world settings by biological monitoring studies remains largely unestablished.

The majority of identified biological monitoring studies looked for SARS-CoV-2 viral RNA in exhaled breath (Table 4) and environmental air samples in different settings (Table 5 and Table 6). These provide moderate quality evidence that viral RNA can either travel or linger in air at some distance from an

infected individual in some settings and conditions. There is limited reporting of information on virus concentration in positive samples, sampling distance from infected individuals, and whether or not there was virus viability documented by cell culture. The lack of these details limit the generalizability of biological monitoring evidence to all indoor settings and all infected individuals, and hinder the identification of settings and conditions that lead to increased concentration of viable virus from exhaled breath and aerosolized particles in the air. Furthermore, it is likely the large range of sample collection settings (e.g., patient care vs. community settings) and techniques (e.g., exhaled breath vs. exhaled breath condensate) may have influenced the sensitivity of viral RNA quantification and viable virus detection tests, applied in biological monitoring samples. Additional research is needed to confirm the infectiousness and viability of SARS-CoV-2 within air samples to know where and when the risk of aerosol transmission of SARS-CoV-2 becomes more likely.

This review summarizes the evidence on aerosol transmission of SARS-CoV-2 and characterizes the settings and/or conditions that have been studied. Additional evidence is needed to address knowledge gaps on aerosol transmission of SARS-CoV-2:

1) Quantifying the infectious dose of SARS-CoV-2;

2) The case attributes and environmental conditions under which viable virus is likely to be present in exhaled breath, remain suspended and be circulated in environmental air;

3) Genomic data from cluster and outbreak investigations suggesting indirect SARS-CoV-2 infection transmission in humans;

4) Confirmation of the relatedness of cases by genotyping data, and better quality data supporting aerosol transmission in the implicated outbreaks/clusters; and

5) Formal review of fluid dynamic literature from experts in this field that best outline the environmental conditions and behavioral activities that increase (or decrease) respiratory aerosol release and infection transmission, as well as quantify aerosol transmission risk estimates.

CONTENTS

CLUSTER/OUTBREAK INVESTIGATIONS

This section provides a summary of twenty six studies describing twenty different COVID-19 cluster/outbreaks in real-world settings that epidemiologically support infection transmission by aerosols (Table 1). In a number of studies the same COVID-19 cluster/outbreaks were investigated by separate groups of investigators who all concluded aerosols or the long-range indirect transmission of virus to have played a role in infection spread among cases. These outbreaks have been organized according to the setting in which infection transmission was assumed to have occurred by the study investigators. The settings included a hematology unit at a hospital, a travel quarantine hotel, passenger buses, fitness classes and facilities, a meat processing plant, dine-in restaurants, a choir practice, a cruise ship, department stores, and different high-rise apartment buildings. The evidence includes epidemiological investigations, computational fluid dynamic analyses/simulations, video surveillance footage, or spatial analysis of cases during the transmission event.

Interestingly, multiple COVID-19 cluster/outbreaks were described to have occurred in settings similar to one another, which suggests these settings may be more favorable to aerosol transmission. Common attributes were closed spaces with minimal ventilation (i.e. few or no windows, insufficient ventilation and air circulation), presence of pre-symptomatic, early symptomatic index case(s), and the spread of virions beyond 2 meters enhanced by artificial air flow, ventilation systems, air ducts, drainage pipes or inefficient ventilation. Additionally, in some situations the infector and infectees were engaged in activities that typically increase exhalation rates (e.g., physical exercise, singing), or were in crowded spaces during the transmission events.

It is worth noting other than for one of the summarized studies, none reported on the genetic sequences of virus isolated from outbreak/cluster cases, and many studies do not describe mask use during the exposure events. These are important gaps within the existing evidence because genotyping data would confirm the relatedness of cases while mask use data would provide insights regarding the effectiveness of this prevention measure. The lack of this information within the summarized outbreak/cluster investigations is a key limitation of this evidence.

Table 1: SARS-CoV-2 cluster or outbreak investigations that have implicated aerosol transmission (n=26)

STUDY	METHOD	KEY OUTCOMES
Hospital hematology setting		
Saidel-Odes (2021) (25) Cluster Investigation Israel Sep – Oct 2020	Investigation of a COVID-19 outbreak linked to an index patient who was immunocompromised with multiple myeloma and underwent stem cell	Seven healthcare staff in the transplant unit housing the index patient were diagnosed with the infection; attack rate of 19% (n=7/37). The infected staff included 2 doctors, 4 nurses, and 1 housekeeping worker. Two of the positive staff did not report any direct contact with the index

new	transplant. Patient was treated in an AIIR following COVID-19 diagnosis, and healthcare staff donned appropriate PPE (i.e., N95, face shield, gown and gloves) prior to entering the patient's isolation room. All staff in the unit wore gowns, gloves and masks.	patient. The outbreak investigation and univariate analysis found infected healthcare workers were more likely to have reported spending time in the unit's corridor or nurses' station ([RR], R = 7.2; 95% CI, 1.22–42.49; *P* = .018), but not in the index patient's room. The investigators suggest aerosol transmission to be the only plausible explanation for this outbreak.
Hotel quarantine and airplane setting		
Eichler (2021) (14) Cluster Investigation New Zealand Sep 2020 *new*	Investigation of a COVID-19 outbreak that occurred during repatriation, at a mandatory isolation and quarantine facility (hotel) and among household contacts in the community. Cases who were returning from other countries were required to complete a mandatory quarantine and isolation at a facility for 14 days after landing at their destination.	Based on the application of video surveillance data and viral genomic analysis of cluster cases, the investigators suggest multiple transmission chains. The suspected sites of transmission were international and domestic flights, the quarantine facility, and households. While aerosol transmission may have been the mode in each transmission event, but an in-depth investigation concluded aerosol transmission was the primary mode of infection transmission at the hotel quarantine facility The case exposures/transmissions in the outbreak are assumed to be as follows: - 2 index cases infected around the time of repatriation travel from India to Christchurch, NZ. 1 exposed on the flight to Christchurch, 2 exposed in hallway at the quarantine facility (by aerosols see below), 1 exposed on the flight from Christchurch to Auckland (transmission from the 2 aerosol exposed cases who tested negative on day 12 of quarantine), with additional cases among household contacts of the last three cases. Based on computer footage the investigators concluded aerosol transmission to have taken place at the doorway of two different hotel rooms

		that housed individuals in quarantine by suspended aerosols. Transmission was assumed to have occurred during a 50-second window between closing the door to the room of one case and opening the door to the room of other cases. Note: A review of the hotel's ventilation system found the rooms in question had a net positive pressure compared with the corridor so air flow into the corridor when the door was open was likely.
Nursing home setting		
de Man (2020) (15) LTE Cluster Investigation Netherlands Jun –Jul 2020 *new*	Investigation of a COVID-19 outbreak in a single ward of a 7 ward Dutch nursing home.	A total of 17/21 residents in the ward and 13/34 healthcare workers from the ward, and an additional 4 laboratory workers were confirmed cases linked to the cluster; attack rate among residents was 81% and among healthcare workers was 50%. All 106 healthcare workers and 95 residents of other wards remained negative for COVID-19. Healthcare workers wore facemasks during patient care and worked in designated wards to limit contacts. The outbreak was limited to a single ward (out of 7 wards in the facility) with a ventilation system that recirculated unfiltered air. The ventilation system was new and monitored CO2 concentrations to determine when to refresh the air with outside air. Viral RNA was detected in the ventilation system (air conditioners and ventilation cabinet dust filters). The investigators state transmission was likely the result of aerosol transmission in an inadequately ventilated setting/ward given the simultaneous detection of a large number of cases limited to one ward, and occurred during a time of low community transmission.
Transportation bus setting		
Luo (2020) (7)	Investigation of a COVID-19 outbreak linked to	A total of 12 cases were identified following the investigation of 243 individuals who were

Cluster Investigation China Jan 2020 *new*	multiple bus trips by the index case, in Hunan China.	epidemiologically linked to multiple bus trips taken by the index case, attack rate of 7.0%. The seated distance of the infected individuals during bus rides ranged from 1-4.5 meters from the index case. The 2.5 hour coach ride resulted in 8 cases and not all cases were clustered close to each other during the trip. Infection was also identified in an individual who sat (approximately) on the same seat as the index case, after the index case had existed the bus. 2 cases were identified from the 1 hour minibus trip. 2 cases were tertiary cases to one of those infected on the bus. None of the identified cases reported wearing face masks during bus rides. The investigators suggest aerosols traveling beyond 2 meters and air flow to have influenced infection transmission in the crowded and closed environment of these transportation buses.
Shen (2020) (26) Cluster Investigation China Jan 2020	A COVID-19 outbreak among 128 people driven to a worship event in Eastern China on two separate buses. Round trip was 100 minutes on the bus. Attack rates were measured for Bus 1 vs. Bus 2 that had the index case. Air conditioning systems of both buses were on recirculation mode. Spatial analysis of passenger seating was estimated.	None of the passengers on Bus 1 were infected, 24 of the 68 passengers on Bus 2 developed COVID-19. Passengers riding Bus 2 with the index case had an attack rate of 34.3% (95% CI, 24.1%-46.3%), compared to passengers on bus 1. Although sitting near bus windows and doors appeared to have had a protective effect on infection transmission, the authors conclude, the lack of a significant increase in infection risk between individuals sitting in high risk zones (i.e. closer to the index case) and low risk zones, and elevated attack rates among bus passengers riding with the index case, to be partially explained by aerosol transmission of infection.
Meat processing plant setting		
Guenther (2020) (27) *preprint*	Investigation of a super-spreader event among	The analysis of index cases (flatmates) and 18 co-worker cases suggest working the early morning

Cluster Investigation Germany Spring 2020*	meat processing plant workers that included: possible routes of transmission, spatial relationship between workers, climate/ventilation conditions, sharing of living quarters and transportation, and genetic typing of oropharyngeal swab samples.	shift (140 early shift workers) to be the common source of infection. Statistically significant infection rates were observed for workers working within an 8-meter radius of the suspect index case. Authors conclude indoor confined settings, demanding physical work, and the facility's environmental conditions (i.e. air being constantly re-circulated and cooled to 10°C, with low air exchange rates) all created conditions for aerosol transmission. Note: quantitative risk estimates were not provided.
Restaurant setting		
Kwon (2020) (8) Cluster Investigation Korea Jun 2020 *new*	Investigation of a cluster among 3 patrons at a restaurant. The investigation considered epidemiological data, television images, air flow patterns and cell phone location information.	The investigators concluded infection transmission occurred from an infected customer to two individuals at the restaurant venue, attack rate of 15.4% (2/13). Source and time of exposure was assumed to be one day prior to symptom onset in the index case. The assumed mode of transmission was aerosols that travelled greater than 6.5 meters via air conditioner air flow current inside the restaurant venue. The exposure time between the infector and the infected is reported to be approximately 5 minutes. Mask use is reported to have been improper among staff and patrons.
Lu (2020) (28) Cluster Investigation China Jan-Feb 2020	Investigation of a COVID-19 cluster among restaurant patrons. The investigation included a spatial analysis of restaurant table arrangement and where cases were seated.	An outbreak among 91 individuals at a restaurant, 83 had dined at 15 tables, and the remaining 8 individuals were staff. A single asymptomatic case led to 9 COVID-19 infections among diners from three families. None of the families had met previously and did not have any close contact during lunch. No additional cases were identified during the 14 days quarantine of the remaining diners.

		Spatial analysis of case tables during lunch (i.e., exposure event reveal) found the affected tables had been arranged in line with airflow from an air conditioning unit. Authors suggest infection transmission could not be explained by droplets alone, and aerosols travelling with air flow may have contributed to infection transmission.
Li (2020) (29) *In silico* study China Feb 2020 Note: Same outbreak described by Lu (2020).	An investigation and analysis of a COVID-19 cluster among 3 families who ate at the same restaurant. The analysis included: epidemiological data, spatial analysis of restaurant table arrangement, video surveillance data, and computer fluid dynamic and tracer gas simulations of event's fine droplet spread.	10 people from three different families seated at different tables were found to have been infected with SARS-CoV-2 following a Chinese New Year's Eve (January 24, 2020) lunch. None of the waiters or patrons at the remaining tables became infected. Ventilation rate was estimated to be 0.9L/s (0.75-1.04 L/s) per person. No close contact or fomite contact was observed among cases, aside from back-to-back sitting by some patrons. Using computer simulations the authors demonstrate infection distribution to be consistent with the spread pattern of exhaled virus aerosols. These results highlight transmission occurring in a crowded and poorly ventilated indoor situation.
Choir practice setting		
Charlotte (2020) (16) Cluster Investigation France Mar 2020 *new*	The investigation of a COVID-19 outbreak linked to a choir practice, in Whir au Val, France.	Twenty-seven participants (25 singers, 1 conductor and 1 accompanist) attended the indoor choir practice that took place in a non ventilated space of 45 m^2. No attendees reported being symptomatic in the 14 days prior to the practice date. 19/27 attendees developed COVID-19 infections at 1 to 12 days post practice date (median of 5.1 days). The secondary attack rate was 70% among all attendees. The investigators assume infection transmission occurred by aerosols from presymptomatic or

		asymptomatic individual(s) who attended the choir practice as the index case was not definitively identified.
Hamner (2020) (30) Cluster Investigation USA Mar 2020 Note: Same outbreak described by Miller (2020).	The investigation of a COVID-19 outbreak linked to a choir practice, in Skagit County, Washington. The practice lasted for 2.5h. During practice people were singing and seated 6-10 inches apart, socializing with communal snacks, and stacking chairs. None of the attendees reported physical contact.	Among the 61 choir members attending the practice, at least one singer was known to be a symptomatic COVID-19 case. The epidemiological investigation reported 53 cases (33 confirmed, 20 probable cases). Secondary attack rates were 53.3% among confirmed cases and 86.7% among all cases. The odds of infection were 125.7 (95% CI: 31.7-498.9) times greater among members who attended the March 10 practice (assumed exposure event). The investigators introduce the potential for aerosol emission and COVID-19 transmission during singing in the COVID-19 literature.
Miller (2020) (31) *In silico* study USA Mar 2020 Note: Same outbreak described by Hamner (2020).	Monte Carlo simulations and mathematical modeling were used to estimate aerosol emission rates in the outbreak linked to a choir practice, in Skagit County. The applied model assumes infection transmission during the outbreak was dominated by inhalation of respiratory aerosols in a well mixed indoor environment (i.e. the aerosols were evenly distributed in the air). The viral load emitted was expressed as quanta emission rate (quanta per hour^{-1}) where a quantum	*In silico* analysis supported aerosol transmission from respiratory aerosols based on assumption that high emission rates occurred given the high attack rate (53-87%), which was higher than would be expected if the transmission was due to fomites or large respiratory droplets. The model estimates the mean respiratory aerosol emission rate for a single infected case at the exposure event to be 970 [IQR 680-1190] quanta per hour^{-1}.

	was defined as the dose of aerosol droplet nuclei required to cause infection in 63% of susceptible persons.	
Multiple outbreaks		
Buonanno (2020) (32) *In silico* study China and US (sites of applied outbreaks) Feb-Mar 2020 Note: A different analysis of restaurant and choir practice outbreaks described above	This is an emission and exposure model that used a step-wise approach to quantify individual infection risk among susceptible subjects exposed to an asymptomatic/ mildly symptomatic case in choir practice and dine-in restaurant. Also used Monte Carlo method; individual infection risks were calculated as a function of quanta emission characteristics.	The model illustrated individual infection risk increased based on ventilation rates, activities and amount of virus exhaled. For instance, sedentary activities for 1 hour may have an infection risk of 2.1%, which can increase to 27% with higher emission rates. Based on risk assessment approach and available data, quanta emission rates were estimated to be 61 quanta/hour for the restaurant and 341 quanta/hour for the Skagit Valley choir practice. In both of the examples, varying the ventilation would not have achieved an individual risk <0.1. The authors concluded aerosol transmission represents the main route of transmission for both outbreaks.
Kriegel (2020) (33) *In silico* study Germany, China, USA, (sites of applied outbreaks) Feb-Mar 2020 Note: Included the following clusters: Meat Processing plant- Guenther (2020), Choir Practice- Hamner	An extension of the Wells-Riley equation was used to estimate predicted infection risk via aerosols in twelve published and unpublished COVID-19 outbreaks. Predicted infection risks were compared to observed attack rates in each event. To estimate a "credible interval" for model predicted infection risks, the quanta emission rate,	In nine out of the twelve outbreaks the observed attack rates were in range with the predicted infection risk via aerosols and the corresponding ranges (with the variation of the boundary conditions). Predicted Infection Risk via Aerosols (PIRA)/attack rate (AR) Meat processing plant: 25% (17-35)/ 26% Choir: 97% (88-99)/ 87% Restaurant: 40% (35-56)/ 45% Bus tour: 35% (19-58)/ 34%

(2020), Bus Passengers – Shen (2020), and Restaurant – Lu (2020)	the respiratory rate as well as the air volume flows were varied. The analysis assumes long range aerosol transmission in an ideally mixed environment.	The attack rates from all these outbreaks are reported to be in-line with estimated infection risk via aerosols.
Cruise ship settings		
Azimi (2021) (34) *In silico* study Cruise ship Jan-Feb 2020 Note: Same outbreak described by Almilaji (2020) and Xu (2020)	Analysis of case data from the Diamond Princess cruise ship outbreak. Applied a framework based on stochastic Markov chain and negative exponential dose-response modeling with empirical data, to inform a modified version of the Reed-Frost epidemic model, to predict case count rates. Assumed infected individuals could be infectious upto 1 day post incubation period, effective incubation periods were estimated to be 5-11/13 days, and considered different modes of transmission. Note: Case data from early 2020 were included in the analysis.	712 COVID-19 cases were identified in 3711 passengers and crew members, yielding an attack rate of 19%. Key estimates derived from the model included - short-range droplets and aerosols (35%), long-range aerosols (35%), and fomite (30%) as modes of infection transmission - large respiratory droplets (41%) and small respiratory aerosols (59%) as source of infectious virus - Case transmission proportions prior to and after the passenger quarantine was 58% (±5% SD) and 42% (±5% SD), respectively. T - Effective reproduction number before and after the quarantine period was 3.8 (±0.9 SD) and 0.1 (±0.2 SD). Based on the modeled estimates the authors concludes smaller respiratory aerosols contributed to a greater proportion to infection transmission aboard the cruise ship, on average, across all time periods (i.e., both before and after passenger quarantine). It was estimated that aerosol transmission was the dominant mode of transmission (>70% of cases) despite the high ventilation rates (9-12 air changes per hour) with no air recirculation in the cruise ship.
Almilaji (2020) (35)	Analysis of clinical and case count data from	Infection rates among passengers in cabins without previously confirmed cases was 1.2%,

Cluster Investigation Cruise ship Jan-Feb 2020 Note: Same outbreak described by Azimi (2020) and Xu (2020)	Diamond Princess cruise ship outbreak. Post quarantine symptomatic infection onset rates (SIRR) among lab confirmed cases were examined and the design of the cruise ship's air conditioning system was considered. Note: Case data up to February 20, 2020 were included in the analysis, and a median 5 day incubation period was assumed.	which was higher than rates among passengers in cabins with previously confirmed cases 0.8%. Based on this difference, the authors suggest airborne transmission of SARS-CoV-2 through the cruise ship's ventilation system may have contributed to the outbreak, and explain the higher infection rates in cabins without previously confirmed cases.
Xu (2020) (36) *preprint* Cluster Investigation Cruise ship Jan-Feb 2020 Note: Same outbreaks described by Azimi (2020) and Almilaji (2020).	Analysis of COVID-19 case data from the Diamond Princess cruise ship outbreak was analyzed based on individual risk factors, stateroom occupancy and the air conditioning (i.e. HVAC) system of the ship to explore the most plausible modes of transmission. Case data from January 20 to February 18, 2020 were included in this analysis.	Daily infection rates for passenger cases (n=146) were predicted based on close contact vs. non-close contact status, and pre- and post-quarantine data (February 5 was the start of quarantine). The investigators concluded most passenger cases were likely exposed before the passengers were quarantined and the cruise ship's air conditioning system did not play a role in long-range aerosol transmission of COVID-19.
Fitness/sports facility settings		
Groves (2021) (9) Cluster Investigation US Jun 2020	Investigation of a COVID-19 outbreak associated with multiple exposure events in Hawaii between a stationary cycling class instructor, a kick	20 cases were linked to two pre-symptomatic fitness instructors, at different fitness classes. The kick boxing/personal training instructor was a secondary case of the stationary cycling class instructor.

new	boxing/personal training instructor and their clients. Note: The average community transmission rate at the time of the outbreak was 2–3 cases per 100,000 persons per day, which suggests alternative exposures were unlikely.	The index instructor wore a face mask during the stationary bike class but the participants did not. The instructor was > 6 feet away and facing participants during the class. The room windows and doors were closed and floor fans (for cooling) directed air at participants. The transmission events with the second instructor are assumed to have occurred during small group kick boxing and personal training sessions when the instructor did not wear a mask and mask use was minimal among participants. Both instructors taught classes prior to symptom onset and the following aggregate attack rates for were calculated: - <1 day pre symptom onset (attack rate 95%) - 1 to <2 days pre symptom onset (attack rate 13%) - ≥2 days pre symptom onset (attack rate 0%) The outbreak investigators suggest infection transmission to have been facilitated by the lack of face mask use, extended close contact, poor room ventilation, and aerosol emission during physical activity and loud speech.
Lendacki (2021) (10) Cluster Investigation US Aug-Sep 2020 *new*	Investigation of a COVID-19 outbreak associated with indoor fitness classes that were conducted at ≤25% capacity (i.e., 10–15 persons) with participants ≥6 ft apart. Note: the building was not originally designed for exercise classes and the	55 COVID-19 cases (49 confirmed and 6 probable cases) were identified among 81 individuals who participated in indoor high-intensity exercise classes, attack rate of 68%. Mask use during the exercise sessions was reported to have been infrequent and approximately 75%. Outbreak was attributed to 2 index cases who attended multiple exercise classes when symptomatic and potentially infectious. Both attendees reported mask use ≤60% of the time in class (infrequent mask use). The odds of infrequent mask use compared to consistent mask use during classes was more

	buildings ventilation system was not assessed.	common among attendees with COVID-19 than attendees not diagnosed with COVID-19 (odds ratio [OR] = 3.5; 95% CI = 0.9–15.1). Attendees diagnosed with COVID-19 also reported attending more exercise classes (median of 5 vs. 3 classes) The authors suggest infrequent mask use, increased respiratory exertion during exercise, aerosol transmission, and sub-optimal ventilation may have contributed to infection transmission in this outbreak.
Jang (2020) (37) Cluster Investigation South Korea Feb-Mar 2020	Investigation of a COVID-19 outbreak associated with Zumba classes at 12 different fitness sports facility locations following an instructor workshop in Cheonan, South Korea.	The initial transmission event is assumed to have occurred among instructors at a 4-hour workshop where 8 of the 27 attendees tested positive for SARS-CoV-2. In the following weeks case counts associated with infected instructors grew to 112 cases across multiple fitness facilities. The workshop attack rate was 26.3% (95% CI 20.9%–32.5%) and the secondary attack rate from 8 instructors was 4.10% (95% CI 2.95%–5.67%, 830 close contacts). The investigators state approximately half of identified cases (50.9%) were due to transmission from instructors to fitness class participants; 38 cases (33.9%) were in-family transmission from instructors and students; and 17 cases (15.2%) were from transmission during meetings with coworkers or acquaintances. No secondary cases were observed among Pilates and yoga class students, led by an infected instructor. Authors state intense physical activity, large number of participants in a fitness class (i.e. crowded space), and the moist warm atmosphere of the sports facility may have contributed to high rates of infection in the outbreak.

Brlek (2020) (38) Cluster Investigation Slovenia Feb-Mar 2020	Investigation of a COVID-19 cluster linked to a squash court in a fitness facility.	The cluster involved 6 cases assumed to be linked through indirect transmission of infection. Epidemiological investigation indicated the index case developed symptoms during the game of squash, and four confirmed and one suspect case were linked to the same squash hall and potentially the same change rooms. None of the cases shared sports equipment or had contact with the facility staff. No additional cases were identified. Authors suggest the infection transmission within the cluster likely occurred due to aerosolization of virus in the indoor setting including small confined space, inadequate ventilation and strenuous physical activity.
Apartment building settings		
Hwang (2021) (11) Cluster Investigation South Korea Aug 2020 *new*	Investigated the role of aerosol transmission in a COVID-19 outbreak associated with an apartment building in Seoul.	10 COVID-19 cases in 7 households were identified along two vertical lines of apartments in a building, each line of apartments were connected through a single air duct in the bathroom for natural ventilation. Attack rate of 2% among the apartment building residents (n=10/437). None of the tested surfaces, including household ventilation grills and drains were positive for viral RNA. Transmission through droplets when occupying the same common space (e.g., an elevator) was assumed to have been unlikely due to the spatial arrangement of case apartments. The outbreak investigators assume vertical air flow through a single air duct in the bathroom (consistent with air flow in a vertical shaft) to have spread the infection to upstairs and downstairs apartment residents in the building.

Lin (2021) (12) Cluster Investigation China Jan – Feb 2020 *new* Note: A different analysis of the cluster described by Kang (2020).	Investigation of a COVID-19 cluster linked to families living in three vertically aligned units of the same apartment building. The index family reported possible travel related exposure in Wuhan, but the two other families with subsequent cases did not. Tracer gas was used to simulate air flow among units.	10 COVID-19 cases were identified in 3 households, phylogenetic analysis confirmed all cases were infected by the same strain. Video surveillance footage did not identify exposures between the index household members and other cases. Investigators conclude infection transmission to have likely occurred through drain pipes connected to the toilet which were connected to sewer pipes and flood drains, a system that was shared by the vertically aligned apartments.
Kang 2020 (39) Cluster Investigation China Jan – Feb 2020 *new* Note: A different analysis of the cluster described by Lin (2021).	Investigate infection transmission among three families living in the same apartment building. The index family reported possible travel related exposure in Wuhan, but the two other families with subsequent cases did not. Investigators used Ethane tracer gas as a surrogate for gas in the buildings drainage system and computational fluid dynamics to investigate possible sources of infection and transmission among families.	10 COVID-19 cases among three families who lived in vertically aligned apartments connected by drainage pipes in the master bathrooms. Attack rate of 4% among apartment building residents and staff (n=10/217) No exposure from the building's elevators were identified, and viral RNA was not detected on elevator buttons or air vent surfaces. The surfaces most frequently contaminated with viral RNA were in the master bathrooms, suggesting these areas to be probable infection transmission sites. Based on the epidemiological and *in-silico* analyses the investigators conclude infection transmission from the index family to the other two families likely occurred through fecal aerosols traveling within vertical drainage stacks of the apartment building. Note: none of the collected air samples from this setting were positive for viral RNA.
Shopping malls/stores		
Jiang (2020) (13) Cluster Investigation	Investigation of 43 SARS-CoV-2 cases linked to a cluster at a department store in Baodi, China.	43 COVID-19 cases linked to the outbreak at a department store: 6 salespersons, 18 customers, and 19 of their close contacts. The close contact

China Jan – Feb 2020 *new*	Epidemiological data, video surveillance footage, store layout and ventilation conditions were considered in the investigation.	cases were determined to have been secondary cases without exposure to the department store. The investigators conclude aerosols to have been a significant mode of transmission among 11 cases of the outbreak. The index case was not identified but it was assumed to have been one of the infected salespersons.
Cai 2020 (40) Cluster Investigation China Jan 2020	Investigation of a SARS-CoV-2 cluster linked to a shopping mall. Clinical, epidemiological and laboratory (RT-PCR) data of cases was analyzed to assess possible modes of infection transmission.	Two shopping mall co-workers were the index cases: this was associated with 7 infections among co-workers on the same floor, 7 mall staff from other floors, 10 mall shoppers, and 2 close case contacts outside of the mall. Shoppers and co-workers from other floors denied close contact with the index cases. Based on the available data the authors suggest infection spread could have resulted from spread via fomites or virus aerosolization in a confined public space (e.g. restrooms or elevators).

LTE= letter to the editor

ANIMAL EXPERIMENTS ON AEROSOL EXPOSURE AND TRANSMISSION OF SARS-COV-2

This section summarizes the six identified animal model studies that provided experimental evidence supporting aerosol transmission of SARS-CoV-2 (Table 2). The animal models used in the studies were non-human primates, ferrets and hamsters, all of which have been established as suitable animal models for the study of SARS-CoV-2 transmission in humans (41, 42)

Two experiments involved the controlled exposure of non-human primates and hamsters to artificially generated infectious aerosols at different virus concentrations to determine if infection can occur and to follow the clinical course of the infected host animals (17, 43). These studies provide evidence that SARS-CoV-2 infection can occur from exposure to infectious aerosols in a controlled setting. One of the studies in hamsters, that compared multiple modes of transmission (i.e., aerosol, fomite and intranasal) reported virus replication and shedding in the animals to be linked to the type of exposure. The authors observed earlier viral replication, higher viral loads, acute manifestation of respiratory symptoms, and different viral shedding patterns in the respiratory tissue of animals infected through aerosols compared to animals infected by intranasal and fomites mode of exposure (17).

Five experiments investigated SARS-CoV-2 transmission between infected and susceptible host animals (i.e., transmission pairs) that were physically separated by different barriers and cage setups (17, 18, 44-46). In most experiments, transmission pairs were separated by barriers that prevented direct contact but allowed for air flow. This led to 25-100% of the susceptible animals becoming infected after some duration of exposure. These experiments provide evidence supporting aerosol transmission among host animals in experimental settings.

Additional evidence from two experiments demonstrate how air flow and ventilation can impact indirect transmission of infection (17, 45). In one of these experiments transmission pairs of ferrets were housed in physically separated cages but shared air through connected air ducts, which led to 50% of the susceptible animals becoming infected (45). In another experiment the influence of air flow direction on likelihood of infection transmission was investigated, and results show infection only occurred in the susceptible hamster housed downwind from the infected hamster (17).

The small sample sizes, animals not being separated by large distances, the lack of details on animal behavior during the experiment (e.g., coughing or sneezing symptoms in infected animals), and at times the lack of detail regarding the permeability of separation barriers to respiratory and oral fluids, fecal and food particle movement, limit this evidence from completely supporting aerosol transmission.

Table 2: Animal experiments on aerosol exposure and indirect transmission of SARS-CoV-2 (n=6)

STUDY	METHOD	KEY OUTCOMES
Edwards (2020) (43) *In Vivo Study* USA Oct 2020*	Eight non-human primates Macaca mulatta (rhesus macaque) and Chlorocebus aethiops (African green monkey)) were infected with aerosols (≈2 µm) containing SARS-CoV-2 (~2.5x10^3 TCID50) using a laboratory inhalation system	Mucosal sampling by nasal swabs showed viral RNA detected as early as +1 day post infectious aerosol exposure with viral titers reaching peak levels at +7 days post infection, and clear decline of RNA by day +14 days post infection, and undetectable by +28 days post infection. These findings confirm SARS-CoV-2 infection by infectious aerosols can occur. Mucosal sampling by nasal swabs showed viral RNA detected as early as +1 day post infectious aerosol exposure. Exhaled breath particle production started 3 days post infection rose to day 7 and decreased to baseline by day 14 in primates. Exhaled breath particle production was temporally consistent with viral replication in nasal swab samples.

		There was a significant association between exhaled breath particles and viral load in most primates and correlated with viral kinetics. Viral RNA was undetectable in nasal swab samples of infected primates by day 28 post-infection.
Port (2020) (17) *Preprint* *In Vivo Study* USA Dec 2020* *new*	Three groups of female *Mesocricetus auratus* (Syrian hamsters) (n=36) were infected with SARS-Cov-2 virus aerosols and other types of exposures (i.e., fomites and intranasal). Infected animals were compared to unexposed controls (n=12). Exposure by SARS-CoV-2 aerosols ($1.5x10^3$ TCID50) was by a 3 jet collision nebular; particle size ranged from 1-5 um. Viral shedding and replication patterns measured in respiratory tissue and by fecal and oropharyngeal swabs. During separate airborne transmission experiments two transmission pairs (n=4) were co-housed in cages separated by a perforated plastic divider that prevented direct contact. The susceptible animals were placed in the direction or against the air flow from infected animals; four transmission pairs (n=8). Infection	The authors found mode of SARS-CoV-2 infection transmission played a factor in disease severity, viral load, and virus shedding in the animal model. Early virus replication (1 day post infection), peak respiratory shedding of virus at 2 days from exposure, and higher early viral loads in lung and tracheal tissue (p = <0.0001), was observed among aerosol exposed animals when compared to other exposure types. Viral titers in lung tissue showed a positive relationship with upper and lower respiratory tract pathology and weight loss, which lead the authors to suggest early respiratory shedding (as observed among animals infected by aerosols) may predict acute disease manifestation. In the indirect contact experiments assessing airflow based transmission no symptoms linked to infection were observed in the susceptible animals but 25% (n=1/4) seroconverted. This seroconversion (i.e., virus exposure) was linked to directional airflow from the infected to host animals. Of note, it was observed fomite transmission was linked to delayed disease manifestation with longer duration of time between exposure and viral replication in respiratory tissue, which led to reduced disease severity.

	detected based on serum seroconversion.	
Zhang (2021) (18) *Preprint* *In Vivo Study* USA Jan 2021* *new*	Investigated the risk of SARS-CoV-2 infection transmission from aerosol exposure, and risk of re-infection at re-challenge between naïve infected and previously infected transmission pairs of *Mesocricetus auratus* (Syrian hamsters). In the aerosol transmission experiments infected and donor hamsters (n=6) were housed in transmission cages with wire mesh partitions that prevent indirect and direct contact between animals, but permitted airflow. Live virus levels in respiratory tissue over the post exposure period was measured to confirm re-infection.	Experiments found SARS-CoV-2 was efficiently transmitted from infected naïve hamsters to previously infected hamsters by airborne transmission, among all transmission pairs. Based on viral RNA levels in respiratory tissue, the investigators conclude prior infection to have provided provide some good protective immunity but not complete immunity against re-infection at re-challenge; replicating live virus was present in the re-infected animals.
Sia (2020) (44) *In Vivo* Study Hong Kong* May 2020*	Experimental study that investigated SARS-CoV-2 infection transmission via aerosols in Mesocricetus auratus (Syrian hamsters). Infected and susceptible animals were housed in adjacent wire cages placed 1.8 cm away from one another (3 different pairs)	Efficient indirect transmission of infection to susceptible hamsters occurred in all three pairs within experimental settings. Peak viral load in aerosol exposed hamster was at 3 days post contact.

	were exposed to one another for 8 hours.	
Kutter (2020) (45) *Preprint* *In Vivo Study* Netherlands* Oct 2020*	An experimental set-up where infected and susceptible pairs (i.e. transmission pairs) of individually housed *Mustela putorius furo* (ferret) (n=8) were connected through a hard 15 cm air duct opening with multiple 90^0 turns. Airflow was directed upwards from the donor to indirect recipient animals. Air travelled an average of 118 cm (approx. 3 ft.) through the tube systems. Note: transmission of SARS-CoV-2 and SARS-CoV was investigated.	Indirect transmission of SARS-CoV-2 between two ferrets more than 1 meter away was confirmed in 50% separately housed transmission pairs. Infection in susceptible animals were confirmed through the detection of viral RNA in throat and nose swabs.
Kim (2020) (46) *In Vivo Study* South Korea* May 2020*	An experimental study of SARS-CoV-2 transmission between *Mustela putorius furo* (ferret) separated by a partition (n=6). Indirect contact of ferrets was maintained by a permeable partition between cages to separate susceptible and infected ferrets.	The authors found 33% of indirect contact ferrets were positive for viral RNA in nasal washes and fecal specimens. Authors suggest aerosol transmission to have occurred among indirect contact ferrets.

SARS-COV-2 VIABILITY IN AEROSOLS

Three studies measured the half-life of viral particles suspended in artificial aerosols within experimental settings studies and confirmed the viability of virus in artificial aerosols by plaque assays and cell culture (19, 47, 48). These studies found SARS-CoV-2 virus titers remained stable in artificially created aerosols up to timeframes that ranged from 2 to 16 hours (19, 47, 48). The stability and infectiousness of virus in artificial aerosols appear to be dependent on environmental factors such as temperature, humidity and simulated sunlight levels, as previously suggested in some computer generated analysis. One experimental study demonstrated simulated sunlight had the largest impact on decay rate, high temperatures (only 10-40°C were tested) had a moderate impact and a significant interaction with sunlight whereas relative humidity had the least influence on decay overall and only at high (70%) relative humidity (19).

Table 3: Experimental evidence confirming SARS-CoV-2 virus stability in aerosols (n=3)

STUDY	METHOD	KEY OUTCOMES
Dabisch (2020) (19) Simulation experiments USA* Aug 2020* *new*	Measured the viability and persistence of SARS-CoV-2 in artificially generated aerosols within a drum aerosol chamber across a range of temperatures (10 °C, 20 °C, 30 °C and 40°C), relative humidity (20%, 45% and 70%), and simulated sunlight levels of zero integrated UVB irradiance (i.e., indoor/night/darkness), 0.9 W/m2 UVB irradiance and 1.9 W/m2 integrated UVB irradiance (i.e., summer midday sunlight). Viral concentration was held at mean value of 2.3 ± 0.4 $\log_{10}$ $TCID_{50}$/L-air during the experiment. Infectiousness of virus within aerosols was measure using micro titration assay and Vero cells. Experiment results informed a regression model predicting	The time needed for a 90% decrease in infectious virus at 400C, 20% relative humidity increased from 4.8 min with sunlight representative of noon on a clear summer day outdoors, to more than 2 hours under conditions representative of indoors or at night. Across other temperature and humidity levels the decay per minute in midday sun simulations ranged from 38.1% ± 8.9% per minute at 40 °C and 20% relative humidity, to 18.9 ± 4.8% per minute at 10 °C and 20% relative humidity. For moderate sunlight representing spring and fall intensity at 40 °C, decay rates ranged from18.0 ± 6.2% per minute at 30 °C and 45% relative humidity, to 11.1 ± 4.6% per minute at 10 °C and 20% relative humidity. In the absence of sunlight <2% decay (mean) per minute rate was estimated, for

	aerosolized SARS-CoV-2 decay under variable conditions.	most tested temperature and humidity levels. Exceptions were in the higher temperature and/or humidity ranges: - Decay rate at 30 °C with 70% relative humidity was 6.3 ± 2.6% per minute. - Decay rate at 40 °C with 20% relative humidity was 3.9 ± 0.4%. In the regression analysis sunlight had the largest influence on decay followed by temperature and a sunlight x temperature interaction. Humidity (relative or absolute) had the lowest influence on the decay constant. Thus, more intense sunlight and high temperatures >30°C had faster decay rates.
Fears (2020) (47) Simulation experiments USA* Sep 2020*	The long-term persistence of artificially generated viral aerosol suspensions of SARS-CoV-2 was measured at different time intervals. Viral contents were quantified by RT-PCR, and infectiousness of virus was measured by plague assay. Samples were qualitatively assessed by electron microscopy.	Infectious SARS-CoV-2 was detected at 10 minutes, 30 minutes, 2, 4, and 16 hours during the aerosol suspension stability experiment. A minimal reduction in viral genome copies in aerosol samples (as measured by RT-PCR) was noted for the measured time points. A minor but constant fraction of the SARS-CoV-2 virus in aerosols maintained replication-competence at all measured time points, including at 16 hours. Qualitative assessment of virion integrity revealed virions were either ovoid or spherical in shape, and maintained the expected morphologies up to 16 hours in aerosol suspension.
Van Doremalen (2020) (48) *LTE* Simulation experiment	In this experiment SARS-CoV-2 and SARS-CoV-1 virus titer stability and decay was measured from artificially generated aerosols, in Vero 6	SARS-CoV-2 virus remained viable in experimentally generated aerosols up to 3 hours (duration of the experiment), with a reduction in infectious titer from $10^{3.5}$ to $10^{2.7}$ $TCID_{50}$ per liter of air

USA* Spring 2020*	cell culture. Analysis used a Bayesian regression model.	In aerosols the half life of SARS-CoV-2 virus was estimated to be 1.1-1.2 with a 95% credible interval of 0.64-2.64.

SARS-COV-2 RNA IN EXHALED BREATH

Six studies investigated the presence of viral RNA in exhaled air samples or exhaled breath condensate samples of SARS-CoV-2 from human cases (20, 50-53).

Two different exhaled breath sampling techniques were identified across the studies: some studies collected exhaled breath condensate while others collected exhaled air samples from infected individuals. Exhaled breath condensate techniques collect 1-2 ml of condensate by the cooling and condensation of exhaled air during quiet breathing. Some investigators have suggested the exhaled breath condensate technique is better suited for identifying biomarkers expelled from the lower respiratory tract, and results in reduced false negative results by RT-PCR (50, 54).

Five of the included studies reported at least one exhaled air sample positive for viral RNA. Among the identified studies that confirmed the presence of viral RNA in some exhaled samples, four applied the exhaled breath condensate technique while two were based on exhaled air sampling. Sample positivity ranged from 16%-93.5% in exhaled breath condensate sampling studies to 40% in the single exhaled breath sampling study with positive results. One study reported no positive samples, for both exhaled breath condensate and exhaled air collection techniques (53). The variability in viral RNA positivity across exhaled breath samples may be linked to the infectious course of sampled individuals. However, the lack of clinical information on exposure and symptom onset dates, symptoms, as well as viral loads and viral replication in respiratory tissue, at the time of sample collection limit inferences between viral exhalation and infection course. Based on evidence that peak viral load occurs between one day before and up to five days post symptom onset, hospitalized or symptomatic individuals several days into their infection may not be an appropriate sample for measuring viral RNA within exhaled breath (43, 55). Hospitalized individuals may no longer be infectious at the time of sample collection, which should not be interpreted as a lack of evidence supporting infection emission by exhaled breath during the early infection period.

Table 4: Biological monitoring studies on SARS-CoV-2 RNA in exhaled breath (n=6)

STUDY	METHOD	KEY OUTCOMES
Reporting SARS-CoV-2 in samples		
Ryan (2020) (50)	Exhaled breath condensate samples were collected	93.5% (29/31) of the collected exhaled breath samples from SARS-CoV-2 patients (clinically

Exhaled breath condensate monitoring study Ireland Apr - May 2020 *new*	from COVID-19 patients using RTUBE condensers. The sample included nasopharyngeal swab positive (n=16) and nasopharyngeal swab negative with clinical diagnosis of COVID (n=15) patients. Additional samples from pre-SARS-CoV-2 were included as controls (n=14). Virus in samples was detected by RT-PCR using different viral gene assays. Note: Clinical diagnoses of COVID-19 were based on clinical expertise and imaging results.	confirmed and/or positive nasopharyngeal swab results) were positive by RT-PCR targeting all four genes (E, S, N, ORF1ab). All pre-pandemic control samples were negative. In this study exhaled breath was shown to be a sensitive and non-invasive sample type. Positivity of samples varied by RT-PCR assay target sequence among nasopharyngeal swab negative patients (n=15): - 66% (10/15) positivity for viral envelope (E)/ spike (S) proteins gene assays (used for the nasopharyngeal swab). - 73% (11/15) positivity for viral nucleocapsid (N)/open reading frame (ORF1ab) gene assays. The combined results equated to 14/15 clinically diagnosed cases positive on at least one assay.
Zhou (2021) (49) Exhaled breath condensate monitoring study China Feb - Mar 2020 *new* Note: Additional results on viral RNA in air samples are summarized in Table 5.	COVID-19 patients (n=10) about to be discharged from hospital (as per negative throat and nasal swabs) were recruited from multiple hospital sites. Exhaled breath condensate was sampled using using a BioScreen II device. SARS-CoV-2 RNA in breath samples was quantified using RT-PCR.	22.2% of 9 COVID-19 patients about to be discharged from hospital had SARS-CoV-2 in their exhaled breath samples at a concentration of ~10^5 RNA copies/m^3. Both patients were over the age of 70. It was estimated that some COVID-19 patients in the sample were exhaling the virus at a rate of ~1400 RNA copies per minute into the air at discharge.
Ma (2020) (51) *Preprint*	Exhaled breath condensate samples were collected from COVID-19 patients	The study confirms the emission of SARS-CoV-2 virus RNA into the air from exhaled breath condensate of infected individuals (16.7% n=5/30). The positive samples were detected either <3 days from symptom onset

Exhaled breath condensate monitoring study China Spring 2020* Note: Additional results on viral RNA in environmental air samples are summarized in Table 5.	(n=30) using a BioScreen device.	(n=3) or within 7-14 days from symptom onset (n=2). SARS-CoV-2 levels in exhaled breath were estimated to reach 10^5-10^7 copies/m^3 if an average breathing rate of 12 L/min is assumed and is highest during early stages of infection.
Di Carlo (2021) (20) Exhaled air monitoring study Italy Apr - Jun 2020 Note: Additional results on viral RNA in environmental air samples are summarized in Table 5 *new*	Tests the release of SARS-CoV-2 RNA into the air during normal breathing – without coughing, sneezing or talking among infected cases (n=5). These cases were all in hospital patients admitted to hospital for non-COVID symptoms who later developed COVID symptoms during hospital stay. Sampled individuals were housed in airborne infection isolation rooms (AIIR) and exhaled breath samples were collected using Sartorius AirPort sampler. Patient oropharyngeal, nasopharyngeal and salivary swabs samples were also collected at the time of breath samples.	The days since symptom onset to sample collection varied from 7- 56 days in the patient sample. Oropharyngeal and nasopharyngeal swabs of 4 patients were positive at the time of sampling. Viral RNA was detected at 1 cm distance from patients' mouths in two patients (40% n=2/5). Both had positive oropharyngeal, nasopharyngeal and salivary swabs. Salivary swabs were negative in the patients with negative exhaled air samples who were reported to be infected based on consecutive positive swab samples. In one of these patients, wearing a surgical mask effectively blocked viral RNA detection at 1 cm (masked samples were not collected from the other patient with positive exhaled air samples). Air samples at 1 cm from RT-PCR negative patients were negative for viral RNA.
Feng (2020) (52)	Sampled exhaled breath and environmental air of COVID-19 patients using a NIOSH bio-aerosol sampler.	SARS-CoV-2 RNA was not detected in any of the patients' expired breath samples (n=0/9). Viral RNA was isolated in exhaled breath

Exhaled air & exhaled breath condensate monitoring study China Feb - Mar 2020 Note: Additional results on viral RNA in environmental air samples are summarized in Table 5.	Exhaled breath condensate was sampled using a sterile laboratory-made collection system. Air samples were segregated by aerosol size. Samples were collected from COVID-19 patients in the later stages of infection in hospital settings.	condensate (25%; n=2/8), and bedside environmental air samples (8%; n=1/12). The authors attributed minimal contamination of viral RNA in study samples to reduced respiratory viral shedding among patients in later stages of infection.
Reporting NO SARS-CoV-2 in samples		
Ding (2020) (53) *Preprint* Exhaled air and exhaled breath condensate monitoring study Hong Kong Feb 2020 Note: Additional results on viral RNA in environmental air samples are summarized in Table 5.	Exhaled breath condensate samples (n=2) and expired air samples (n=2) were collected from COVID-19 patients housed in airborne infection isolation rooms (AIIR). Multiple devices were used for air sample collection (n=27), which was conducted on different days. Note: sample collection distances from patient(s) are not reported.	All collected exhaled condensate samples and expired air samples were negative for SARS-CoV-2 RNA.

*Estimated based on author affiliations and publication date.

SARS-COV-2 RNA IN ENVIRONMENTAL AIR

Forty-nine biological monitoring studies that investigated SARS-CoV-2 in air samples collected from patient care settings, such as airborne infection isolation rooms (AIIR), ICU, emergency wards, hospital wards, nursing homes, diagnostic areas (e.g., CT scan) and outpatient clinics, were identified (Table 5). All of these studies report the presence of confirmed case(s) in the proximity of sample collection. The majority of studies (n=29/40) reported the isolation of viral RNA from at least one collected air sample by RT-PCR. Three studies successfully cultured virus particles isolated from a very small number of positive air samples in cell culture, thus providing evidence to support virus viability in air (56-58). All of these air

samples with viable virus were collected close (<2 meters) to confirmed cases. Furthermore, air samples taken at 1-4.8 m from confirmed cases consistently identified SARS-COV-2 RNA, with higher concentrations of viral RNA when the collection apparatus was positioned closer to the case (21, 56-61, 64, 65, 93)

A single study in a patient care setting demonstrated opening the windows in the COVID-19 patient's room to be beneficial and reduced the viral concentration in the air sample from 10^5/ml to less than 10^4 (61). Another study compares environmental air samples collected from inpatient hospital rooms and quarantine households with active cases (24). The household environmental air samples were estimated to be approximately eight times (OR 8.75 [95% CI 1.21-63.43; p=0.058]) more likely to be contaminated with viral RNA than hospital air samples. The investigators suggested variability in air exchanges and ventilation between patient care and community settings to be the main difference that influenced air contamination between the two settings, as such room ventilation was suggested to be a more important factor than disease acuity with respect to environmental air contamination.

Nine biological monitoring studies of SARS-CoV-2 in air samples from community settings (i.e., a car driven by an infected case, shopping mall, concert hall, hotel quarantine rooms and households, mink farm, public buses and subway trains) were identified (Table 6). The majority of these studies (n=5/9) confirm the presence of viral RNA by RT-PCR and in one study, air samples from a car with a COVID-19 case isolated virus in cell culture (23). The study in the car highlights that significant quantities of viable SARS-CoV-2 can be expelled from even mild cases over short periods of time (23). A study on a mink farm with an ongoing outbreak highlights high levels of virus within the farm, which is a risk for the workers, however there was low risk outside of the farm to the surrounding community (66). The identification of positive air samples from quarantine households and hotel rooms with active cases was variable and requires further investigation, as some studies identified positive samples while others did not (24, 67, 68). Two environmental sampling studies of public venues, including a concert hall, a shopping mall, and public buses and subway trains also confirm the presence of viral RNA in air samples (61, 69). Interestingly, these studies do not confirm the presence of cases in the proximity of air sample collection but indicated high levels of community transmission in sampled settings (61, 69).

A range of air sampling methods were used across the included biological monitoring studies. Some studies used different air sampler models while others used fluid filled petri dishes, gelatin filters, agar plates and novel COVID-19 traps to sample environmental air. The variability in sampling methodologies may have contributed to the observed differences in viral RNA detection and confirmation of virus viability and infectiousness in environmental air samples. Only a small number of studies confirmed the viability of virus in cell culture and all samples were very close (<2 meters) to infected individuals.

The authors who reported no virus contamination in air samples collected from patient care settings often suggested effective disinfection, high efficiency air ventilation and filtration systems fitted to AIIR as possible reasons for negative results. This rationale is further supported by one biological monitoring study which was unable to detect viral RNA in collected samples when the air sampler inlet was covered with a HEPA filter (56).

Among the identified studies, viral RNA concentration within contaminated samples, isolated aerosol particle sizes and fractions, sampling distance from COVID-19 cases, air sample volume, and any attempts to culture isolated virus particles were not consistently reported. Moreover, the majority of studies did not provide clinical information, such as symptom onset data or presence of respiratory symptoms, on the cases present during air sample collection, nor ventilation and air flow in the sampled setting. These data gaps make it difficult to determine the conditions upon which infectious virus in environmental air samples becomes more frequent.

Table 5: Biological monitoring studies investigating SARS-CoV-2 within air in patient care settings (n=40)

STUDY	METHOD	KEY OUTCOMES
SARS-CoV-2 in cell culture samples		
Lednicky (2020) (56) Biological monitoring study USA* Nov 2020*	Air samples were collected in triplicate from hospital rooms of COVID-19 patients in the absence of aerosol generating procedures. Air samples were collected using a VIVAS air sampler at 2 to 4.8 meters away from patients, with and without a HEPA filter on the air sampler inlet tube. Virus in isolated air samples was measured using RT-PCR, and infectiousness was measured based on cytopathic effects in cell culture (LLC-MK2 and Vero-E6). The genomes of isolated virus was sequenced.	Viable (infectious) SARS-CoV-2 was found to be present in aerosols sampled from hospital patient rooms by RT-PCR and cell culture (via cytopathic effects) All air samples collected without a HEPA filter was positive for viral RNA. A single nearly complete virus sequence was isolated from the air samplers that collected environmental air. This genetic sequence matched the virus strain isolated from nasopharyngeal sample of one of the two patients who occupied the room during sampling. The matched person was diagnosed with acute infection at the time of air sampling.
Santarpia (2020) (57) *Preprint* Biological monitoring study USA Apr 2020	Patient generated aerosols in hospital air samples were collected using a NIOSH BC251 aerosol sampler at the foot of COVID-19 patient beds. Aerosol sizes and concentration was concurrently measured during sample collection using an	RNA was detected in all six patient rooms, and included all aerosol particle size fractions (defined as >4.1 µm, 1-4 µm, and <1 µm). Replicating virus in cell culture was observed in most <1 µm aerosol samples, two of the 1-4 µm size aerosol

	Aerodynamic Particle Sizer Spectrometer. Aerosols were distinguished by the proportion of different sizes (>4.1 µm, 1-4 µm, and <1 µm) among samples. Presence of the virus in isolated aerosols (<5µm) was measured using RT-PCR, western blot, and transmission electron microscopy and infectiousness of isolated viral particles was examined using cell culture (Vero-E6). Note: The study does not specify if the patients were housed in regular wards or AIIR.	samples and two of the >4.1µm samples. Western blot and TEM analysis of these samples also showed evidence of viral proteins and intact virions. The authors conclude the infectious nature of the aerosols collected in this study suggests that aerosol transmission of COVID-19 is possible.
Santarpia (2020) (58) Biological monitoring study USA Mar 2020	Air samples from negative pressure isolation spaces and wards housing COVID-19 cases were collected using a Sartorius Airport MD8 air sampler and tested for SARS-CoV-2 viral RNA by RT-PCR. A subset of positive samples were examined for viral propagation in Vero E6 cells. Several indicators were utilized to determine viral replication including cytopathic effect, immunofluorescent staining, time course PCR of cell culture supernatant, and electron microscopy.	63.2% of in-room air samples were positive by RT-PCR (mean concentration 2.42 copies/L of air). Two samples placed at different proximity to a patient, including a sample from <2 meters away the patient, were positive. Viral concentration was higher in the air sample collected closer to the patient (4.07 vs. 2.48 copies/L of air). 58.3% of air samples collected from hallways were positive (mean concentration of 2.51 copies/L of air). Some viral replication was observed in a single positive sample collected from a hallway.
SARS-CoV-2 RNA in samples		
Munoz-Price (2021) (24) Biological monitoring study US Spring 2021*	Air samples (n=16) collected from hospital ICU inpatient rooms occupied by confirmed COVID-19 cases. Air samples were collected using the Sartorius MD8 airscan sampler, positioned at 0.3 -1.8	12.5% (n=2/16) of hospital air samples were only positive for viral RNA. These samples where collected at 0.3 meters from confirmed cases. The patients had mild severity of illness and were not on

new Note: Additional results on viral RNA in environmental air from household settings are summarized in Table 6.	meters from patients' head. Viral RNA in samples was measured by RT-PCR.	supplemental oxygen at the time of sample collection.
Razzini (2020) (70) Biological monitoring study Italy Apr 2020* *new*	Air samples (n=5) collected from hospital areas with COVID-19 cases using a MD8 Airport Portable Air Sampler with gelatin membrane filters. Samples were collected from three zones, contaminated (corridor for patients and ICU), semi-contaminated (undressing room) and clean areas (medical staff dressing and locker areas). Viral RNA in samples was measured by RT-PCR.	All the air samples collected from COVID-19 cases' ICU and corridor were positive for viral RNA; samples from other areas were negative. Viral concentration in (mean Ct) across ICU air samples was 22.6, and 31.1 for corridor air samples.
Ge (2020) (71) Biological monitoring study China Jun 2020* *new*	Air samples (n=33) were collected using the NIOSH bioaerosol sampler BC251. Sampled settings were ICU, hemodialysis clinics, fever clinics, and respiratory wards. Viral RNA in samples was measured by RT-PCR.	All air samples (n=3) from the ICU setting were positive for viral RNA. Viral concentrations in samples ranged from Ct 36.5 - 37.8.
Hu (2020) (72) Biological monitoring study Feb – Mar 2020 China *new*	Air (aerosol) samples were collected from multiple hospital sites using a centrifugal aerosol-to-hydrosol sampler (n=123). Viral RNA in samples was measured by RT-PCR and viability by Vero-E6 cell culture.	Eight air samples (21%) from ICU environments and one same from (16%) from the CT (computerized tomography) room were positive for viral RNA. The range of virus concentrations in the positive air (aerosol) samples was 1.11×10^3 to 1.12

		× 10^4 RNA copies m^{-3}. The virus could not be cultured from positive samples.
Seyyed (2020) (73) Biological monitoring study Iran May 2020* *new*	Air samples (n=10) were collected from COVID-19 patient ICU wards using a sampling pump with a porous midget impeller. Viral RNA in samples was measured by RT-PCR.	60% of air samples were positive for viral RNA. The highest RNA concentrations were measured in samples from between patient beds (3913 copies per ml). These were air samples collected at 1.5 to 2 meters from patient beds.
Moore (2020) (59) Biological monitoring study England Mar –May 2020 *new*	Air samples (n=55) were collected from COVID-19 patients with and without respiratory symptoms, from eight different hospitals. Sampled settings included AIIR, general COVID-19 wards and non-COVID-19 wards. Samples were collected using a Coriolis µ air sampler and/or Sartorius MD8 air sampler. Viral RNA in samples was measured by RT-PCR, and viability by Vero-E6 cell culture.	7% (n=4) of air samples were positive for viral RNA, at low concentrations from <10 to 460 genomic copies/m^3 air. The virus could not be cultured from positive samples. All positive samples were collected at 1 meter distance from patients, and days since symptom onset among the patients ranged from 8-10 days.
Hernández López (2021) (60) Biological monitoring study Jan 2021* Mexico *new*	Air samples (n=15) from emergency, internal medicine and COVID-19 patient rooms and multiple bed patient care rooms in two hospitals were collected using a Millipore sampler. Viral RNA in samples was measured by RT-PCR.	Three air samples (20%) were positive for viral RNA. All positive samples were from the COVID-19 patient room and near the patient.
Tan (2020) (74) Biological monitoring study China Mar 2020 *new*	Air samples (n=12) were collected from ICU and isolation wards of COVID-19 cases in hospital, and corridors. Air samples were collected at 1 meter from a patient's head.	A single air sample from a patient care area, collected when the patient was undergoing intubation, was positive for viral RNA.

Gehrke (2021) (61) *Preprint* Biological monitoring study Germany Oct 2020 - Jan 2021 *new* Note: Additional results on viral RNA in community setting air samples are summarized in Table 6.	Air samples were collected from patient rooms in two COVID-19 isolation units, and an outpatient endoscopy facility using non-powered cold traps. Viral RNA was quantified by RT-PCR.	Hospital setting samples: No viral RNA was isolated from the first isolation unit ventilated permanently by two windows. Viral RNA was detected in samples collected from a non-ventilated corridor next to the isolation room. In the second isolation unit samples, SARS-CoV-2 RNA levels reached concentrations of 10^5/mL in non-ventilated rooms, but when windows were open to increase ventilation SARS-CoV-2 RNA concentrations in samples were reduced to 10^4/mL or less. In the endoscopy facility, 50% of cold traps were positive for viral RNA (n=6/12). 57% of cold traps (n=4/7) from endoscopy operation rooms were positive for SARS-CoV-2, but RNA concentrations (initially at 12 copies/ml) and the number of positive samples were reduced when the ventilation levels in the room was increased.
Zhou (2021) (80) Biological monitoring study China Feb- Mar 2020 *new* Note: Additional results on viral RNA in exhaled breath samples are summarized in Table 4.	Air samples (and exhaled breath samples) of hospitalized COVID-19 patients were collected from multiple hospital sites. Air samples were collected from hospital corridors, waste storage rooms, ICU rooms, toilets, medical preparation rooms, clinical observation rooms, and general wards. Air samples were collected using the Air-nCoV-Watch (ACW) system and viral RNA quantified by RT-PCR.	6.8% of the air samples (n =3/ 44) were positive for viral RNA at digital PCR concentration levels ranging from 9-219 viruses/m^3.
Yarahmadi (2021) (64)	Air samples were collected (n=20) from an ICU ward at, 1) a	50% (n=2/4) of samples from the patient breathing zone were positive for

Biological monitoring study Iran Feb 2021* *new*	COVID-19 patient breathing zone (i.e., side table next to patient's head), general area (10 meters from the ICU unit), and breathing zone of health care personnel near the COVID-19 patient's bed, and 1 meter from the patient's bed. Samples were collected using NIOSH and ASHRAE bioaerosol samplers. Viral RNA was detected by RT-PCR.	viral RNA. The positive samples were from a confirmed case, and negative samples were from a suspected case. 12.5% (n=1/8) of samples from health care personnel breathing zone were positive for viral RNA. 12.5% (n=1/8) of samples from the general area were positive for viral RNA. Authors suggest bioaerosols maybe present due to the re-aerosolization of previously airborne SARS-CoV-2 particles from health care personnel walking between different wards and stations of the ICU.
Ong (2021) (93) Biological monitoring study Singapore Jan 2021*	Air samples were collected from AIIR in a hospital and community isolation facility (naturally ventilated) housing confirmed COVID-19 patients, at 1 meter away from the patient. Air samples were collected using a BioSpot-VIVAS BSS300-P bioaerosol sampler (collecting particles <4.34 µm in size). NIOSH aerosol samplers were used to validate the Biospot results. SARS-CoV-2 RNA was detected by RT-PCR, and cultured using Vero C1008 cell culture.	50% of BioSpot air samples from hospital AIIR (n=6/12) were positive for SARS-CoV-2 RNA (concentrations ranging from 178.9 to 2,738.4 copies/m^3). Positive samples were collected from rooms with at least one symptomatic patient (<7 days post symptom onset). NIOSH aerosol samplers detected SARS-CoV-2 RNA in aerosols <1 µm, 1–4 µm, and >4 µm in diameter. Only 1 of 9 samples from the community isolation facility was positive for SARS-CoV-2 RNA, with a concentration of 978.3 copies/m^3. Virus cultures of all positive samples were negative.
Dumont-Leblond (2020) (21) Biological monitoring study Canada Mar-June 2020	Sampled air from AIIR rooms from a Quebec hospital housing non-severe COVID-19 patients (n=22). Air samples were collected (with 3 µm gelatine filters and 0.8 µm polycarbonate filters) using a SASS 3100 dry sampler, at 1.5m	11% (n=11/100) of air samples collected at the bedside of 6 patients were positive for viral RNA. These patients had higher frequency of fever, dyspnoea, and cough compared to others in the sample. Most were males

new	away from the patient bedside. Viral contamination was measured by RT-PCR and Vero E6 cell culture.	and had a slightly longer duration of hospitalization. Average SARS-CoV-2 viral load in the positive sample rooms was estimated at 4.86E+4 virus genomes per hour. No virus isolated from air samples could be cultured.
Binder (2020) (75) Biological monitoring study USA Apr-May 2020 *new*	Environmental swabs and aerosol samples were collected from single patient hospital rooms housing COVID-19 patients (n=20, 16 symptomatic and 4 asymptomatic) within a dedicated COVID-19 ward. Bioaerosols were collected using a NIOSH BC 251 sampler placed at different distanced from the patients' heads (1, 1.4, 2.2, and 3.2 meters). Empty hospital rooms, hallways, staff break room and staff workstations were sampled as controls. SARS-CoV-2 viral contamination was measured by RT-PCR, and Vero EC6 cell culture.	Three samples collected from three of the COVID-19 patient rooms were positive for viral RNA; samples were collected at 1.4-2.2 meters from the patients. These patients were 4-10 days post symptom onset (runny nose, headache, fever, cough, difficulty breathing, fatigue, loss of smell, gastrointestinal symptoms). Viable virus could not be identified in bio aerosols samples via cell culture. Samples from other area were negative for SARS-CoV-2 RNA.
Passos (2021) (76) Biological monitoring study May-Aug 2020 *new*	Air samples were collected from two different hospital environments (n=52) using active and passive aerosol sampling methods. Active sampling used multiple portable/hand-held air sampler models (AIRIDEAL 3P, MD-8 AirPort, HANDI-VOL) and filter types (cellulose, PTFE or quartz microfiber filters). The passive method used petri dishes for the collection of sedimentable particles. Both hospitals housed	Air samples from four areas sampled in one hospital (at 100% ICU occupancy at the time of sampling) were positive for viral RNA in suspended particles (filter pore size >0.2 µm and >0.3 µm), as well as 11% of sedimentable particles (n=4/36). Positive suspended air particle samples were detected from inside the COVID-19 ICU ward (concentration of 0.33 genomic units m^{-3} @ distance >2 from patient), in a protective apparel removal room (0.14 genomic units m^{-3}), storage room for patient mobile toilets and

	COVID-19 patients in dedicated ICU wards at the time of sample collection. Aerosol samples were also collected from multiple outdoor public spaces using high-volume air samplers (AGV, Energética). SARS-CoV-2 RNA in samples was detected by RT-PCR.	soiled patient linens (0.19 genomic units m^{-3}). The storage room was open to natural ventilation. SARS-CoV-2 RNA positive sedimentable particles were detected in samples collected from an external corridor adjacent to the COVID-19 dedicated ICU. All outdoor air samples and samples collected at the other hospital (i.e., Hospital 1) l (at 33% occupancy at the time of sampling) were negative for SARS-CoV-2 RNA.
Lane (2021) (65) Biological monitoring study Jan 2021* *new*	Air samples were collected from multiple hospital units, AIIR, ICU nursing stations, family/visitor corridors outside of ICUs, medical unit, and patient room hallways. NIOSH 251 2-stage cyclone samplers collected air samples (limit of detection of 8 viral copies/m^3 of air). Two patient rooms housing COVID-19 patients were used as positive control samples. Viral RNA was detected by RT-PCR.	The two positive control samples collected from two confirmed COVID-19 patient rooms were positive for viral RNA. None of the air samples (n=528) from other sampling area were positive for SARS-CoV-2 RNA.
Liu (2020) (77) Biological monitoring study China Feb-Mar 2020	SARS-CoV-2 RNA concentration and aerosol size distributions in air samples (n=30) from multiple sites within or near a hospital and field hospital. All aerosol samples (n=30) were collected on pre-sterilized gelatin filters (Sartorius). Three size-segregated aerosol samples were collected using a miniature cascade impactor (all sampled	SARS-CoV-2 contamination in air samples was low to undetectable. In the field hospital setting, the greatest suspended SARS-CoV-2 RNA in aerosols was identified in a temporary patient toilet room (1 m^2 area) with low ventilation, likely from the patient breathing or aerosolization of virus from feces and urine of infected patients. Samples from the field hospital staff personal rooms demonstrated the

	from staff areas). Viral RNA was detected by RT-PCR.	greatest virus concentrations. Aerosols from 0.25 to > 2.5 µm were identified. The authors hypothesize this came from healthcare worker PPE surfaces and apparel. Low but detectable viral RNA concentrations were found at a department store entrance and an outdoor site near the hospital suggesting this may have occurred due to high traffic flow and crowding. Note: The specific concentrations of airborne SARS-CoV-2 in each aerosol sample by site are provided in the publication.
Chia (2020) (78) Biological monitoring study Singapore Spring 2020*	Detection of air contamination by SARS-CoV-2 in airborne infection isolation rooms (AIIR) housing COVID-19 patients, in hospital settings. Air samples were collected, and aerosol sizes were measured by NIOSH BC 251 bio-aerosol samplers. Viral RNA was detected by PCR.	66% (n=2/3) of the air samples collected from AIIR environments were SARS-CoV-2 RNA positive. The smallest aerodynamic size fraction that contained detectable levels of SARS-CoV-2 RNA was 1–4 µm. Total SARS-CoV-2 concentrations in air ranged from 1.84×10^3 to 3.38×10^3 RNA copies per m^3 air sampled. The authors suggest the presence of SARS-CoV-2 in the sampled air is likely highest during the first week of illness, when respiratory viral load is high.
Jin (2021) (79) Biological monitoring study China Feb-Mar 2020 *new*	Air samples were collected from an ICU housing a single ready-for-discharge COVID-19 patient, 2 days after the patient tested negative for SARS-CoV-2. Air samples were collected from the isolation room and staff PPE dressing room. High-volume air samples were collected using a WA 400 Portable viral aerosol	A single air sample from the ICU ward isolation room was positive (1/7, 14.29%) for viral RNA. The authors state their findings suggest the virus may be shed via aerosol for days, even after a patient has tested negative.

	sampler. Viral RNA in samples was detected using RT-PCR.	
Zhou (2020) (81) Biological monitoring study UK Apr 2020	Three to five air samples were collected from multiple hospital environments using a Coriolis air sampler, viral RNA was measured by RT-PCR, Vero E6 and Caco2 cells cultures were used to culture virus.	38.7% (n=14/31) of the collected air samples were positive for viral RNA, but SARS-CoV-2 virus could not be cultured due to low recovered viral loads. The odds of contamination in public areas was lower than areas immediately occupied by a COVID-19 patient (OR 0.5 95% CI 0.2-0.9).
Orenes-Piñero (2020) (81) Biological monitoring study Spain Spring 2020*	Investigators develop and apply "COVID traps" to measure the capacity of SARS-CoV-2 aerosol transmission in hospital patient care settings. "COVID traps" were placed 1 meter away from patients in ICU and ward settings. Viral RNA was detected by RT-PCR.	In the ICU, none of the "COVID traps" were positive for COVID-19; all COVID-19 patients were intubated. In the ward setting, two "COVID traps" were positive for SARS-CoV-2, both were near a patient requiring the use of respiratory assistance. The authors conclude it was unequivocally the result of virus transmission in air.
Feng (2020) (52) Biological monitoring study China Feb-Mar 2020 Note: Additional results on viral RNA in exhaled breath samples are summarized in Table 4.	Environmental air from the rooms of recovering COVID-19 patients in isolation hospital wards and ICU were sampled using a NIOSH sampler. Air samples (n=12) were collected and aerosol size measured. Samplers were also placed on a tripod 1.2 m in height and 0.2 m away from the bed at the side of the patient's head for 30 minutes.	SARS-CoV-2 RNA was detected in a single air sample from SARS-CoV-2 patients. The maximum viral RNA concentrations detected in the positive air sample by particle size was 1112 copies/m^3 (<1 µm) and 745 copies/m^3 (>4 µm). The authors attribute minimal contamination of viral RNA in study samples to reduced respiratory viral shedding among patients in later stages of infection.
Ding (2020) (53) *Preprint* Biological monitoring study Hong Kong Feb 2020	Air samples (n=46) were collected from airborne infection isolation rooms (AIIR) housing COVID-19 patients, nursing stations, corridor and air-conditioning units at a hospital treating COVID-19 cases. Multiple air samplers were used	A single air sample (n=1/46) from the corridor outside a storage room with a medical waste bin was weakly positive for SARS-CoV-2 RNA. All other tested air samples from patient rooms, washrooms, and air supply inlets were negative.

Note: Additional results on viral RNA in exhaled breath samples are summarized in Table 4.	for sample collection, which was conducted on different days, and RNA was detected by RT-PCR.	RNA copies for the weakly positive sample was not quantified.
Guo (2020) (82) Biological monitoring study China Feb-Mar 2020	Air samples were collected from hospital ICU (n=40) and general wards housing (n=6) COVID-19 patients, at different distances from patients and the doctors office (n=8). Air samples were collected using a SASS 2300 Wetted Wall Cyclone Sampler.	SARS-CoV-2 virus particles were identified in 35% (n=14/40) of ICU air samples, 12.5% (n=2/16) of general ward air samples. SARS-CoV-2 aerosol was detected in 35.7% (n=5/14) of samples near air outlets, 44.4% (n=8/18) of samples in patients' rooms, and 12.5% (n=1/8) in the doctors' office area. No SARS-CoV-2 virus were identified in patient corridor air samples. Based on site(s) of positive air sample collection authors conclude virus-laden aerosols to concentrate near and downstream from patients, and the maximum transmission distance of virus laden aerosols to be 4 meters.
Nissen (2020) (83) Biological monitoring study - Hospital setting Sweden Spring 2020*	Open liquid containing petri dishes were placed at air entrances to ward rooms and near exhaust filters of a hospital's ventilation system for 24 hrs to collect viable virus. Infectivity was assessed using Vero E6 cell culture.	SARS-CoV-2 RNA was detected in fluid samples placed in the ventilation system, and in 33% of samples (n=1/3) placed near air entrances of wards. Viability of the isolated virus could not be established by cell culture.
Zhang (2020) (84) *Preprint* Biological monitoring study - Hospital setting China Mar-Apr 2020	The study sampled outdoor environment aerosols (n=16) at three hospitals receiving COVID-19 patients. Aerosol samples were collected using bioaerosol samplers WA-15. Viral RNA was quantified by RT-PCR.	SARS-CoV-2 virus was identified within sampled aerosols at 285-1,130 copies/m^3 concentrations, similar to contamination levels observed in ICU units. Viral RNA was identified up to 5 meters away from outpatient buildings (n=1/2),

		as well as in hospital waste water treatment areas (n=1/3).
No SARS-CoV-2 RNA in samples		
Dumont-Leblond (2021) (22) Biological monitoring study Canada Spring 2020 *new*	Air and no-touch surfaces of 31 rooms from multiple long-term care facilities (n=7) in Quebec were sampled. The air samples were collected 8 to 30 days after the residents' symptom onset using an IOM Multidust sampler attached to a portable pump Gillian Air 5, placed ~2m from SARS-CoV-2 positive residents. The sampled rooms did not have significant aerosol mitigation measures in place. SARS-CoV-2 RNA was quantified by RT-PCR, and cultured by Vero E6 cells. Note: the distance of surfaces from SARS-CoV-2 patients was not provided.	All air samples (n=31) were negative, but viral RNA was recovered from 32% (n= 20/62) no-touch surface samples of door frames and shelving units (concentrations range 13-36,612 genomes/surface). Authors suggested the viral load recovered from the no touch surfaces without direct contact to be indicative of viruses spread through air. Virus could not be cultured from positive samples.
Song (2020) (85) Biological monitoring study China Feb 2020 *new*	Air samples were collected from Airborne infection isolation rooms (AIIR) housing COVID-19 cases. Air samples were collected using the automatic sampling system Derenda PNS 16T-3.1, at approximately 1 meter from patient beds. Viral RNA in samples was measured by RT-PCR.	All of the samples were negative for SARS-CoV-2 RNA.
Faridi (2020) (86) Biological monitoring study Iran Mar 2020 *new*	Air samples (n=10) were collected from COVID-19 patient wards housing individuals with server and critical symptoms. Air samples were collected into the sterile standard midget impingers using a vacuum pump.	All of the samples were negative for SARS-CoV-2 RNA.

	Air samplers placed 1.5 to 1.8 m above the floor and approximately 2 to 5 m away from patients' beds. Some patients coughed during the sample collection. Viral RNA in samples was measured by RT-PCR.	
Declementi (2020) (87) Biological monitoring study Italy Sept 2020* *new*	Air samples (n=8) were collected from a COVID-19 non-Intensive Care Unit, following cleaning and disinfection processes. Viral RNA in samples was measured by RT-PCR. Note: The sampler model, the presence of COVID-19 cases during sampling nor the sampling distance from cases are provided.	All of the samples were negative for SARS-CoV-2 RNA.
Anh (2020) (88) Biological monitoring study Korea Mar 2020 *new*	Air samples were collected from the isolation rooms of severe COVID-19 patients requiring mechanical ventilation or high-flow oxygen therapy. Samples were collected using a SKC BioSampler and swab sampler. Viral RNA was measured by RT-PCR.	All of the samples were negative for SARS-CoV-2 RNA.
Masoumbeigi (2020) (89) Biological monitoring study Iran Sept 2020* *new*	Air sampling (n=31) was conducted in a hospital with COVID-19 patients; all of the patients had a severe form of cough and sneezing. Air samples were collected from Emergency wards, ICU, CT-SCAN, and laundry unit. Air sampling was performed by all-glass impinger (AGI) at ~0.5-4 m away from patients' beds. Viral RNA was detected by RT-PCR.	All of the samples were negative for SARS-CoV-2 RNA.

Alsved (2020) (90) Biological monitoring study Sweden* Spring 2020*	SARS-CoV-2 RNA measured from COVID-19 cases (n=2) within 2 days of symptom onset. Air samples were collected 0.8 meters away from the case, as the individual was talking or singing. The measurements were carried out in an experimental airtight chamber with human volunteers.	Air samples collected within 0.8 meters of COVID-19 cases were negative for viral RNA. Viral loads in subject airways at the time of the experiment could not be obtained. Authors state qPCR Ct values of 22–25 to have been reported in clinical reports for the subjects within 24hrs of the experiment.
Cheng (2020) (91) Biological monitoring study China Jan-Apr 2020	Air samples were collected within 10 cm of asymptomatic and symptomatic COVID-19 patients (n=6) with and without surgical masks in AIIR were tested for SARS-CoV-2 contamination. Viral loads in respiratory patient fluid samples were also tested by having patients sneeze and spit into gelatin filters within air samplers. Viral loads were measured using assays (not specified) and RT-PCR.	No virus was detected in air samples from rooms with both surgical masked and non-masked patients. Except for one patient who had a respiratory fluid viral load of 2.54×10^4 copies/ml, all other patients' samples from sneezing were negative for virus RNA. Authors suggest aerosol transmission is not the predominate mode of infection transmission in the sampled settings. Appropriate PPE use, environmental disinfection, and single occupancy within AIIR are provided as reasons for observed results.
Kim (2020) (92) Biological monitoring study South Korea Mar-Apr 2020	Air samples (n=52) were collected 2 meters away from COVID-19 patients (n=8), before admission, and on hospital days 3, 5, and 7 using a MD8 Airport Portable Air Sampler. Some patients were housed in negative pressure rooms (e.g. AIIR). RNA was measured by RT-PCR.	All collected air samples were negative for viral RNA.
Ong (2020) (93) Biological monitoring study	Air samples were collected from COVID-19 patients (n=3) in AIIR at a dedicated SARS-CoV-2	No air samples were positive for SARS-CoV-2 viral RNA.

Singapore Jan-Feb 2020	outbreak center between day 4 and day 11 from symptom onset using SKC Universal pumps a Sartorius MD8 microbiological sampler. RNA was measured using RT-PCR.	
Ma (2020) (51) *Preprint* Biological monitoring study China Spring 2020* Note: Additional results on viral RNA in exhaled breath samples and community setting air samples are summarized in Table 4 and Table 6.	Air samples (n=26) were collected from hospital settings and unventilated quarantine hotel rooms of cases using a robot. RNA was detected by RT-PCR.	No air samples from hospital settings were positive for SARS-CoV-2 viral RNA.

Table 6: Biological monitoring studies investigating SARS-CoV-2 within air in community settings (n=9)

SARS-CoV-2 in cell culture samples		
Lednicky (2021) (23) *Preprint* Biological monitoring study USA Jan 2021* *new*	Air samples were collected from a car driven by a COVID-19 patient (mildly symptomatic, no cough) using a Sioutas personal cascade impactor sampler at multiple sampling stages of aerosol sizes (PCIS); the sampler was attached to the sun-visor on the passenger side of the car and approximately 3 feet from the subject's face. The air conditioner in the car was on during the 15 minute long drive.	SARS-CoV-2 viral RNA was detectable at all PCIS aerosol size sample stages, at concentrations ranging from 1.24E+03 to 3.14E+04 genome/ m^3 of air. These findings suggest virions are present in different sized respiratory secretions. SARS-CoV-2 was cultured from the sampling stages collecting particles in the 0.25 to 0.50µm size range.

	SARS-CoV-2 RNA was detected by RT-PCR, virus viability measured by Vero E6 cell culture, as well as genome sequencing.	
SARS-CoV-2 RNA in samples		
Munoz-Price (2021) (24) Biological monitoring study US Spring 2021* *new* Note: Additional results on viral RNA in environmental air from patient care settings are summarized in Table 5.	Air samples (n=9) collected from households occupied by confirmed COVID-19 cases. Air samples were collected using the Sartorius MD8 airscan sampler, positioned at 0.3 -1.8 meters from patients' head. Viral RNA in samples was measured by RT-PCR.	55% (n=5/9) of air samples, collected from three different households, were positive for viral RNA. The odds of positive air samples in household settings, when compared to hospital settings, were estimated to be 8.75 [95% CI 1.21–63.43; P = .058]. The median number of days from the last positive SARS-CoV-2 test to the day of air sampling was 3 (range, 2.5–5). Of the households with positive air samples, one had A/C running and all three had opened windows or doors immediately prior to air sampling. Anecdotally, most households felt warm and humid at the time of sample collection.
Gehrke (2021) (61) *Preprint* Biological monitoring study Germany Oct 2020 - Jan 2021 *new* Note: Additional results on viral RNA in hospital settings air samples are summarized in Table 5.	Air samples were collected from a concert hall and a shopping mall for 6 hours during operation using non-powered cold traps. Viral RNA was quantified by RT-PCR in an area with high community transmission in an effort to identify potential hotspots for transmission.	Indoor COVID-19 hotspots were found in non-ventilated areas and in zones that are predisposed to a buoyancy (chimney) effect. In the concert hall, 1/10 cold traps were positive for viral RNA. In the shopping mall, 35% of traps were positive for viral RNA (n=5/14) located on the ground floor, 2nd and 3rd kiosk area as well as around the escalators. The 4th floor fashion section that usually has 25% capacity was negative. The highest viral concentration (2.7-5.4 x10^3 copies/mL) was found on the ground level between the escalators. However, follow-up measurements where cold

		traps were placed directly under 2 inflows and 2 outflows on the 3rd floor (to exclude any contamination of the central ventilation system) were negative. Samples taken on Friday with a high volume of patrons were twice as high as those taken on Monday.
Moreno (2021) (69) Biological monitoring study Spain May- Jul 2020 *new*	Air samples were collected from subway trains and buses during operation. Ambient air ($PM_{2.5}$) was sampled using Teflon filters with PEM (Personal Environmental Monitor) equipment, A/C filters were also sampled. Viral RNA in samples was measured by RT-PCR.	2/6 subway train air samples were SARS-CoV-2 positive and none of the air conditioner filter samples were positive. 1/6 bus air samples and 4/9 air-conditioning filters were positive. Cleaning and disinfection results indicated this process was successful at decontamination.
de Rooij (2021) (66) *Preprint* Biological monitoring study Netherlands Apr-Jun 2020 *new*	Air samples were collected from mink farms with ongoing COVID-19 outbreaks (3 farms at late stage of outbreak, 1 at early stage of outbreak). Samples were collected from indoor farm environments, outdoors at the farm premises, and nearby residential sites. Air samples were collected using teflon filters, and in parallel with particulate size fraction PM_{10} (<10µm) and inhalable dust (<100µm) collection. Personal air samples from the investigation field staff were also collected. Viral contamination in air samples was measured by RT-PCR.	Based on sample contamination the investigators conclude mink farms to be highly contaminated with viral RNA inside but the dispersion of virus outdoors and to nearby areas to be negligible. Farm in acute stage of outbreak: - SARS-CoV-2 RNA was detected in 62.5% (n=5/8) of the inhalable dust samples and 50% (n=4/8) of PM_{10} samples collected inside the farm. All (n=2) personal air samples were positive for viral RNA. - SARS-CoV-2 RNA was also detected in outdoor samples at 1.5-10 meters from the farm's open entrance, but samples collected at 20m from this entrance were negative. Farms in late stage of outbreak:

		- Viral RNA was detected in 9.8% (n=4/41) of inhalable dust samples, at ~4x10^3 copies/m^3. SARS-CoV-2 RNA was not detected in the inhalable dust samples collected outside the mink houses (n=9) or from the PM_{10} samples collected inside the farm (n=9) or near the mink houses (n=9). One of the personal air samples was positive for SARS-CoV-2 RNA. - All of air samples from residential sites were negative for SARS-CoV-2 RNA.
Ma (2020) (51) *Preprint* Biological monitoring study China Spring 2020* Note: Additional results on viral RNA in exhaled breath samples and hospital settings air samples are summarized in Table 4 and Table 5.	Air samples (n=26) were collected from hospital settings and unventilated quarantine hotel rooms of cases using a robot. RNA was detected by RT-PCR.	A single positive air sample (3.8%) was identified in an unventilated quarantine hotel toilet room.
NO SARS-CoV-2 RNA in samples		
Wong (2020) (67) *Preprint* Biological monitoring study Singapore Feb-Mar 2020	Air samples (n=6) were collected from accommodation rooms, corridors, toilets and elevators used by COVID-19 cases in community settings (not specified). Viral RNA in samples was measured by RT-PCR.	All air samples were negative for viral RNA.

new		
Döhal (2020) (68) *Preprint* Biological monitoring study Germany Mar 2020 *new*	Environmental air from 21 quarantine households (n=15) were collected by cyclone sampling using a Coriolis 154 Micro Air sampler. Viral RNA in samples was measured by RT-PCR and Vero-E6 cell culture. Note: At least one person in each included household was positive for SARS-CoV-2 at the time of sample collection.	All air samples were negative for viral RNA.
Di Carlo (2020) (94) Biological monitoring study Italy May 2020 *new*	Samples were collected on a city bus in a town which had a high number of COVID-19 cases, during the last week of lockdown and first week of gradual opening (approx. 1100 passengers used the bus during the study period). Air was sampled using microbiological gelatin membrane sample filters of 80 mm. Viral RNA in samples was measured by RT-PCR.	No air samples (or surface samples) were positive for SARS-CoV-2. Public health measures in place included hand sanitized upon entry to the bus, mandatory masks and keeping the bus windows open. Authors state these precautions prevented SARS-CoV-2 circulation and detection in the investigation.

SARS-COV-2 VIRAL LOADS IN RESPIRATORY PARTICLES

A systematic review and meta-analysis informed a model to estimate the relationship between viable SARS-CoV-2 virus, case viral loads, and virus laden droplet and aerosol emission (55). This review found that peak viral load occurred between one day before to five days post symptom onset (55). The model estimated the likelihood of viable virus in respiratory aerosols expelled by an individual at peak viral load was ≤61.1% (95% CI: 51.8-70.4%), and the likelihood estimate was substantially lower, at ≤ 0.69% (95% CI: 0.43-0.95%), for an individual with a mean viral load.

Table 7: SARS-CoV-2 viral load in respiratory particles (n=1)

STUDY	METHOD	KEY OUTCOMES
Chen (2020) (55) *Preprint* Systematic Review informed *in-silico* analysis Canada* Aug 2020	A systematic review and meta-analysis were conducted (Aug 2020) to developed a dataset and summarize data on SARS-CoV-2 respiratory viral load (rVL). A model was developed to estimate the likelihood of respiratory droplets and aerosols containing viable virus assuming different viral load estimates, and different activities.	The meta-analysis showed there was a large degree of heterogeneity in viral loads across individuals, studies, and stages of infection. This suggests intrinsic virological factors mediate the over dispersion seen in the pandemic. Many cases present minimal transmission risk, whereas highly infectious individuals were estimated to shed 9.84 (95% CI 9.17-10.56,) $\log_{10}$ SARS-CoV-2 virions/ml via droplets and aerosols while breathing, talking and singing. The model estimates coughing increased the contagiousness of symptomatic cases. The likelihood of viable virus in respiratory aerosols at peak viral load was estimated to be ≤61.1% (95% CI: 51.8-70.4%) for the most infectious cases, and ≤ 0.69% (95% CI: 0.43-0.95%) for cases with mean viral load.

*Estimated based on author affiliations and publication date.

Methods:

A daily scan of the literature (published and pre-published) is conducted by the Emerging Science Group, PHAC. The scan has compiled COVID-19 literature since the beginning of the outbreak and is updated daily. Searches to retrieve relevant COVID-19 literature are conducted in Pubmed, Scopus, BioRxiv, MedRxiv, ArXiv, SSRN, Research Square and cross-referenced with the literature on the WHO COVID literature list, and COVID-19 information centers run by Lancet, BMJ, Elsevier and Wiley. The daily summary and full scan results are maintained in a Refworks database and an excel list that can be searched. Targeted keyword searching is conducted within the COVID-19 database to identify relevant citations using search terms: aerosol, airborne, droplet.

Each potentially relevant citation was examined for relevance, the full text of potentially relevant research was examined to confirm relevance and a synopsis of the study was extracted into the review. This review contains research published up to March 12, 2020.

Peer-review

This document underwent peer-review by a subject matter expert, and editorial and science to policy review by the Office of the Chief Science Officer.

Prepared by: Chatura Prematunge and Lisa Waddell. NML, Emerging Science Group, PHAC.

Knowledge mobilized by the Office of the Chief Science Officer: phac.ocsoevidence-bcscdonneesprobantes.aspc@canada.ca

Nouveaux éléments de preuve sur la COVID-19

Revue rapide sur la transmission par les aérosols du SRAS-CoV-2, Mise à jour 2

Introduction

Quelles sont les preuves émergentes en ce qui concerne les grappes de cas ou les éclosions, ainsi que les preuves expérimentales et biologiques en lien avec la transmission du SRAS-CoV-2 par les aérosols?

Les preuves scientifiques et la compréhension des modes de transmission du SRAS-CoV-2 ont évolué rapidement au cours de la dernière année. Les particules respirables expulsées contenant des agents pathogènes infectieux peuvent se présenter sous différentes tailles et les particules respirables plus petites (souvent appelées aérosols) peuvent rester en suspension dans l'air et se disperser sur de plus grandes distances que les grosses gouttelettes respiratoires. Il a été établi que d'autres agents pathogènes connus pour être principalement transmis par de grosses gouttelettes (par exemple, la grippe, le SRAS-CoV-1, la pneumonie pneumococcique et la légionellose) peuvent également se propager par des aérosols dans certains milieux et conditions (1 à 6). Ainsi, un éventail de données probantes a été produit pour décrire les caractéristiques et l'importance relative des aérosols dans la transmission du SRAS-CoV-2 dans différents milieux et conditions.

La présente synthèse en bref résume la documentation scientifique qui fournit des données probantes sur la transmission du SRAS-CoV-2 par les aérosols publiées jusqu'au 12 mars 2021. Elle comprend différentes sections portant sur les données probantes suivantes :

1) Les enquêtes sur les grappes de cas ou les éclosions de SRAS-CoV-2 associées à la transmission par les aérosols;
2) Les expériences sur la transmission indirecte du virus SRAS-CoV-2 à l'aide de modèles animaux;
3) Les preuves expérimentales sur la stabilité et la viabilité du virus du SRAS-CoV-2 dans les aérosols;
4) Les études de biosurveillance portant sur l'ARN du SRAS-CoV-2 dans des échantillons d'air expiré;
5) Les études de suivi biologique de l'ARN du SRAS-CoV-2 et de sa viabilité dans des échantillons d'air ambiant prélevés dans des milieux de soins aux malades et dans la collectivité (c.-à-d. milieux non hospitaliers/soins aux patients).

La section sur les données probantes portant sur les simulations dynamiques des fluides et les analyses *in silico* a été omise de cette mise à jour en raison de la quantité croissante de données empiriques à l'appui du potentiel de transmission du SRAS-CoV-2 par les aérosols.

Quoi de neuf

- Cette mise à jour a relevé 46 nouvelles études prépubliées et publiées entre le 6 novembre 2020 (la dernière date de mise à jour) et le 12 mars 2021 sur le potentiel de transmission du SRAS-CoV-2 par les aérosols. Ces études sont résumées ci-dessous et portent la mention *nouvelle* dans les tableaux présentant les données probantes.
- La mise à jour comprend également douze nouveaux rapports d'enquête portant sur des éclosions ou des grappes de cas de SRAS-CoV-2 dans des contextes réels (tableau 1). Ces événements avec transmission par les aérosols se seraient produits dans un hôtel où se trouvaient des voyageurs en quarantaine, dans une maison de soins infirmiers, dans l'unité d'hématologie d'un hôpital, dans un autobus avec passagers, dans un restaurant, dans des installations de conditionnement physique, dans un grand magasin et dans des appartements à la verticale dans une tour d'habitation (7 à 16). Ces rapports indiquaient notamment que le masque ou le couvre-visage était peu porté ou qu'il était porté de façon inadéquate au moment de la transmission présumée par les aérosols, alors que les cas index en étaient aux stades présymptomatiques ou symptomatiques précoces de l'infection.
- Deux nouvelles expériences fondées sur des modèles animaux ont fait état de multiples modes de transmission du SRAS-CoV-2, incluant les aérosols, entre des paires de hamsters infectés et vulnérables (17, 18). Une étude suggérait même que l'exposition aux aérosols avait entraîné une réplication précoce du virus, l'excrétion dans les tissus respiratoires et des manifestations plus aiguës de la maladie chez les hamsters, comparativement aux expositions fomites et intranasales (17). L'autre étude a révélé que les aérosols provenant de hamsters naïfs infectés pouvaient infecter des hamsters ayant déjà été infectés, ce qui indique que la guérison, après avoir eu une infection primaire au SRAS-CoV-2, n'éliminait pas le risque d'infection subséquente par des aérosols (18).
- Une étude expérimentale nouvellement incluse sur la viabilité et les taux de désintégration du virus SRAS-CoV-2 dans les aérosols a révélé que l'infectiosité du virus dans les aérosols dépendait fortement des conditions environnementales, selon l'ordre d'influence suivant : (mi-journée en été, mi-journée au printemps, intérieur/soirée) >température (entre 10 et 40 °C)> humidité (20 à 70 %) (19). L'on a estimé qu'il fallait 4,8 minutes (à 40 °C, avec 20 % d'humidité relative) avec une exposition à la lumière du soleil en mi-journée pour réduire de 90 % les virus infectieux alors que sans exposition à la lumière du soleil (c.-à-d. à l'intérieur ou la nuit), il fallait plus de 2 heures (à 40 °C, avec une humidité relative de 20 %) pour atteindre le même niveau de réduction. La lumière du soleil a eu la plus grande influence sur le taux de désintégration, mais on a aussi noté une plus grande désintégration à 30 °C avec un taux élevé d'humidité (70 %) ou à 40 °C sans égard à l'humidité.
- Une nouvelle étude de suivi biologique portant sur les échantillons d'air expiré de cinq patients a révélé que l'ARN viral n'avait été détecté que dans les échantillons provenant de patients atteints

de la COVID-19 ayant obtenu des résultats positifs lorsque l'échantillonnage avait inclus des prélèvements oropharyngés, naso-pharyngés ou salivaires (20).

- Vingt-huit nouvelles études de suivi biologique portant sur la contamination par le virus du SRAS-CoV-2 dans des échantillons d'air ambiant prélevés dans des milieux de soins aux patients (y compris des études sur les hôpitaux et les soins de longue durée) et dans des milieux communautaires (c.-à-d. soins non prodigués aux patients) sont incluses dans la présente mise à jour.
    - Deux études canadiennes ont révélé une contamination par l'ARN viral dans des échantillons d'air ambiant prélevés dans un hôpital (à environ 3 mètres de patients atteints de la COVID-19) et sur des surfaces sans contact dans des foyers de soins de longue durée (21, 22) indiquant que le SRAS-CoV-2 peut se propager dans les aérosols.
    - Une nouvelle étude a confirmé la présence d'un virus viable dans des échantillons d'air prélevés dans une voiture conduite par un individu légèrement symptomatique (23). Cela met en évidence le fait que le virus du SRAS-CoV-2 peut être expulsé dans l'air ambiant, même chez une personne atteinte d'une forme légère, pendant une courte période de temps (23).
    - Une autre étude a comparé des échantillons d'air ambiant prélevés dans des chambres d'hôpital et chez des ménages en quarantaine où se trouvaient des cas actifs (24). On a estimé que les échantillons d'air ambiant provenant des ménages étaient environ huit fois (RC 8,75 [IC à 95 % 1,21 à 63,43; p = 0,058]) plus susceptibles d'être contaminés par de l'ARN viral que les échantillons d'air provenant des hôpitaux. D'après les résultats de l'étude, les experts cliniques suggèrent que les différences dans les échanges d'air et la ventilation sont une différence clé plus importante que l'acuité même de la maladie, en ce qui concerne la contamination de l'air ambiant.

Points clés

- Au total, 84 études sur le potentiel de transmission par les aérosols ont été recensées dans les publications et préimpressions. Des enquêtes effectuées dans les cas d'éclosions multiples et de grappes de cas suggèrent que la transmission du SRAS-CoV-2 par les aérosols peut se produire dans certains contextes. De nouvelles preuves expérimentales chez des animaux séparés indiquent que l'infection peut se propager à la suite d'une exposition aux aérosols, et que le virus infectieux peut demeurer stable et viable dans les aérosols en suspension. Des études de suivi biologique confirment la présence d'ARN viral dans des échantillons d'air expiré et d'air ambiant. Une revue systématique et une méta-analyse fondées sur des données cliniques permettent d'estimer la durée pendant laquelle le virus respiratoire du SRAS-CoV-2 est viable.
- Vingt-six enquêtes sur vingt éclosions ou grappes de cas différentes de COVID-19 dans différents contextes réels (p. ex., une maison de soins infirmiers, l'unité d'hématologie d'un hôpital, un hôtel ou

un établissement où se trouvaient des voyageurs en quarantaine, des usines de transformation de viande, une pratique d'un groupe de chorale qui avait lieu à l'intérieur, un restaurant, un navire de croisière, un autobus avec passagers, des installations de conditionnement physique, une tour d'habitation et un centre commercial) ont contribué à la transmission par les aérosols parmi les cas (tableau 1). Les enquêtes épidémiologiques suggèrent que la transmission par les aérosols est amplifiée ou plus susceptible de se produire dans certains environnements et dans certaines conditions, comme dans des espaces intérieurs mal ventilés ou surpeuplés, lorsque des personnes symptomatiques ou présymptomatiques précoces sont présentes ou lorsque les personnes prennent part à différentes activités physiques (par exemple, chanter, faire du conditionnement physique).

- Une revue systématique et une méta-analyse des estimations cliniques ont révélé que la probabilité qu'un virus viable soit présent dans les aérosols respiratoires expulsés par une personne ayant une charge virale maximale était de 61,1 % (IC à 95 % : 51,8 à 70,4 %), alors que les estimations de vraisemblance étaient très inférieures à ≤ 0,69 % (IC à 95 % : 0,43 à 0,95 %) pour une personne ayant une charge virale moyenne. On a estimé que le pic de la charge virale se produisait entre un jour après l'apparition des symptômes et cinq jours après l'apparition de ceux-ci (tableau 7). Cette constatation est conforme à celles qui ont été obtenues pour l'ensemble des éclosions dans lesquelles le cas index était habituellement présymptomatique ou à un stade précoce de la maladie symptomatique lors de la transmission.
- Les études sur les animaux fournissent des preuves de l'infection par les aérosols et de la transmission de l'infection même lorsque les animaux infectés et vulnérables sont séparés par des cages ou des barrières. Les experts cliniques responsables de l'étude ont déterminé que cette transmission indirecte de l'infection était au moins partiellement attribuable aux aérosols et à la circulation d'air (tableau 2).
- Trois études font état de la stabilité et de la viabilité du virus dans les aérosols, ainsi que de l'influence des facteurs environnementaux (p. ex., température, humidité et exposition à la lumière du soleil) sur la persistance du virus dans les aérosols (tableau 3). Des preuves expérimentales ont démontré la viabilité prolongée pendant plusieurs heures (entre 2 et 16 heures) du virus du SRAS-CoV-2 dans les aérosols en laboratoire.
- Les études de biosurveillance mesurent l'ARN viral dans des échantillons d'haleine expirés provenant de personnes infectées (tableau 4) ainsi que dans l'air ambiant dans des milieux communautaires et de soins aux patients (tableaux 5 et 6). Le nombre croissant d'études qui confirment la présence du SRAS-CoV-2 dans l'air ambiant fournit des preuves supplémentaires à l'appui de la transmission par les aérosols dans les collectivités. Les quelques études qui ont confirmé la viabilité du virus dans la culture cellulaire ont aussi mentionné la collecte d'échantillons d'air ambiant près des personnes infectées (< 2 mètres) (tableaux 5 et 6).

Vue d'ensemble des éléments de preuve

Les éléments de preuves disponibles en ce qui concerne la transmission potentielle du SRAS-CoV-2 par les aérosols dans les documents publiés et en préimpression évoluent rapidement. La présente revue comprend les études (n = 84) consultées jusqu'au 12 mars 2021 et jugées pertinentes par un seul examinateur. La qualité globale des éléments de preuve examinés est décrite de manière générale ci-dessous pour chacune des sections des éléments de preuve présentés selon le plan d'étude, la quantité et l'uniformité des données présentées. En gros, la hiérarchie des données probantes et les évaluations générales de la qualité jugent que les essais contrôlés randomisés effectués de façon appropriée sont de grande qualité en raison de leur faible risque de biais. D'autres études expérimentales qui peuvent être vues comme étant de qualité moyenne peuvent également être déclassées en raison de problèmes associés à l'autorité ou à la conduite des études. Les expériences utilisant des modèles animaux sont vues comme des preuves de faible qualité. Les études d'observation sont, quant à elles, généralement considérées comme présentant un risque élevé de biais et, par conséquent, une faible qualité, mais certaines grandes études de cohorte prospectives bien menées peuvent être évaluées comme présentant un risque modéré ou faible de biais, et peuvent donc être vues comme de qualité modérée à élevée.

Parmi toutes les études, 26 études d'enquête sur des éclosions ou des grappes de cas portant sur 20 différentes éclosions chez les humains suggèrent une transmission du SRAS-CoV-2 par les aérosols (tableau 1). Il s'agit d'études d'observation rétrospectives qui risquent de comporter de nombreux biais. La nature rétrospective de ces enquêtes et le manque de données de génotypage pour la majorité des cas indiqués signifient que les inférences sur la transmission par les aérosols se limitent aux liens épidémiologiques. Les études en grappes multiples incluent une description de l'enquête et des simulations *in silico* qui explorent le potentiel de transmission par les aérosols dans des contextes réels.

Les modèles animaux fournissent des données expérimentales sur l'infection découlant de l'exposition à des aérosols, en évaluant la transmission indirecte des animaux infectés à des animaux vulnérables en raison de l'écoulement d'air passif ou dirigé, lorsqu'ils ne sont séparés que par des cages et des barrières (tableau 2). Ces études n'ont cependant pas fourni suffisamment de détails sur les symptômes et les comportements des animaux infectés (p. ex., éternuements et transfert de liquide respiratoire par reniflement ou léchage des barrières) ou la configuration expérimentale pour exclure la transmission de l'infection par contact avec les liquides respiratoires et buccaux dans la plupart des expériences. Dans l'ensemble, les modèles animaux de transmission offrent la plus faible qualité de données probantes sur la transmission par les aérosols.

Trois études expérimentales fournissent des preuves confirmant la stabilité et la viabilité du virus infectieux dans les aérosols artificiellement générés et en suspension (tableau 3). Bien que ces études fournissent des preuves solides qui appuient la longévité du virus infectieux en laboratoire pendant une période pouvant aller jusqu'à 16 heures, l'application de ces résultats à des contextes réels par l'entremise d'études de suivi biologique demeure en grande partie non établie.

La majorité des études de suivi biologique indiquées recherchaient l'ARN viral du SRAS-CoV-2 dans l'air expiré (tableau 4) et dans des échantillons d'air ambiant provenant de différents milieux (tableaux 5 et 6). Ces données fournissent des preuves de qualité modérée indiquant que l'ARN viral peut se déplacer dans l'air ou y demeurer à une certaine distance d'une personne infectée dans certains milieux et dans certaines conditions. Il y a un nombre limité de rapports sur la concentration du virus dans les échantillons positifs, sur la distance d'échantillonnage des personnes infectées et sur la viabilité du virus documentée grâce à la culture cellulaire. L'absence de ces détails limite donc le caractère généralisable des données de suivi biologique à tous les environnements intérieurs et à toutes les personnes infectées et entrave la détermination des paramètres et des conditions qui favorisent une augmentation de la concentration du virus viable se trouvant dans l'air expiré et des particules aérosolisées dans l'air. Il est également probable que la vaste gamme de milieux dans lesquels les échantillons ont été prélevés (p. ex., milieux de soins aux patients ou milieux communautaires) et de différentes techniques de prélèvement (p. ex., air expiré ou condensat de l'air expiré) ait influé sur la sensibilité de la quantification de l'ARN viral et des tests viables de détection de virus utilisée dans les échantillons de suivi biologique. Des recherches supplémentaires sont donc nécessaires pour confirmer l'infectiosité et la viabilité du SRAS-CoV-2 dans les échantillons d'air afin de savoir où et quand augmente le risque de transmission du SRAS-CoV-2 par les aérosols.

Cette revue résume donc les données probantes sur la transmission du SRAS-CoV-2 par les aérosols et caractérise les milieux et conditions ayant été étudiés. D'autres données probantes sont cependant nécessaires pour combler les lacunes dans les connaissances sur la transmission du SRAS-CoV-2 par les aérosols :

1) Quantification de la dose infectieuse de SRAS-CoV-2;

2) Caractéristiques du cas et conditions environnementales dans lesquelles un virus viable est susceptible d'être présent dans l'air expiré, de demeurer en suspension dans l'air ambiant et d'y circuler;

3) Données génomiques tirées des enquêtes sur les grappes de cas et les éclosions qui suggèrent une transmission indirecte de l'infection par le SRAS-CoV-2 chez les humains;

4) Confirmation du lien entre les cas grâce aux données de génotypage, et données de meilleure qualité appuyant la transmission par les aérosols dans les éclosions ou grappes de cas visées;

5) Examen officiel de la documentation sur la dynamique des fluides effectuée par des experts dans ce domaine afin qu'ils puissent mieux décrire les conditions environnementales et les activités comportementales qui augmentent (ou diminuent) l'émission d'aérosols respiratoires et la transmission des infections, et quantification des estimations des risques de transmission par les aérosols.

TABLE DES MATIÈRES

ENQUÊTES SUR LES GRAPPES DE CAS ET LES ÉCLOSIONS

Cette section présente un résumé de vingt-six études décrivant vingt grappes de cas ou éclosions de COVID-19 différentes dans des contextes réels qui soutiennent épidémiologiquement la transmission d'infections par les aérosols (tableau 1). Dans un certain nombre d'études, les mêmes grappes de cas ou éclosions de COVID-19 ont été étudiées par des groupes distincts d'expert clinique qui ont tous conclu que les aérosols ou la transmission indirecte longue distance du virus avaient joué un rôle dans la propagation de l'infection entre les cas. Ces éclosions ont été organisées en fonction du milieu dans lequel les experts cliniques responsables de l'étude ont supposé que la transmission de l'infection s'était produite. Les installations comprenaient une unité d'hématologie dans un hôpital, un hôtel où des voyageurs restaient en quarantaine, des autobus avec passagers, des cours et des installations de conditionnement physique, une usine de transformation de viande, des restaurants avec salle à manger, une pratique d'un groupe de chorale, un navire de croisière, des grands magasins et différentes tours d'habitation. Les preuves incluent des enquêtes épidémiologiques, des analyses et des simulations dynamiques numériques des fluides, des images de surveillance vidéo ou une analyse spatiale des cas pendant l'événement de transmission.

Il est intéressant de noter que plusieurs grappes de cas et éclosions de COVID-19 se sont produites dans des milieux semblables, ce qui laisse entendre qu'ils pourraient être plus favorables à la transmission par les aérosols. Les caractéristiques communes étaient des espaces fermés avec ventilation minimale (c.-à-d. peu ou pas de fenêtres, ventilation et circulation d'air insuffisantes), la présence de cas index présymptomatiques ou avec symptômes précoces et la propagation des virions au-delà des deux mètres favorisée par un débit d'air artificiel, des systèmes de ventilation, des conduits d'air, des tuyaux d'évacuation ou une ventilation inefficace. De plus, dans certains cas, tant l'infecteur que les personnes infectées participaient à des activités qui augmentaient généralement les taux d'expiration (p. ex., exercice physique, chant) ou se trouvaient dans des espaces surpeuplés pendant les événements de transmission.

Il est également important de noter qu'à l'exception d'une des études résumées, aucune ne déclarait les séquences génétiques du virus isolé dans les cas d'éclosion ou de grappe de cas, sans oublier que nombreuses études ne décrivent pas le port du couvre-visage ou du masque pendant les événements d'exposition. Il s'agit là de lacunes importantes dans les données probantes existantes, car les données de génotypage confirmeraient le lien entre les cas, tandis que les données sur le port des couvre-visages ou des masques donneraient une idée de l'efficacité de cette mesure de prévention. Le fait que ces informations ne figurent pas dans le résumé des enquêtes sur les éclosions et les grappes de cas est l'une des principales limites de cette preuve.

Tableau 1 : Enquêtes sur les grappes de cas ou les éclosions de SRAS-CoV-2 associées à la transmission par les aérosols (n = 26)

ÉTUDE	MÉTHODE	RÉSULTATS PERTINENTS
Unité d'hématologie dans un hôpital		
Saidel-Odes (2021) (25) Enquête sur les grappes Israël Septembre et octobre 2020 *nouvelle*	Enquête sur une éclosion de COVID-19 liée à un cas de référence qui était immunodéprimé en raison d'un myélome multiple et qui a subi une greffe de cellules souches. Le patient a été traité dans une chambre d'isolement des infections aéroportées après un diagnostic de COVID-19, et le personnel médical a revêtu l'EPI approprié (c.-à-d. masque N95, écran facial, blouse et gants) avant d'entrer dans la salle d'isolement du patient. Tous les membres du personnel de l'unité portaient des blouses, des gants et des masques.	Sept membres du personnel soignant de l'unité de transplantation qui hébergeait le cas de référence ont eu un diagnostic d'infection, soit un taux d'attaque de 19 % (n = 7 sur 37). Le personnel infecté comprenait deux médecins, quatre infirmières et un préposé à l'entretien ménager. Deux des employés qui ont eu un résultat positif n'ont signalé aucun contact direct avec le cas de référence. L'enquête épidémiologique et l'analyse univariée ont révélé que les travailleurs de la santé infectés étaient plus susceptibles d'avoir dit avoir passé du temps dans le corridor de l'unité ou au poste d'infirmières ([RR], R = 7,2; IC à 95 %, 1,22 à 42,49; P = 0,018), mais pas dans la chambre du cas de référence. Selon les experts cliniques, la transmission par les aérosols est la seule explication plausible de cette éclosion.

Quarantaine dans un hôtel et voyages en avion		
Eichler (2021) (14) Enquête sur les grappes Nouvelle-Zélande Septembre 2020 *nouvelle*	Enquête sur une éclosion de COVID-19 qui s'est produite pendant le rapatriement, dans un établissement d'isolement et de quarantaine obligatoire (hôtel) et parmi les contacts des ménages dans la collectivité. Les personnes qui revenaient d'autres pays étaient tenues de se soumettre à une quarantaine et à un isolement obligatoires dans un établissement pendant 14 jours après leur arrivée à destination.	L'utilisation des données de vidéosurveillance et de l'analyse génomique virale des grappes de cas a permis aux experts cliniques de dire qu'il devait y avoir plusieurs chaînes de transmission. Les sites de transmission soupçonnés étaient les vols internationaux et intérieurs, l'installation dans laquelle a eu lieu la quarantaine et les ménages. Bien que la transmission par les aérosols ait pu être le mode de transmission dans chacun des événements de transmission, une enquête approfondie a permis de conclure que la transmission par les aérosols était le principal mode de transmission de l'infection dans l'hôtel utilisé pour la quarantaine. Les expositions ou transmissions de cas dans l'éclosion sont présumées être les suivantes : - 2 cas de référence infectés au moment du rapatriement de l'Inde à Christchurch, en Nouvelle-Zélande. 1 cas d'exposition pendant le vol vers Christchurch, 2 cas d'exposition dans le couloir de l'hôtel utilisé pour la quarantaine (par les aérosols, plus de détails ci-dessous), 1 cas d'exposition pendant le vol de Christchurch à Auckland (transmission à partir des deux cas ayant été exposés aux aérosols qui avaient reçu un résultat de test négatif le jour 12 de leur quarantaine), ainsi que des cas supplémentaires parmi les contacts du ménage pour les trois derniers cas. En fonction des séquences vidéo obtenues, les experts cliniques ont pu conclure que la transmission par les aérosols avait eu lieu à la porte de deux chambres d'hôtel différentes où se trouvaient des personnes en quarantaine et cette transmission découlait des aérosols en suspension dans l'air. On a supposé que la transmission s'était produite pendant une fenêtre de 50 secondes

		entre le moment où la porte d'une chambre a été fermée dans un cas et l'ouverture de la porte de la chambre dans l'autre cas. Remarque : Un examen du système de ventilation de l'hôtel a révélé que les chambres en question avaient une pression positive nette par rapport au corridor, de sorte que l'air s'écoulait probablement dans le corridor lorsque la porte était ouverte.
Maison de soins infirmiers		
de Man (2020) (15) LTE Enquête sur les grappes Pays-Bas Juin et juillet 2020 *nouvelle*	Enquête sur une éclosion de COVID-19 dans une unité d'une maison de retraite néerlandaise comprenant sept unités.	Au total, 17 des 21 résidents de l'unité, 13 des 34 travailleurs de la santé œuvrant dans cette unité et 4 autres travailleurs de laboratoire ont été confirmés comme étant des cas liés à la grappe; le taux d'attaque parmi les résidents était de 81 % alors qu'il était de 50 % parmi les travailleurs de la santé. Les 106 travailleurs de la santé et les 95 résidents des autres unités ont tous continué à recevoir des résultats négatifs pour la COVID-19. Les travailleurs de la santé portaient des masques lorsqu'ils s'occupaient des patients et travaillaient dans des salles désignées pour limiter les contacts. L'éclosion s'est limitée à une seule unité (sur les sept que compte l'établissement) avec un système de ventilation qui recirculait l'air non filtré. Le système de ventilation était neuf et a permis de surveiller les concentrations de CO_2 pour déterminer à quel moment l'air devait être rafraîchi avec de l'air provenant de l'extérieur. L'ARN viral a été détecté dans le système de ventilation (climatiseurs et filtres à poussière du système de ventilation). Les experts cliniques ont déclaré que la transmission par les aérosols était probablement le résultat d'une mauvaise ventilation de l'unité, compte tenu de la détection simultanée d'un grand nombre de cas limités à une seule unité, et

		qu'elle s'est produite pendant une période de faible transmission dans la communauté.
Autobus pour passagers		
Luo (2020) (7) Enquête sur les grappes Chine Janvier 2020 *nouvelle*	Enquête sur une éclosion de COVID-19 liée à de multiples trajets en autobus du cas index à Hunan, en Chine.	Un total de 12 cas ont été recensés à la suite de l'enquête sur 243 personnes qui étaient associées épidémiologiquement à de multiples trajets en autobus effectués par le cas index, avec un taux d'attaque de 7,0 %. La distance à laquelle les personnes infectées se sont assises pendant les déplacements en autobus variait de 1 à 4,5 mètres du cas index. Le trajet de 2,5 heures en autobus a entraîné huit cas qui n'étaient pas tous assis les uns près des autres pendant le trajet. L'infection a également été décelée chez une personne qui se serait assise (probablement) sur le même siège que le cas index, une fois que cette personne soit débarquée de l'autobus. Deux cas ont été identifiés après le trajet d'une heure en autobus. Deux cas étaient des cas tertiaires pour l'une des personnes ayant été infectées dans l'autobus. Aucun des cas déterminés n'a déclaré avoir porté de couvre-visage pendant les déplacements en autobus. Les experts cliniques suggèrent que le fait que les aérosols puissent parcourir plus de deux mètres et la circulation de l'air ont influencé la transmission de l'infection dans l'environnement bondé et fermé de ces autobus.
Shen (2020) (26) Cluster Investigation China Jan 2020	A COVID-19 outbreak among 128 people driven to a worship event in Eastern China on two separate buses. Round trip was 100 minutes on the bus.	None of the passengers on Bus 1 were infected, 24 of the 68 passengers on Bus 2 developed COVID-19. Passengers riding Bus 2 with the index case had an attack rate of 34.3% (95% CI, 24.1%-46.3%), compared to passengers on bus 1. Although sitting near bus windows and doors appeared to have had a protective effect on

	Attack rates were measured for Bus 1 vs. Bus 2 that had the index case. Air conditioning systems of both buses were on recirculation mode. Spatial analysis of passenger seating was estimated.	infection transmission, the authors conclude, the lack of a significant increase in infection risk between individuals sitting in high risk zones (i.e. closer to the index case) and low risk zones, and elevated attack rates among bus passengers riding with the index case, to be partially explained by aerosol transmission of infection.
Usine de transformation de viande		
Guenther (2020) (27) *préimpression* Enquête sur les grappes de cas Allemagne Printemps 2020*	Enquête sur un événement de super-contamination parmi les travailleurs d'une usine de transformation de la viande, comprenant : les voies de transmission possibles, la relation spatiale entre les travailleurs, les conditions de climat et de ventilation, le partage des habitations et du transport, et le type génétique des échantillons prélevés dans la gorge.	L'analyse des cas index (colocataires) et de 18 cas de collègues de travail suggère que le fait de travailler au poste du matin (140 travailleurs de l'équipe du matin) est la source commune d'infection. Des taux d'infection statistiquement significatifs ont été observés chez les employés travaillant dans un rayon de 8 mètres autour du cas index suspect. Les auteurs concluent que les environnements intérieurs confinés, le travail physique exigeant et les conditions environnementales de l'installation (c'est-à-dire l'air constamment en recirculation et refroidi à 10 °C, avec un faible taux d'échange d'air) ont tous créé des conditions propices à la transmission par les aérosols. Remarque : aucune évaluation quantitative des risques n'a été fournie.
Restaurant		
Kwon (2020) (8) Enquête sur les grappes Corée Juin 2020 *nouvelle*	Enquête sur un groupe de trois clients dans un restaurant. L'enquête a tenu compte des données épidémiologiques, des images fournies par la télévision, des patrons de	Les experts cliniques ont conclu que la transmission de l'infection s'était produite d'un client infecté à deux personnes se trouvant dans le restaurant, avec un taux d'attaque de 15,4 % (2 sur 13). On a présumé que la date de l'exposition (et la source de l'exposition) a eu lieu une journée avant l'apparition des symptômes chez le cas index. Les aérosols étaient le mode de

	flux d'air et l'emplacement des téléphones cellulaires.	transmission présumé puisqu'ils ont pu parcourir plus de 6,5 mètres en raison du courant d'air créé par le climatiseur à l'intérieur du restaurant. Le temps d'exposition entre l'infecteur et l'infecté est d'environ 5 minutes. On précise que le port du masque ou du couvre-visage est inapproprié parmi les membres du personnel et les clients.
Lu (2020) (28) Enquête sur les grappes de cas Chine Janvier-février 2020	Analyse d'une grappe de cas de COVID-19 dans des petits restaurants offrant le dîner. L'enquête comprenait une analyse spatiale de la disposition des tables dans les restaurants et de l'endroit où les cas étaient assis.	Une éclosion parmi 91 personnes dans un restaurant; 83 personnes assises à 15 tables, et les huit personnes restantes étaient des membres du personnel. Un seul cas asymptomatique a conduit à neuf infections à la COVID-19 parmi les clients des familles A, B et C. Aucune des familles ne s'était rencontrée auparavant et n'avait eu de contact étroit pendant le dîner. Aucun cas supplémentaire n'a été identifié pendant les 14 jours de quarantaine des clients restants. L'analyse spatiale des tables de cas pendant le dîner (c'est-à-dire l'événement d'exposition) a révélé que les tables touchées avaient été disposées en fonction du flux d'air provenant d'une unité de climatisation. Les auteurs suggèrent que la transmission de l'infection ne pouvait pas être expliquée uniquement par les gouttelettes, et que les aérosols voyageant avec le flux d'air pourraient avoir contribué à la transmission de l'infection.
Li (2020) (29) *préimpression* Étude in silico Chine Février 2020	Une enquête et une analyse d'un grappe de cas de COVID-19 parmi trois familles qui ont mangé dans le même restaurant. L'analyse comprenait : des données épidémiologiques, une analyse spatiale de la	Dix personnes de trois familles différentes assises à des tables différentes ont été infectées par le SRAS-CoV-2 à la suite d'un dîner de la veille du Nouvel An chinois (24 janvier 2020). Aucun des serveurs ou des clients des autres tables n'a été infecté. Le taux de ventilation a été estimé à 0,75-1,04 L/s par personne.

Remarque : Voir également une analyse distincte de la grappe de cas décrite par Lu (2020).	disposition des tables du restaurant, des données de surveillance vidéo, et des simulations informatiques de la dynamique des fluides et des gaz traceurs de la propagation des fines gouttelettes lors de l'événement.	Aucun contact étroit ou contact avec des matières contaminées n'a été observé parmi les cas, à part le fait que certains clients s'asseyaient dos à dos. À l'aide de simulations informatiques, les auteurs démontrent que la distribution de l'infection est conforme au schéma de propagation des aérosols de virus expirés. Une mauvaise ventilation dans le restaurant peut également avoir contribué à la propagation de l'infection.
Pratique de chorale		
Charlotte (2020) (16) Enquête sur les grappes France Mars 2020 *nouvelle*	L'enquête sur une éclosion de COVID-19 liée à une pratique chorale, à Whir au Val, en France.	Vingt-sept participants (25 chanteurs, un chef d'orchestre et un accompagnateur) ont assisté à la pratique de la chorale à l'intérieur, pratique qui s'est déroulée dans un espace non ventilé de 45 m^2. Aucun participant n'a déclaré avoir eu de symptômes dans les 14 jours ayant précédé la date de la pratique. 19 participants sur 27 ont développé une infection à la COVID-19 entre 1 et 12 jours après la date de la pratique (médiane de 5,1 jours). Le taux d'attaque secondaire était de 70 % parmi tous les participants. Les experts cliniques supposent que la transmission de l'infection s'est produite par des aérosols provenant de personnes présymptomatiques ou asymptomatiques qui ont assisté à la pratique, puisque le cas de référence n'a pas été identifié de façon définitive.
Hamner (2020) (30) Enquête sur les grappes de cas États-Unis Mars 2020 Remarque : Voir également une	Une enquête épidémiologique sur un groupe de cas liés à une chorale, dans le comté de Skagit, Washington. La pratique était d'une durée deux heures trente. Pendant la pratique, les	Parmi les 61 choristes présents à la pratique, au moins une personne était un cas symptomatique de COVID-19. L'enquête épidémiologique a fait état de 53 cas (33 cas confirmés, 20 cas probables). Les taux d'attaque secondaire étaient de 53,3 % parmi les cas confirmés et de 86,7 % parmi l'ensemble des cas.

analyse distincte de la grappe de cas décrite par Miller (2020).	gens ont chanté et se sont assis à une distance de 15 à 25 cm les uns des autres, ils se sont réunis autour d'une collation et ont empilé des chaises. Aucun des participants n'a signalé de contact physique.	La probabilité d'infection était de 125,7 fois (IC à 95 % : 31.7-498.9) plus importante parmi les membres qui ont assisté à la pratique du 10 mars (événement d'exposition supposé). Les enquêteurs introduisent la possibilité de transmission de la COVID-19 par les aérosols pendant le chant dans la documentation sur la COVID-19.
Miller (2020) (31) Étude in silico États-Unis Mars 2020 Remarque : Voir également une analyse distincte de la grappe de cas décrite par Hamner (2020).	Des simulations de Monte Carlo et une modélisation mathématique ont été utilisées pour estimer les taux d'émission des aérosols dans l'éclosion liée à une pratique de chorale, dans le comté de Skagit. Le modèle appliqué suppose que la transmission de l'infection lors de l'éclosion a été dominée par l'inhalation d'aérosols dans un environnement intérieur bien distribué (c'est-à-dire que les aérosols étaient répartis uniformément dans l'air). La charge virale émise a été exprimée sous forme de taux d'émission *quanta* (*quanta* par heure) où *quantum* a été défini comme la dose de noyaux de gouttelettes dans les aérosols nécessaire pour provoquer une infection	L'analyse in silico a soutenu la transmission des aérosols en se basant sur l'hypothèse que des taux d'émission élevés se produisaient étant donné le taux d'attaque élevé (53-87 %), qui était plus élevé que ce à quoi on pourrait s'attendre si la transmission était due à des vecteurs passifs ou à de grosses gouttelettes respiratoires. Le modèle estime le taux moyen d'émission d'aérosols pour un seul cas infecté lors de l'exposition à 970 [EI 680-1190] quanta par heure. Remarque : Les conclusions de l'étude sont en accord avec les résultats de Buonanno, 2020.

	chez 63 % des personnes sensibles.	
Éclosions multiples		
Buonanno (2020) (32) Étude in silico Chine et États-Unis (sites d'éclosions) Février-mars 2020 Remarque : Une analyse différente des éclosions dans les restaurants et les pratiques de chorales décrite ci-dessus.	Il s'agit d'un modèle d'émission et d'exposition qui utilise une approche par étapes pour quantifier le risque individuel d'infection parmi les sujets sensibles exposés à un cas asymptomatique ou peu symptomatique dans une chorale et un restaurant. La méthode de Monte Carlo a également été utilisée; les risques d'infection individuels ont été calculés en fonction des caractéristiques d'émission *quanta*.	Le modèle a illustré l'augmentation du risque d'infection individuel en fonction des taux de ventilation, des activités et de la quantité de virus expirée. Par exemple, des activités sédentaires pendant une heure peuvent présenter un risque d'infection de 2,1 %, qui peut passer à 27 % avec des taux d'émission plus élevés. Sur la base de l'approche d'évaluation des risques et des données disponibles, les taux d'émission *quanta* ont été estimés à 61 *quanta* par heure pour le restaurant et à 341 *quanta* par heure pour la chorale de Skagit Valley. Dans les deux exemples, varier la ventilation n'aurait pas permis d'atteindre un risque individuel <0,1. Les auteurs ont conclu que la transmission par les aérosols représente la principale voie de transmission pour les deux éclosions.
Kriegel (2020) (33) Étude in silico Allemagne, Chine, États-Unis (sites d'éclosions) Février-mars 2020 Remarque : Comprend les grappes de cas suivantes : Usine de transformation de la viande –Guenther (2020), Pratique de chorale –Hamner	Une extension de l'équation de Wells-Riley a été utilisée pour estimer le risque d'infection prévisible par les aérosols dans 12 éclosions de COVID-19 publiées et non publiées. Les prédictions des risques d'infection ont été comparées aux taux d'attaque observés dans chaque événement. Pour estimer un intervalle de crédibilité pour les prédictions de risques d'infection par le modèle, le taux d'émission *quanta*,	Dans neuf des douze éclosions, les taux d'attaque observés étaient conformes aux prédictions de risques d'infection par les aérosols et aux fourchettes correspondantes (avec la variation des conditions limites). Prédiction du risque d'infection par les aérosols (PIRA)/taux d'attaque (TA) Usine de transformation de la viande : 25 % (17-35)/26 % Chorale : 97 % (88-99)/87 % Restaurant : 40 % (35-56)/45 % autocar : 35 % (19-58)/34 % Les taux d'attaque de toutes ces éclosions seraient conformes à la prédiction du risque d'infection par les aérosols.

(2020), passagers d'autocar –Shen (2020), et restaurant –Lu (2020).	la fréquence respiratoire ainsi que les débits volumétriques de l'air ont été variés. L'analyse suppose une transmission par les aérosols à longue distance dans un environnement idéalement homogène.	
Navires de croisière		
Azimi (2021) (34) Étude in silico Bateau de croisière Janvier-février 2020 Remarque : Même éclosion décrite par Almilaji (2020) et Xu (2020).	Analyse des données sur les cas de l'éclosion du Diamond Princess à l'aide d'un cadre qui applique une chaîne de Markov stochastique et un modèle de la relation dose-réponse exponentielle négative avec des données empiriques, afin d'informer une version modifiée du modèle de Reed-Frost sur les épidémies, pour prédire les taux de comptage des cas. La période d'incubation effective a été estimée à 6-15 jours, et considérée comme ayant différents modes de transmission. Remarque : Les données des cas du 20 janvier au 24 février 2020 ont été incluses dans l'analyse.	Il y a eu 712 cas de COVID-19 parmi 3 711 passagers et membres d'équipage (taux d'attaque de 19 %). Les contributions moyennes des gouttelettes et des aérosols à courte distance (35 %), des aérosols à longue distance (35 %) et des vecteurs passifs (30 %) aux modes de transmission de l'infection à bord du bateau ont été estimées, tout comme les contributions des grosses gouttelettes respiratoires (41 %) et des petits aérosols (59 %). Sur la base des estimations de l'analyse modélisée, les auteurs concluent que les transmissions par les aérosols à courte et à longue distance sont les principaux modes de transmission de l'infection dans l'éclosion. La mise en quarantaine des passagers dans leurs cabines a fait chuter la valeur Rt à presque zéro. Les auteurs suggèrent que sur le bateau de croisière, la transmission par les aérosols était le mode de transmission dominant (>70 % des cas) malgré les taux de renouvellement d'air (9 à 12 renouvellements d'air par heure) sans recirculation de l'air.
Almilaji (2020) (35)	Analyse des données cliniques et du nombre de	Les taux parmi les passagers des cabines sans cas infectés étaient de 5,4 %, ce qui était plus élevé

Enquête sur les grappes de cas Bateau de croisière Janvier-février 2020 Remarque : Même éclosion décrite par Azimi (2020) et Xu (2020).	cas de l'éclosion du bateau de croisière Diamond Princess. Les taux d'apparition des infections symptomatiques après quarantaine parmi les cas confirmés en laboratoire ont été examinés et la conception du système de climatisation du bateau de croisière a été étudiée. Remarque : Les données des cas jusqu'au 20 février 2020 ont été incluses dans l'analyse.	que les taux parmi les passagers des cabines avec des cas confirmés 2,4 %. La différence entre les taux était de -3,1 % ($IC_{élevé}$ de 95 %; 9,1 %). En se basant sur cette différence, les auteurs suggèrent que la transmission par les aérosols du SRAS-CoV-2 par le système de ventilation du bateau de croisière pourrait avoir contribué à l'éclosion. Remarque : Tous les cas dans les deux types de cabines se sont produits dans les dix jours suivant le début de la quarantaine sur le bateau. L'utilisation d'une période d'incubation de six jours par l'auteur a conduit aux résultats ci-dessus.
Xu (2020) (36) *préimpression* Enquête sur les grappes de cas Bateau de croisière Janvier-février 2020 Remarque : Une analyse différente de la grappe de cas décrite par Azimi (2020) et Almilaji (2020).	L'analyse des données des cas de COVID-19 de l'éclosion du bateau de croisière Diamond Princess a été effectuée sur la base des facteurs de risque individuels, de l'occupation des cabines et du système de climatisation (c'est-à-dire CVCA) du bateau afin d'explorer les modes de transmission les plus plausibles. Les données des cas du 20 janvier au 18 février 2020 ont été incluses dans cette analyse.	Les taux d'infection quotidiens des cas de passagers (n = 146) ont été prédits sur la base de l'état de contact étroit par rapport à l'état de sans contact étroit, et des données avant et après la quarantaine (le 5 février étant le début de la quarantaine). Les enquêteurs ont conclu que la plupart des cas de passagers ont probablement été exposés avant la mise en quarantaine et que le système de climatisation du bateau de croisière n'a pas joué de rôle dans la transmission de la COVID-19 par les aérosols à longue distance.
Centres de conditionnement physique/centre sportif		

Groves (2021) (9) Enquête sur les grappes États-Unis Juin 2020 *nouvelle*	Enquête sur une épidémie de COVID-19 associée à de multiples événements d'exposition à Hawaï entre un instructeur dans des cours sur vélo stationnaire, un instructeur de kick-boxing/entraînement personnel et leurs clients. Remarque : Au moment de l'éclosion, le taux de transmission moyen dans la collectivité était de 2 à 3 cas par 100 000 personnes par jour, ce qui porte à croire qu'il était peu probable qu'il y ait d'autres expositions.	Vingt cas ont été liés à deux instructeurs de conditionnement physique présymptomatiques, dans différents cours. L'instructeur de kickboxing/entraînement personnel était un cas secondaire de l'instructeur responsable des cours sur vélo stationnaire. L'instructeur, le cas index, portait un couvre-visage pendant le cours sur vélo stationnaire, mais pas les participants. L'instructeur était à plus de 6 pieds de distance des participants et leur faisait face pendant le cours. Les fenêtres et les portes de la salle étaient fermées et les ventilateurs au sol (pour le refroidissement) envoyaient de l'air sur les participants. On suppose que les événements de transmission avec le deuxième instructeur se sont produits pendant les séances de kickboxing en petits groupes et les séances d'entraînement personnel alors que l'instructeur ne portait pas de couvre-visage et que peu de participants en portaient un. Les deux instructeurs ont donné des cours avant l'apparition des symptômes et les taux d'attaque globaux suivants ont été calculés : - < 1 jour avant l'apparition des symptômes (taux d'attaque de 95 %). - 1 à < 2 jours avant l'apparition des symptômes (taux d'attaque de 13 %). - ≥ 2 jours avant l'apparition des symptômes (taux d'attaque de 0 %). Les experts cliniques responsables de l'enquête épidémiologique indiquent que la transmission de l'infection a été facilitée par le fait que presque personne de portait de couvre-visage, qu'il y a eu des contacts étroits et prolongés, qu'il y avait une mauvaise ventilation dans la pièce et qu'il y a eu

		émission d'aérosols pendant l'activité physique et lorsque l'instructeur criait pour se faire entendre.
Lendacki (2021) (10) Enquête sur les grappes États-Unis Août et septembre 2020 *nouvelle*	Enquête sur une éclosion de COVID-19 associée à des cours de conditionnement physique à l'intérieur, cours qui ont été donnés à 25 % de la capacité maximale (c.-à-d. de 10 à 15 personnes) et dont les participants se trouvaient à 2 m (6 pi) les uns des autres. Remarque : le bâtiment n'a pas été conçu à l'origine pour des cours de conditionnement physique et son système de ventilation n'a pas été évalué.	55 cas de COVID-19 (49 cas confirmés et 6 cas probables) ont été identifiés parmi les 81 personnes qui ont suivi des cours avec exercices haute intensité à l'intérieur, avec un taux d'attaque de 68 %. On a signalé que peu de gens portaient un couvre-visage pendant les cours, soit environ 75 % des participants. L'éclosion a été attribuée à deux cas de référence qui ont suivi plusieurs cours alors qu'ils étaient symptomatiques et étaient potentiellement infectieux. Les deux participants ont déclaré porter un couvre-visage 60 % du temps pendant les cours (port peu fréquent). La probabilité du port peu fréquent du couvre-visage comparativement au port constant de ce dernier pendant les cours était plus fréquente chez les participants qui avaient eu la COVID-19 que chez ceux qui ne l'avaient pas eu (RC = 3,5; IC à 95 % = 0,9 à 15,1). Les participants ayant reçu un diagnostic de COVID-19 ont également déclaré suivre un plus grand nombre de cours (médiane de 5 par rapport à 3 cours). Les auteurs suggèrent que le port peu fréquent du couvre-visage, l'augmentation de l'effort respiratoire pendant l'exercice, la transmission par les aérosols et une ventilation sous-optimale peuvent avoir contribué à la transmission de l'infection pendant cette éclosion.
Jang (2020) (37) Enquête sur les grappes de cas Corée du Sud Février-mars 2020	Enquête sur une éclosion de COVID-19 associée à des cours de Zumba dans 12 lieux différents d'installations de conditionnement physique, suite à un atelier	La transmission initiale est supposée avoir eu lieu entre les instructeurs lors d'un atelier de quatre heures où 8 des 27 participants ont été testés positifs pour le SRAS-CoV-2. Dans les semaines qui ont suivi, le nombre de cas associés à des instructeurs infectés a atteint 112 cas dans plusieurs centres de conditionnement physique.

	pour les instructeurs à Cheonan, en Corée du Sud.	Le taux d'attaque lors de l'atelier était de 26,3 % (IC de 95 % 20,9 %-32,5 %) et le taux d'attaque secondaire de huit instructeurs était de 4,10 % (IC de 95 % 2,95 %-5,67 %, 830 contacts étroits). Les enquêteurs déclarent qu'environ la moitié des cas identifiés (50,9 %) étaient dus à une transmission par des instructeurs à des participants à des cours de conditionnement physique; 38 cas (33,9 %) étaient des transmissions au sein de la famille par des instructeurs et des clients; et 17 cas (15,2 %) étaient des transmissions lors de rencontres avec des collègues ou des connaissances. Aucun cas secondaire n'a été observé parmi les clients des cours de Pilates et de yoga, donnés par un instructeur infecté. Les auteurs affirment qu'une activité physique intense, le grand nombre de participants à un cours de conditionnement physique (c'est-à-dire un espace bondé) et le milieu chaud et humide de l'installation sportive peuvent avoir contribué aux taux élevés d'infection dans l'éclosion.
Brlek (2020) (38) Enquête sur les grappes de cas Slovénie Février-mars 2020	Enquête sur une grappe de cas de SRAS-CoV-2 lié à un court de squash.	La grappe de cas comprenait six cas censés être liés par une transmission indirecte de l'infection. L'enquête épidémiologique a indiqué que le cas index a développé des symptômes pendant la partie de squash, et que quatre cas confirmés et un cas suspect étaient liés à la même salle de squash et potentiellement aux mêmes vestiaires. Aucun des cas ne partageait des équipements sportifs ou n'avait de contact avec le personnel de l'établissement. Aucun autre cas n'a été identifié. Les auteurs suggèrent que la transmission de l'infection au sein de la grappe de cas s'est probablement produite en raison de l'aérosolisation du virus dans un environnement intérieur, notamment dans un espace restreint,

		une ventilation inadéquate et une activité physique intense.
Immeubles d'habitation		
Hwang (2021) (11) Enquête sur les grappes Corée du Sud Août 2020 *nouvelle*	Enquête sur le rôle de la transmission par les aérosols dans une éclosion de COVID-19 associée à une tour d'habitation à Séoul.	10 cas de COVID-19 dans 7 ménages ont été identifiés dans des appartements situés sur deux lignes verticales dans une tour d'habitation. Chaque ligne d'appartements était reliée par une seule conduite d'air installée dans la salle de bain pour assurer une ventilation naturelle. Taux d'attaque de 2 % chez les résidents de la tour d'habitation (n = 10 sur 437). Aucune des surfaces testées, incluant les grilles de ventilation et les drains domestiques, n'a révélé la présence d'ARN viral. On a supposé que la transmission par gouttelettes, lorsque les personnes se trouvaient dans un même espace commun (p. ex., un ascenseur), était peu probable en raison de la disposition spatiale des logements. Les responsables de l'enquête épidémiologique présument que la circulation verticale de l'air dans une seule conduite d'air qui traverse la salle de bain (ce qui correspond à la circulation d'air dans un puits vertical) a propagé l'infection aux résidents des appartements dans le haut et dans le bas de la tour.
Lin (2021) (12) Enquête sur les grappes Chine Janvier et février 2020 *nouvelle*	Étude d'une grappe de COVID-19 liée à des familles vivant dans trois appartements sur une même ligne verticale dans une tour d'habitation. La famille de référence a déclaré une exposition possible à la suite d'un voyage à Wuhan, mais les deux autres familles qui	10 cas de COVID-19 ont été identifiés dans 3 ménages et l'analyse phylogénétique a confirmé que tous les cas avaient été infectés par la même souche. Les images de surveillance vidéo n'ont pas permis d'identifier d'expositions entre les membres du ménage de référence et d'autres cas. Les experts cliniques concluent que la transmission de l'infection s'est probablement produite en raison des tuyaux d'évacuation

Remarque : Analyse différente de la grappe décrite par Kang (2020).	ont eu des cas subséquents n'y sont pas allées. Un gaz traceur a été utilisé pour simuler le débit d'air entre les unités.	raccordés aux toilettes qui étaient ensuite raccordés aux tuyaux d'égout et aux drains de crue, un système que se partageaient les appartements se trouvant sur une même ligne verticale.
Kang 2020 (39) Enquête sur les grappes Chine Janvier et février 2020 *nouvelle* Remarque : Analyse différente de la grappe décrite par Lin (2021).	Enquête sur la transmission de l'infection entre trois familles qui vivaient dans le même immeuble. La famille de référence a déclaré une exposition possible à la suite d'un voyage à Wuhan, mais les deux autres familles qui ont eu des cas subséquents n'y sont pas allées. Les experts cliniques ont utilisé l'éthane comme gaz traceur en remplacement du gaz dans le système d'évacuation des bâtiments et ont calculé la dynamique des fluides pour étudier les sources possibles d'infection et de transmission entre les familles.	10 cas de COVID-19 dans trois familles qui vivaient dans des appartements se trouvant sur la même ligne verticale et reliés par des tuyaux d'évacuation dans les salles de bain principales. Taux d'attaque de 4 % chez les résidents et les membres du personnel de la tour d'habitation (n = 10 sur 217) Aucune exposition provenant des ascenseurs du bâtiment n'a été identifiée, et l'ARN viral n'a pas été détecté sur les boutons des ascenseurs ou sur les surfaces de ventilation. Les surfaces les plus fréquemment contaminées par de l'ARN viral se trouvaient dans les salles de bain principales, ce qui suggère que ces zones sont probablement des sites de transmission d'infection. Sur la base des analyses épidémiologiques et *in silico*, les experts cliniques supposent que la transmission de l'infection de la famille index aux deux autres familles s'est probablement produite par des aérosols fécaux dans la tuyauterie verticale. Remarque : aucun des échantillons d'air prélevés dans cette installation n'était positif pour l'ARN viral.
Centres commerciaux/magasins		
Jiang (2020) (13) Enquête sur les grappes Chine	Enquête sur 43 cas de SRAS-CoV-2 liés à une grappe dans un grand magasin à Baodi, en Chine. L'enquête a tenu compte des données épidémiologiques, des	43 cas de COVID-19 liés à une éclosion dans un grand magasin : 6 vendeurs, 18 clients et 19 de leurs proches. On a déterminé que les cas avec contact étroit étaient des cas secondaires dont l'exposition n'était pas liée au magasin.

Janvier et février 2020 *nouvelle*	images de surveillance vidéo, de l'aménagement du magasin et des conditions de ventilation.	Les experts cliniques ont conçu que les aérosols ont été un mode de transmission important parmi 11 cas dans cette éclosion. Le cas index n'a pas été identifié, mais on a supposé qu'il s'agissait d'un des vendeurs infectés.
Cai 2020 (40) Enquête sur les grappes de cas Chine Janvier 2020	Enquête sur une grappe de cas de SRAS-CoV-2 liée à un centre commercial. Les données cliniques, épidémiologiques et de laboratoire (méthode RT-PCR) des cas ont été analysées pour évaluer les modes possibles de transmission de l'infection.	Deux collègues du centre commercial étaient les cas index : cela a été associé à sept infections parmi les collègues du même étage, sept membres du personnel d'autres étages, dix clients du centre commercial et deux contacts étroits à l'extérieur du centre commercial. Les clients et les collègues des autres étages ont dit ne pas avoir eu de contact étroit avec les cas répertoriés. Sur la base des données disponibles, les auteurs suggèrent que la propagation de l'infection pourrait avoir résulté d'une propagation par vecteur passif ou par aérosolisation du virus dans un espace public confiné (par exemple, toilettes ou ascenseurs).

EXPÉRIENCES SUR LES ANIMAUX DE LABORATOIRE ET EXPOSITION PAR LES AÉROSOLS ET TRANSMISSION DU SRAS-COV-2

La présente section résume les six études sur les modèles animaux qui ont fourni des preuves expérimentales à l'appui de la transmission du SRAS-CoV-2 par les aérosols (tableau 2). Les modèles animaux utilisés dans les études étaient des primates non humains, des putois et des hamsters qui ont tous été établis comme modèles animaux appropriés pour l'étude de la transmission du SRAS-CoV-2 chez l'homme (41, 42)

Deux expériences ont porté sur l'exposition contrôlée de primates non humains et de hamsters à des aérosols infectieux générés artificiellement à différentes concentrations de virus afin de déterminer s'il peut y avoir infection et de suivre le cours clinique chez les animaux hôtes infectés (17, 43). Ces études démontrent que l'infection par le SRAS-CoV-2 peut se produire par l'exposition à des aérosols infectieux dans un milieu contrôlé. L'une des études sur les hamsters, qui comparait de multiples modes de transmission (c.-à-d. aérosols, fomite et intranasal) a indiqué que la réplication et l'excrétion du virus chez les animaux étaient liées au type d'exposition. Les auteurs ont observé une réplication virale antérieure, une charge virale plus élevée, une manifestation aiguë des symptômes respiratoires et des modèles différents d'excrétion virale dans les tissus respiratoires des animaux infectés par les aérosols comparativement aux animaux infectés par les modes d'exposition intranasaux et fomites (17).

Cinq expériences ont porté sur la transmission du SRAS-CoV-2 entre des animaux hôtes infectés et vulnérables (c.-à-d. des paires de transmission) qui étaient physiquement séparés par des barrières et des cages différentes (17, 18, 44 à 46). Dans la plupart des expériences, les paires de transmission étaient séparées par des barrières qui empêchaient le contact direct, mais permettaient la circulation de l'air. Ainsi, 25 à 100 % des animaux sensibles ont été infectés après une certaine durée d'exposition. Ces expériences fournissent des preuves à l'appui de la transmission par les aérosols chez les animaux hôtes dans un milieu expérimental.

Des preuves supplémentaires tirées de deux expériences démontrent comment la circulation de l'air et la ventilation peuvent avoir une incidence sur la transmission indirecte de l'infection (17, 45). Dans l'une de ces expériences, des paires de putois étaient logées dans des cages séparées physiquement, mais qui se partageaient de l'air amené par des conduits d'air connectés, ce qui a mené à l'infection de 50 % des animaux vulnérables (45). Dans le cadre d'une autre expérience, l'influence de la direction du flux d'air sur la probabilité de transmission de l'infection a été étudiée, et les résultats montrent que l'infection ne s'est produite que chez le hamster susceptible installé en aval de l'air que respirait le hamster infecté (17).

La petite taille des échantillons, les animaux n'aient pas été séparés par de grandes distances, le manque de détails sur le comportement des animaux pendant l'expérience (p. ex., symptômes de toux ou d'éternuement chez les animaux infectés), et parfois le manque de détails concernant la perméabilité des

barrières de séparation aux fluides respiratoires et oraux, aux mouvements des particules fécales et alimentaires, limite cette preuve de la transmission des aérosols.

Tableau 2 : Expériences sur les animaux de laboratoire en ce qui concerne l'exposition par les aérosols et la transmission indirecte du SRAS-CoV-2 (n = 6)

RÉFÉRENCE	MÉTHODE	RÉSULTATS PERTINENTS
Edwards (2020) (43) Expérience de simulation États-Unis Octobre 2020* Remarque : Des résultats supplémentaires sur les émissions d'aérosols sont résumés dans le tableau 7.	Huit primates non humains (Macaca mulatta [macaque rhésus] et Chlorocebus aethiops [singe vert]) ont été infectés par des aérosols (≈2 µm) contenant le SRAS-CoV-2 (~2,5x103 DICT50) en utilisant un système d'inhalation de laboratoire.	L'échantillonnage des muqueuses par écouvillonnage nasal a montré que l'ARN viral était détecté dès le jour suivant l'exposition à l'aérosol infectieux. La production de particules par l'air expiré a commencé trois jours après l'infection, a augmenté jusqu'au septième jour et a diminué jusqu'au 14e jour chez les primates. Il y avait une association significative entre les particules respiratoires expirées et la charge virale chez la plupart des primates et une corrélation avec la cinétique virale. L'ARN viral était indétectable dans les échantillons de prélèvement nasal des primates infectés au 28e jour suivant l'infection.
Port (2020) (17) *Préimpression* *Étude in vivo* États-Unis Décembre 2020* *nouvelle*	Trois groupes de femelles de *Mesocricetus auratus* (hamsters syriens) (n = 36) ont été infectés par des aérosols du virus SRAS-CoV-2 et par d'autres types d'expositions (c.-à-d. fomites et intranasal). Les animaux infectés ont été comparés aux témoins non exposés (n = 12). L'exposition aux aérosols du SRAS-CoV-2 (1,5 x 103 $DICT_{50}$) a été causée par une collision de 3 jets envoyés par nébulisation avec une	Les auteurs ont constaté que le mode de transmission utilisé par l'infection par le SRAS-CoV-2 jouait un rôle dans la gravité de la maladie, la charge virale et l'excrétion du virus dans le modèle animal. Une réplication précoce du virus (1 jour après l'infection), une excrétion respiratoire maximale du virus 2 jours après l'exposition et une charge virale précoce plus élevée dans les tissus pulmonaires et trachéaux (p = < 0,0001), ont été observées chez les animaux exposés aux aérosols comparativement aux autres types d'expositions. Les titres viraux dans les tissus pulmonaires ont montré une relation positive avec la pathologie des voies respiratoires supérieures et inférieures et la perte de poids, ce qui a amené les auteurs à suggérer que l'excrétion respiratoire précoce (observée chez les animaux

	taille des particules variant de 1 à 5 µm. Mesure des tendances en ce qui concerne l'élimination du virus et les modèles de réplication dans les tissus respiratoires et avec des écouvillons oropharyngés et fécaux. Dans des expériences distinctes de transmission aéroportée, deux paires de transmission (n = 4) ont été hébergées ensemble dans des cages séparées par une cloison en plastique perforé qui empêchait tout contact direct. Les animaux sensibles ont été placés dans la direction du flux d'air des animaux infectés ou à l'inverse de celui-ci; quatre paires de transmission (n = 8). Infection détectée d'après la séroconversion sérique.	infectés par des aérosols) pouvait prédire la manifestation aiguë de la maladie. Dans les expériences avec contacts indirects utilisées pour évaluer la transmission fondée sur le flux d'air, aucun symptôme lié à l'infection n'a été observé chez les animaux sensibles, mais 25 % (n = 1 sur 4) ont eu une séroconversion. Cette séroconversion (c.-à-d. l'exposition au virus) a été liée au flux d'air directionnel provenant des animaux infectés vers les animaux hôtes. Il convient de noter qu'on a observé que la transmission fomite était liée à une manifestation tardive de la maladie, soit à une période plus longue entre l'exposition et la réplication virale dans les tissus respiratoires, ce qui a réduit la gravité de la maladie.
Zhang (2021) (18) *Préimpression* *Étude in vivo* États-Unis Janvier 2021* *nouvelle*	Enquête sur le risque de transmission de l'infection par le SRAS-CoV-2 attribuable à l'exposition par les aérosols, et sur le risque de réinfection lors d'une reprise entre les paires de transmission naïves infectées et les paires de *Mesocricetus*	Des expériences ont révélé que le SRAS-CoV-2 était efficacement transmis des hamsters naïfs infectés aux hamsters précédemment infectés par transmission aéroportée, dans toutes les paires de transmission. En se fondant sur les concentrations d'ARN viral présentes dans les tissus respiratoires, les experts cliniques concluent que l'infection antérieure a fourni une bonne immunité protectrice, mais pas une immunité complète contre la réinfection au

	auratus (hamsters syriens) ayant déjà été infectées. Dans les expériences de transmission par les aérosols, les hamsters infectés et les hamsters donneurs (n = 6) se trouvaient dans des cages de transmission munies de cloisons à mailles métalliques qui empêchent le contact direct et indirect entre les animaux, mais permettent une circulation d'air. Les niveaux de virus vivants dans les tissus respiratoires au cours de la période suivant l'exposition ont été mesurés pour confirmer la réinfection.	moment de la reprise puisqu'un virus vivant était présent chez les animaux réinfectés.
Sia (2020) (44) Étude in vivo Hong-Kong* Mai 2020*	Étude expérimentale pour étudier la transmission du SRAS-CoV-2 par les aérosols. Les hamsters dorés infectés et sensibles qui étaient logés dans des cages grillagées adjacentes placées à 1,8 cm les unes des autres (trois paires différentes) ont été exposés les uns aux autres pendant huit heures.	Une transmission indirecte efficace de l'infection à des hamsters sensibles s'est produite pour les trois paires dans un cadre expérimental. La charge virale maximale chez le hamster exposé par des aérosols a été atteinte trois jours après le contact.
Kutter (2020) (45) *Préimpression*	Une installation d'étude expérimentale dans laquelle quatre cages de	La transmission indirecte du SRAS-CoV-2 entre deux furets à plus d'un mètre de distance a été confirmée dans deux des quatre paires de

VIABILITÉ DU SRAS-COV-2 DANS LES AÉROSOLS

Trois études ont mesuré la demi-vie des particules virales en suspension dans des aérosols artificiels dans le cadre d'études expérimentales et confirmé la viabilité du virus dans des aérosols artificiels grâce à des essais sur plaque et à la culture cellulaire (19, 47, 48). Ces études ont révélé que les titres viraux du SRAS-CoV-2 sont demeurés stables dans des aérosols créés artificiellement jusqu'à des périodes de 2 à 16 heures (19, 47, 48). La stabilité et l'infectiosité du virus dans les aérosols artificiels semblent dépendre de facteurs environnementaux comme la température, l'humidité et les niveaux simulés de lumière du soleil, comme cela a été suggéré précédemment dans certaines analyses générées par ordinateur. Une étude expérimentale a démontré que la lumière du soleil simulée avait l'effet le plus important sur le taux de désintégration, que les températures élevées (seules les températures variant entre 10 °C et 40 °C ont été testées) avaient un effet modéré et une interaction significative avec la lumière du soleil, tandis que l'humidité relative avait le moins d'influence sur la désintégration globale et seulement à un niveau élevé (70 %) humidité relative (19).

Tableau 3 : Preuves expérimentales confirmant la viabilité du SRAS-CoV-2 dans les aérosols (n = 3)

ÉTUDE	MÉTHODE	RÉSULTATS PERTINENTS
Dabisch (2020) (19) Expériences de simulation États-Unis* Août 2020* *nouvelle*	Mesure de la viabilité et de la persistance du SRAS-CoV-2 dans des aérosols générés artificiellement dans une chambre à aérosol à tambour à différentes températures (10 °C, 20 °C, 30 °C et 40 °C), avec différents niveaux d'humidité relative (20 %, 45 % et 70 %) et différents niveaux d'ensoleillement simulés, soit irradiation UVB intégrée nulle (c'est-à-dire intérieur, nuit, obscurité), avec rayonnement UVB de 0,9 W/m^2 et rayonnement UVB intégré de 1,9 W/m^2 (c'est-à-dire la lumière du soleil le midi, en été). La concentration virale s'est maintenue à une valeur moyenne de 2,3 ± 0,4 $\log_{10}$ $DICT_{50}$ /L d'air pendant l'expérience. L'infectiosité du virus dans les aérosols a été mesurée à l'aide d'un essai de microtitrage et de cellules Vero. Les résultats de l'expérience ont permis d'obtenir un modèle de régression prévoyant la désintégration du SRAS-CoV-2 en aérosol dans des conditions variables.	Le temps nécessaire pour obtenir une réduction de 90 % du virus infectieux à 40 °C, avec une humidité relative de 20 % est passé de 4,8 minutes avec une lumière du soleil correspondant à celle du midi, un jour d'été clair à l'extérieur, à plus de 2 heures dans des conditions représentant l'intérieur ou la nuit. Pour d'autres niveaux de température et d'humidité, la décomposition par minute dans les simulations avec soleil du midi allait de 38,1 % ± 8,9 % par minute à 40 °C avec une humidité relative de 20 %, à 18,9 ± 4,8 % par minute à 10 °C avec une humidité relative de 20 %. Pour la lumière modérée du soleil correspondant à l'intensité que l'on voit au printemps et à l'automne à 40 °C, les taux de désintégration variaient de 18,0 ± 6,2 % par minute à 30 °C avec une humidité relative de 45 %, à 11,1 ± 4,6 % par minute à 10 °C avec une humidité relative de 20 %. En l'absence de lumière du soleil, un taux de désintégration (moyen) inférieur à 2 % par minute a été estimé, pour la plupart des niveaux de température et d'humidité testés. Il y a eu des exceptions dans les plages de température ou d'humidité plus élevées : - Le taux de désintégration à 30 °C avec une humidité relative de 70 % était de 6,3 ± 2,6 % par minute.

		- Le taux de désintégration à 40 °C avec une humidité relative de 20 % était de 3,9 ± 0,4 %. Dans l'analyse de régression, la lumière du soleil a eu la plus grande influence sur la désintégration, suivie de la température et de l'interaction entre la lumière du soleil et la température. L'humidité (relative ou absolue) a eu l'influence la plus faible sur la constante de désintégration. Ainsi, la lumière plus intense du soleil et les températures élevées supérieures à 30 °C ont entraîné un taux de désintégration plus rapide.
Fears (2020) (47) Expériences de simulation États-Unis Sep 2020*	La persistance à long terme des suspensions d'aérosols viraux de SRAS-CoV-2 générées artificiellement a été mesurée à différents intervalles de temps. Le contenu viral a été quantifié par la méthode RT-PCR, et l'infectiosité du virus a été mesurée par la méthode des plages de lyse. Les échantillons ont été évalués qualitativement par microscopie électronique.	Le SRAS-CoV-2 infectieux a été détecté à 10 minutes, 30 minutes, 2, 4 et 16 heures au cours de l'expérience de stabilité de la suspension d'aérosol. Une réduction minimale des copies du génome viral dans les échantillons d'aérosols (mesurée par la méthode RT-PCR) a été constatée pour les points de temps mesurés. Une fraction mineure, mais constante du SRAS-CoV-2 en aérosols a maintenu la capacité de réplication à tous les points de mesure, y compris à 16 heures. L'évaluation qualitative de l'intégrité des virions a révélé que les virions étaient de forme ovoïde ou sphérique, et qu'ils conservaient les morphologies prévues jusqu'à 16 heures en suspension dans les aérosols.
Van Doremalen (2020) (48)	Dans cette expérience, la stabilité et la décomposition des titres des virus SRAS-CoV-	Le virus SRAS-CoV-2 est resté viable dans des aérosols générés de manière expérimentale jusqu'à trois heures (durée de

ARN DU SRAS-COV-2 DANS L'AIR EXPIRÉ

Six études ont examiné la présence de l'ARN viral du SRAS-CoV-2 dans des échantillons d'air expiré ou les échantillons de condensat d'air expiré provenant de cas humains (20, 50 à 53).

Deux techniques différentes d'échantillonnage de l'air expiré ont été cernées dans l'ensemble des études : certaines études ont permis de prélever des échantillons de condensat d'air expiré, tandis que d'autres ont recueilli des échantillons d'air expiré des personnes infectées. Les techniques de récupération de condensat expiré permettent de recueillir de 1 à 2 ml de condensat par le refroidissement et la condensation de l'air expiré pendant la respiration silencieuse. Certains chercheurs ont suggéré que la technique du condensat respiratoire expiré convenait mieux pour déterminer les biomarqueurs expulsés des voies respiratoires inférieures, et entraînerait une réduction des faux négatifs obtenus par RT-PCR (50, 54).

Cinq des études incluses ont rapporté au moins un échantillon d'air expiré positif pour l'ARN viral. Parmi les études qui ont confirmé la présence d'ARN viral dans certains échantillons expirés, quatre ont utilisé la technique du condensat d'air expiré, tandis que deux se fondaient sur un échantillonnage de l'air expiré. La positivité de l'échantillon variait entre 16 % et 93,5 % dans les études d'échantillonnage de condensats d'haleine expirés et jusqu'à 40 % dans l'étude d'échantillonnage unique d'air expiré avec des résultats positifs. Une étude n'a révélé aucun échantillon positif, tant pour les techniques de prélèvement de condensat d'air expiré que pour celles du prélèvement de l'air expiré (53). La variabilité de la positivité de l'ARN viral dans les échantillons d'air expiré peut être liée à l'évolution infectieuse des personnes échantillonnées. Toutefois, le manque d'information clinique sur les dates d'exposition et d'apparition des symptômes, les symptômes, ainsi que la charge virale et la réplication virale dans les tissus respiratoires, au moment du prélèvement des échantillons, limite les inférences entre l'exhalation virale et l'infection. Les données probantes indiquant que la charge virale maximale se produit entre un jour avant l'apparition des symptômes et jusqu'à cinq jours après celle-ci ou chez les personnes hospitalisées ou symptomatiques plusieurs jours après le début de l'infection peuvent ne pas être un échantillon approprié pour mesurer l'ARN viral dans l'air expiré (43, 55). Il se peut que les personnes hospitalisées ne

soient plus contagieuses au moment du prélèvement de l'échantillon, ce qui ne doit pas être interprété comme un manque de preuves à l'appui de l'émission d'infection par l'air expiré pendant la période d'infection précoce.

Tableau 4 : Études de biosurveillance portant sur la présence du virus SRAS-CoV-2 dans l'air expiré (n = 3)

ÉTUDE	MÉTHODE	RÉSULTATS PERTINENTS
Présence du SRAS-CoV-2 dans les échantillons		
Ryan (2020) (50) Étude de surveillance du condensat de l'air expiré Irlande Avril et mai 2020 *nouvelle*	Des échantillons de condensat d'air expiré ont été prélevés sur des patients atteints de la COVID-19 à l'aide de tubes pour condensat RTube. L'échantillon comprenait des écouvillons naso-pharyngés positifs (n = 16) et négatifs avec diagnostic clinique de patients atteints de la COVID (n = 15). D'autres échantillons prélevés avant le SRAS-CoV-2 ont été inclus comme témoins (n = 14). Le virus dans les échantillons a été détecté par RT-PCR et différents tests génétiques viraux. Remarque : Les diagnostics cliniques de COVID-19 étaient fondés sur l'expertise clinique et les résultats d'imagerie.	93,5 % (29 sur 31) des échantillons d'air expiré prélevés sur des patients atteints du SRAS-CoV-2 (résultats cliniques confirmés ou résultat positif obtenu par écouvillonnage du nasopharynx) étaient positifs parce que le test RT-PCR ciblait les quatre gènes (E, S, N, ORF1ab). Tous les échantillons témoins prélevés avant la pandémie étaient négatifs. Dans cette étude, il a été démontré que l'air expiré est un type d'échantillon sensible et non invasif. La positivité des échantillons variait selon la séquence cible du test RT-PCR chez des patients séronégatifs (n = 15) : - Positivité de 66 % (10 sur 15) pour l'enveloppe virale (E)/les tests de gènes des protéines de spicule (S) (utilisés pour l'écouvillonnage du nasopharynx). - Positivité de 73 % (11 sur 15) pour les tests sur gènes nucléocapsides viraux (N)/cadre de lecture ouvert (ORF1ab). Les résultats combinés correspondaient à 14 cas sur 15 ayant obtenu un résultat clinique positif après au moins un test.
Zhou (2021) (49) Étude de surveillance du condensat de l'air expiré	Les patients atteints de la COVID-19 (n = 10) qui étaient sur le point d'obtenir leur congé de l'hôpital (après un	22,2 % des 9 patients du COVID-19 sur le point d'obtenir leur congé de l'hôpital présentaient du SRAS-CoV-2 à une concentration d'environ 105 copies ARN/m^3

Chine Février et mars 2020 *nouvelle* Remarque : Les résultats supplémentaires sur la présence d'ARN viral dans les échantillons d'air sont résumés au tableau 5.	écouvillonnage négatif du nez et de la gorge) ont été recrutés dans plusieurs établissements hospitaliers. Un échantillon de condensat d'air expiré a été prélevé à l'aide d'un appareil BioScreen II. L'ARN du SRAS-CoV-2 dans les échantillons d'air expiré a été quantifié par RT-PCR.	dans l'échantillon d'air expiré obtenu. Les deux patients avaient plus de 70 ans. On a estimé que certains patients atteints de la COVID-19 inclus dans l'échantillon exhalaient le virus à un taux d'environ 1 400 copies d'ARN par minute au moment de leur congé.
Ma (2020) (51) *Préimpression* Étude de biosurveillance Chine Printemps 2020* Remarque : D'autres résultats sur l'ARN viral dans des échantillons d'air ambiant sont résumés dans le tableau 5.	Des échantillons de condensats d'air exhalé ont été prélevés chez des patients atteints de la COVID-19 (n = 30) à l'aide d'un dispositif de BioScreen.	L'étude confirme l'émission d'ARN du SRAS-CoV-2 dans l'air à partir du condensat de l'air exhalé par les personnes infectées (16,7 % n = 5/30). Les échantillons positifs ont été détectés soit <3 jours après l'apparition des symptômes (n = 3), soit dans les 7 à 14 jours suivant l'apparition des symptômes (n = 2). Les niveaux de SRAS-CoV-2 dans l'air expiré ont été estimés à 105-107 copies/m3 si l'on suppose un rythme respiratoire moyen de 12 l/min et qu'il est le plus élevé pendant les premiers stades de l'infection.
Di Carlo (2021) (20) Étude de surveillance de l'air expiré Italie Avril à juin 2020 Remarque : Les résultats supplémentaires sur la présence d'ARN viral	Évalue la quantité d'ARN du SRAS-CoV-2 émise dans l'air pendant la respiration normale – sans tousser, éternuer ou parler chez les personnes infectées (n = 5). Tous ces cas étaient des patients hospitalisés pour des symptômes non liés à la COVID qui ont ensuite	Le nombre de jours qui s'est écoulé entre l'apparition des symptômes et le prélèvement de l'échantillon variait de 7 à 56 dans l'échantillon de patients. Les écouvillons oropharyngés et naso-pharyngés de 4 patients étaient positifs au moment de l'échantillonnage. L'ARN viral a été détecté à 1 cm de la bouche de deux patients (40 % n = 2 sur 5). Les deux avaient des écouvillons oropharyngés, naso-

dans les échantillons d'air ambiant sont résumés au tableau 5. *nouvelle*	développé des symptômes de COVID pendant leur séjour à l'hôpital. Les personnes échantillonnées se trouvaient dans des chambres d'isolement des infections aéroportées et les échantillons d'air expiré ont été prélevés à l'aide d'un échantillonneur Sartorius AirPort. Des écouvillons oropharyngés, naso-pharyngés et salivaires ont également été prélevés avec les échantillons d'air expiré.	pharyngés et salivaires positifs. Les prélèvements de salive étaient négatifs chez les patients dont les échantillons d'air expiré étaient négatifs, même s'ils sont été déclarés infectés à partir d'échantillons positifs obtenus par la suite. Chez l'un de ces patients, le port d'un masque chirurgical a effectivement bloqué la détection de l'ARN viral à 1 cm (des échantillons obtenus lorsque la personne portait un masque n'ont pas été prélevés sur l'autre patient ayant obtenu des échantillons d'air expiré positifs). Les échantillons d'air prélevés à 1 cm chez des patients ayant obtenu des résultats négatifs au test RT-PCR ne contenaient pas d'ARN viral.
Feng (2020) (52) Étude de biosurveillance Chine Février-mars 2020 Remarque : D'autres résultats sur l'ARN viral dans des échantillons d'air ambiant sont résumés dans le tableau 5.	Échantillonnage de l'air expiré et de l'air ambiant de patients atteints de la COVID-19 à l'aide d'un échantillonneur de bioaérosols du NIOSH. Le condensat de l'air exhalé a été prélevé à l'aide d'un système de prélèvement stérile fabriqué en laboratoire. Les échantillons d'air ont été séparés par taille d'aérosols. Des échantillons ont été prélevés sur des patients atteints de la COVID-19 dans les derniers stades de l'infection en milieu hospitalier.	L'ARN du SRAS-CoV-2 n'a été détecté dans aucun des échantillons d'air expiré des patients (n = 0/9). L'ARN a été isolé dans le condensat de l'air exhalé (n = 2/8), et dans des échantillons d'air au chevet (n = 1/12). Les auteurs ont attribué la contamination minimale de l'ARN viral dans les échantillons de l'étude à la réduction de l'excrétion virale respiratoire chez les patients aux stades ultérieurs de l'infection.
Aucune présence de SRAS-CoV-2 dans les échantillons		

Ding (2020) (53) *Préimpression* Étude de biosurveillance Hong Kong Février 2020 Remarque : D'autres résultats sur l'ARN viral dans des échantillons d'air ambiant sont résumés dans le tableau 5.	Des échantillons de condensat exhalé (n = 2) et des échantillons d'air expiré (n = 2) ont été prélevés sur des patients atteints de la COVID-19 hébergés dans des chambres d'isolement des infections aérogènes. Plusieurs dispositifs ont été utilisés pour le prélèvement d'échantillons d'air (n = 27), qui a été effectué à des jours différents. Remarque : les distances de prélèvement des échantillons par rapport aux patients ne sont pas indiquées.	Tous les échantillons de condensat exhalé et les échantillons d'air expiré recueillis étaient négatifs pour l'ARN du SRAS-CoV-2.

*Estimation basée sur les affiliations des auteurs et la date de publication.

ARN DU SRAS-COV-2 DANS L'AIR AMBIANT

Quarante-neuf études de suivi biologique ont évalué des échantillons d'air prélevés dans des établissements de soins aux patients, comme les chambres d'isolement des infections aéroportées, les unités de soins intensifs, les salles d'urgence, les services hospitaliers, les maisons de soins infirmiers, les zones de diagnostic (p. ex., tomodensitométrie) et les cliniques externes, pour déterminer s'ils contenaient ou non des traces de SRAS-CoV-2 (tableau 5). Elles indiquent toutes la présence de cas confirmés à proximité du prélèvement des échantillons. La majorité des études (n = 29 sur 40) ont signalé l'isolement de l'ARN viral d'au moins un échantillon d'air prélevé par RT-PCR. Trois études ont réussi à mettre en culture des particules de virus isolées à partir d'un très petit nombre d'échantillons d'air positifs, ce qui a permis d'obtenir des preuves de la viabilité du virus dans l'air (56 à 58). Tous ces échantillons d'air contenant un virus viable ont été prélevés à proximité (moins de 2 mètres) de cas confirmés. De plus, des échantillons d'air prélevés à une distance variant entre 1 et 4,8 m de cas confirmés ont systématiquement identifié l'ARN du SRAS-COV-2, avec des concentrations plus élevées d'ARN viral lorsque l'appareil de collecte était placé plus près du cas (21, 56 à 61, 64, 65, 93).

Une seule étude dans un milieu de soins aux patients a démontré que l'ouverture des fenêtres dans la chambre du patient atteint de COVID-19 était bénéfique et avait réduit la concentration virale dans l'échantillon d'air de 10^5/ml à moins de 10^4 (61). Une autre étude a comparé des échantillons d'air

ambiant prélevés dans des chambres d'hôpital et chez des ménages en quarantaine où se trouvaient des cas actifs (24). On a estimé que les échantillons d'air ambiant provenant des ménages étaient environ huit fois (RC 8,75 [IC à 95 % 1,21 à 63,43; p = 0,058]) plus susceptibles d'être contaminés par de l'ARN viral que les échantillons d'air provenant des hôpitaux. Les chercheurs ont suggéré que la variabilité des échanges d'air et de la ventilation entre les milieux de soins aux patients et les milieux communautaires était la principale différence qui influençait la contamination de l'air entre les deux milieux. Il a été suggéré que la ventilation de la salle soit un facteur plus important que la gravité de la maladie en ce qui concerne la contamination de l'air ambiant.

Neuf études de suivi biologique de la présence du SRAS-CoV-2 dans des échantillons d'air provenant de milieux communautaires (c.-à-d. une voiture conduite par une personne infectée, un centre commercial, une salle de concert, des chambres d'hôtel utilisées pour la quarantaine et des ménages, un élevage de visons, des autobus publics et des métros) ont été identifiées (tableau 6). La majorité d'entre elles (n = 5 sur 9) ont utilisé un test RT-PCR pour confirmer la présence d'ARN viral alors qu'une étude a indiqué qu'une culture cellulaire à partir d'un virus isolé de COVID-19 a pu être effectuée à partir des échantillons d'air pris dans une voiture (23). L'étude portant sur la voiture met en évidence le fait que des quantités importantes de SRAS-CoV-2 viables peuvent être expulsées par des cas, même légers, sur de courtes périodes de temps (23). Une étude réalisée dans un élevage de visons dans laquelle l'éclosion continue a mis en évidence des niveaux élevés de virus dans l'élevage, ce qui représente un risque pour les travailleurs, mais si le risque à l'extérieur de l'élevage était faible pour la collectivité (66). L'identification d'échantillons d'air positifs prélevés dans des ménages en quarantaine et dans des chambres d'hôtel où se trouvaient des cas actifs était variable et exigera donc un examen plus approfondi, puisque certaines études ont relevé des échantillons positifs, tandis que d'autres ne l'ont pas fait (24, 67, 68). Deux études ayant prélevé des échantillons d'air ambiant dans des lieux publics, ce qui inclut une salle de concert, un centre commercial, des autobus publics et des métros, confirment également la présence d'ARN viral dans les échantillons d'air (61, 69). Fait intéressant, ces études ne confirment pas la présence de cas à proximité des échantillons d'air prélevés, mais indiquent des niveaux élevés de transmission communautaire dans les milieux échantillonnés (61, 69).

Diverses méthodes d'échantillonnage de l'air ont été utilisées dans le cadre des études de suivi biologique incluses. Certaines études ont utilisé différents modèles d'échantillonneurs d'air, tandis que d'autres ont utilisé des boîtes de Pétri remplies de liquide, des filtres en gélatine, des plaques d'Agar et de nouveaux pièges à COVID-19 pour échantillonner l'air ambiant. La variabilité des méthodes d'échantillonnage peut avoir contribué aux différences observées dans la détection de l'ARN viral, la confirmation de la viabilité du virus et de l'infectiosité dans les échantillons d'air ambiant. Seul un petit nombre d'études ont confirmé la viabilité du virus en culture cellulaire et tous les échantillons avaient été prélevés très près (moins de 2 mètres) des personnes infectées.

Les auteurs qui n'ont signalé aucune contamination virale dans les échantillons d'air prélevés dans les milieux de soins aux patients ont souvent suggéré une désinfection efficace, une ventilation d'air à haut rendement et des systèmes de filtration adaptés aux chambres d'isolement des infections aéroportées

comme raisons possibles des résultats négatifs. Cette justification est également appuyée par une étude de suivi biologique qui n'a pas permis de détecter d'ARN viral dans les échantillons prélevés lorsque l'entrée de l'échantillonneur d'air était recouverte d'un filtre HEPA (56).

Parmi les études identifiées, la concentration d'ARN viral dans les échantillons contaminés, la taille et les fractions des particules d'aérosol isolées, la distance d'échantillonnage des cas de COVID-19, le volume de l'échantillon d'air et toute tentative de culture de particules de virus isolées n'ont pas été déclarés de façon uniforme. De plus, la majorité des études n'ont pas fourni d'information clinique, comme des données sur l'apparition des symptômes ou la présence de symptômes respiratoires, sur les cas présents pendant le prélèvement d'échantillons d'air ni sur la ventilation et le débit d'air dans le milieu échantillonné. En raison de ces lacunes dans les données, il est difficile de déterminer les conditions dans lesquelles les virus infectieux présents dans les échantillons d'air ambiant deviennent plus fréquents.

Tableau 5 : Études de suivi biologique sur la présence du virus SRAS-CoV-2 dans l'air (n = 17) dans les milieux de soins aux patients (n = 40)

ÉTUDE	MÉTHODE	RÉSULTATS PERTINENTS
Présence du SRAS-CoV-2 dans les échantillons de culture cellulaire		
Lednicky (2020) (56) Étude de biosurveillance États-Unis* Novembre 2020*	Des échantillons d'air ont été prélevés dans les chambres d'hôpital des patients atteints de la COVID-19 en l'absence d'interventions générant des aérosols. Les échantillons d'air en trois exemplaires ont été prélevés à l'aide d'un échantillonneur d'air de VIVAS, à une distance de 2 à 4,8 mètres de la tête des patients. Les échantillons d'air ont été prélevés avec et sans filtre HEPA sur le tube d'entrée de l'échantillonneur d'air. Les génomes des virus isolés ont été séquencés.	La présence du virus dans des échantillons d'air isolés a été mesurée par la méthode RT-PCR, et l'infectiosité a été mesurée sur la base des effets cytopathologiques en culture cellulaire (LLC-MK2 et Vero-E6). Tous les échantillons d'air prélevés sans filtre HEPA étaient positifs pour l'ARN viral. Une seule séquence virale presque complète a été isolée à partir des échantillons d'air. Cette séquence génétique correspondait à la souche du virus isolé à partir d'un échantillon nasopharyngé d'un des deux patients qui occupaient la chambre lors du prélèvement. Au moment du prélèvement de l'échantillon d'air, le patient correspondant avait une infection aiguë.

Santarpia (2020) (57) *Préimpression* Étude de biosurveillance États-Unis Avril 2020	Les aérosols générés par les patients en milieu hospitalier ont été recueillis à l'aide d'un échantillonneur d'aérosols NIOSH BC251 au pied des lits de patients atteints de la COVID-19. La taille des aérosols et la concentration ont été mesurées lors de la collecte des échantillons à l'aide d'un spectromètre de particules aérodynamique. Les aérosols se distinguent par la proportion de tailles différentes (>4,1 µm, 1-4 µm, et <1 µm) parmi les échantillons.	De l'ARN a été détecté dans les six chambres de patients, et comprenait toutes les fractions de tailles de particules des aérosols (définies comme >4,1 µm, 1-4 µm, et <1 µm). La réplication du virus en culture cellulaire a été observée chez la plupart des d'échantillons d'aérosols <1 µm, deux des échantillons d'aérosols 1-4 µm et deux des échantillons >4,1µm. L'analyse par le transfert Western et la microscopie électronique à transmission de ces échantillons a montré la présence de protéines virales et de virions intacts.
Santarpia (2020) (58) Étude de biosurveillance États-Unis Mars 2020	Des échantillons d'air provenant de lieux d'isolement à pression négative et de salles abritant des cas de COVID-19 ont été prélevés à l'aide d'un échantillonneur AirPort MD8 de Sartorius et testés par la méthode RT-PCR pour détecter l'ARN viral du SRAS-CoV-2. Un sous-ensemble d'échantillons positifs a été examiné pour la propagation du virus dans les cellules Vero E6. Plusieurs indicateurs ont été utilisés pour déterminer la réplication virale, notamment l'effet cytopathologique, la détection par immunofluorescence, le surnageant de culture de cellules par PCR quantitative et la microscopie électronique.	63,2 % des échantillons d'air ambiant étaient positifs par la méthode RT-PCR (concentration moyenne de 2,42 copies/L d'air). Deux échantillons placés à proximité d'un patient, dont un à moins de 2 mètres du patient, étaient positifs. La concentration virale était plus élevée dans l'échantillon d'air prélevé plus près du patient (4,07 par rapport à 2,48 copies/L d'air). 58,3 % des échantillons d'air prélevés dans les couloirs étaient positifs (concentration moyenne de 2,51 copies/L d'air). Dans un seul échantillon positif provenant d'un couloir, on a constaté une certaine présence de réplication virale.
ARN du SRAS-CoV-2 dans les échantillons		

Munoz-Price (2021) (24) Étude de suivi biologique États-Unis Printemps 2021* *nouvelle* Remarque : Les résultats supplémentaires sur la présence de l'ARN viral dans l'air ambiant dans les maisons des ménages sont résumés au tableau 6.	Échantillons d'air (n = 16) prélevés dans les chambres des patients hospitalisés aux soins intensifs occupées par des cas confirmés de COVID-19. Des échantillons d'air ont été prélevés à l'aide de l'échantillonneur d'air Sartorius MD8, placé entre 0,3 et 1,8 mètre de la tête des patients. L'ARN viral dans les échantillons a été mesuré par RT-PCR.	12,5 % (n = 2 sur 16) des échantillons d'air prélevés à l'hôpital n'étaient positifs que pour l'ARN viral. Ces échantillons ont été prélevés à 0,3 m des cas confirmés. Les patients présentaient une forme légère de la maladie et ne prenaient pas d'oxygène d'appoint au moment du prélèvement de l'échantillon.
Razzini (2020) (70) Étude de suivi biologique Italie Avril 2020* *nouvelle*	Échantillons d'air (n=5) prélevés avec un échantillonneur d'air portatif MD8 Airport avec filtres en gélatine à membrane dans des zones de l'hôpital où l'on retrouvait des cas de COVID-19. Les échantillons ont été prélevés dans trois zones contaminées (corridor pour les patients et soins intensifs), semi-contaminées (salle de déshabillage) et propres (vestiaires et vestiaires du personnel médical). L'ARN viral dans les échantillons a été mesuré par RT-PCR.	Tous les échantillons d'air prélevés dans l'unité des soins intensifs et le couloir où l'on trouvait des cas de COVID-19 étaient positifs pour l'ARN viral alors que les autres étaient négatifs. La concentration virale (Ct médian) dans les échantillons d'air prélevés dans l'unité des soins intensifs était de 22,6 alors qu'elle était de 31,1 pour les échantillons d'air prélevés dans le corridor.
Ge (2020) (71) Étude de suivi biologique Chine Juin 2020* *nouvelle*	Des échantillons d'air (n = 33) ont été prélevés à l'aide de l'échantillonneur pour bioaérosols BC251 du NIOSH. Les milieux qui ont été échantillonnés comprenaient l'USI, les cliniques d'hémodialyse, les cliniques pour	Tous les échantillons d'air (n = 3) provenant de l'USI étaient positifs pour l'ARN viral. Les concentrations virales dans les échantillons avaient un Ct variant entre 36,5 et 37,8.

	la fièvre et les salles du service respiratoire. L'ARN viral dans les échantillons a été mesuré par RT-PCR.	
Hu (2020) (72) Étude de suivi biologique Février et mars 2020 Chine *nouvelle*	Des échantillons d'air (aérosols) ont été prélevés dans plusieurs hôpitaux à l'aide d'un échantillonneur centrifugeur aérosol-hydrosol (n = 123). L'ARN viral présent dans les échantillons a été mesuré par RT-PCR et sa viabilité par culture cellulaire Vero E6.	Huit échantillons d'air (21 %) provenant de l'unité des soins intensifs et un échantillon identique provenant de la salle de tomodensitométrie (16 %) étaient positifs pour l'ARN viral. La plage de concentrations du virus dans les échantillons d'air positif (aérosols) variait entre 1,11 x 10^3 et 1,12 x 10^4 copies d'ARN m^{-3}. Le virus n'a pas pu être cultivé à partir des échantillons positifs.
Seyyed (2020) (73) Étude de suivi biologique Iran Mai 2020* *nouvelle*	Des échantillons d'air (n=10) ont été prélevés dans le service des soins intensifs où se trouvaient des patients atteints de la COVID-19 à l'aide d'une pompe d'échantillonnage munie d'une tige agitatrice poreuse. L'ARN viral dans les échantillons a été mesuré par RT-PCR.	60 % des échantillons d'air étaient positifs pour l'ARN viral. Les concentrations d'ARN les plus élevées ont été mesurées dans des échantillons prélevés entre des lits des patients (3 913 copies par ml). Il s'agissait d'échantillons d'air prélevés entre 1,5 et 2 mètres des lits des patients.
Moore (2020) (59) Étude de suivi biologique Angleterre Mars à mai 2020 *nouvelle*	Des échantillons d'air (n = 55) ont été prélevés dans huit hôpitaux différents chez des patients atteints de la COVID-19 qui avaient, ou non, des symptômes respiratoires. Les milieux échantillonnés comprenaient les chambres d'isolement des infections aéroportées, les salles générales où se trouvaient des patients atteints de la COVID-19 général et les autres salles. Les échantillons ont été collectés à l'aide d'un échantillonneur d'air µ	7 % (n = 4) des échantillons d'air étaient positifs pour l'ARN viral, bien qu'à de faibles concentrations variant entre < 10 et 460 copies génomiques/m^3 d'air. Le virus n'a pas pu être cultivé à partir des échantillons positifs. Tous les échantillons positifs ont été prélevés à 1 mètre de distance des patients, et le nombre de jours écoulés depuis l'apparition des symptômes chez les patients variait de 8 à 10 jours.

	Coriolis ou d'un échantillonneur d'air Sartorius MD8. L'ARN viral présent dans les échantillons a été mesuré par RT-PCR et sa viabilité par culture cellulaire Vero E6.	
Hernández López (2021) (60) Étude de suivi biologique Janvier 2021* Mexique *nouvelle*	Des échantillons d'air (n = 15) provenant des salles d'urgence, des salles de médecine interne, des chambres dans lesquelles se trouvaient des patients atteints de la COVID-19 et des salles avec plusieurs lits dans deux hôpitaux ont été prélevés à l'aide d'un échantillonneur Millipore. L'ARN viral dans les échantillons a été mesuré par RT-PCR.	Trois échantillons d'air (20 %) étaient positifs pour l'ARN viral. Tous les échantillons positifs provenaient des chambres des patients atteints de la COVID-19 et avaient été prélevés près des patients.
Tan (2020) (74) Étude de suivi biologique Chine Mars 2020 *nouvelle*	Des échantillons d'air (n = 12) ont été prélevés dans les unités de soins intensifs et les salles d'isolement pour les patients atteints de la COVID-19 et dans les corridors. Des échantillons d'air ont été prélevés à 1 mètre de la tête d'un patient.	Un seul échantillon d'air prélevé dans une zone de soins au patient lors d'une intubation était positif pour l'ARN viral.
Gehrke (2021) (61) *Préimpression* Étude de suivi biologique Allemagne Octobre 2020 à janvier 2021 *nouvelle*	Des échantillons d'air ont été prélevés dans des chambres de patients dans deux unités d'isolement pour les patients atteints de la COVID-19 et dans une salle d'endoscopie ambulatoire utilisant des pièges à froid non alimentés. L'ARN viral a été quantifié par RT-PCR.	Échantillons prélevés en milieu hospitalier : Aucun ARN viral n'a été isolé dans la première unité d'isolation ventilée en permanence par deux fenêtres. L'ARN viral a été détecté dans des échantillons prélevés dans un couloir non identifié à proximité de la salle d'isolement. Dans les échantillons prélevés dans la deuxième unité d'isolement, les concentrations d'ARN du SRAS-CoV-2 ont atteint 10^5/ml dans les pièces non ventilées, mais lorsque les fenêtres

Remarque : Les résultats supplémentaires sur la présence d'ARN viral dans les échantillons d'air en milieu communautaire sont résumés au tableau 6.		étaient ouvertes pour augmenter la ventilation, les concentrations d'ARN du SRAS-CoV-2 dans les échantillons sont passées à 10^4/ml ou moins. Dans la salle d'endoscopie, 50 % des pièges à froid étaient positifs pour l'ARN viral (n = 6 sur 12). 57 % des pièges à froid (n = 4 sur 7) dans les salles d'endoscopie étaient positifs pour le SRAS-CoV-2, mais les concentrations d'ARN (initialement à 12 copies/ml) et le nombre d'échantillons positifs ont été réduits lorsque les niveaux de ventilation dans la salle ont été augmentés.
Zhou (2021) (80) Étude de suivi biologique Chine Février et mars 2020 *nouvelle* Remarque : Les résultats supplémentaires sur l'ARN viral dans les échantillons d'air expiré sont résumés au tableau 4.	Des échantillons d'air (et des échantillons d'air expiré) provenant de patients hospitalisés atteints de la COVID-19 ont été prélevés dans plusieurs établissements hospitaliers. Des échantillons d'air ont été prélevés dans les couloirs d'hôpitaux, les salles d'entreposage des déchets, les salles des soins intensifs, les toilettes, les salles de préparation des médicaments, les salles d'observation clinique et les salles générales. Des échantillons d'air ont été prélevés à l'aide du système Air-nCoV-Watch (ACW) et l'ARN viral a été quantifié par RT-PCR.	6,8 % des échantillons d'air (n = 3 sur 44) étaient positifs pour l'ARN viral à des concentrations numériques variant de 9 à 219 virus/m^3.
Yarahmadi (2021) (64) Étude de suivi biologique Iran Février 2021*	Des échantillons d'air ont été prélevés (n = 20) dans une unité de soins intensifs, précisément dans une zone de respiration d'un patient atteint de COVID-19 (c.-à-	50 % (n = 2 sur 4) des échantillons prélevés dans la zone respiratoire du patient étaient positifs pour l'ARN viral. Les échantillons positifs provenaient

nouvelle	d. une table installée à côté de la tête du patient), dans une zone générale (à 10 mètres de l'unité des soins intensifs) et dans une zone de respiration du personnel soignant près du lit du patient atteint de COVID-19, ainsi qu'à 1 mètre du lit du patient. Les échantillons ont été prélevés à l'aide d'échantillonneurs d'aérosols biologiques du NIOSH et de l'ASHRAE. L'ARN viral a été détecté par RT-PCR.	d'un cas confirmé et les échantillons négatifs d'un cas soupçonné. 12,5 % (n = 1 sur 8) des échantillons prélevés dans la zone respiratoire du personnel soignant étaient positifs pour l'ARN viral. 12,5 % (n = 1 sur 8) des échantillons prélevés dans la région générale étaient positifs pour l'ARN viral. Les auteurs suggèrent que des bioaérosols pourraient être présents en raison de la nouvelle aérosolisation des particules de SRAS-CoV-2 en suspension dans l'air provenant du personnel de soins de santé qui se promène entre différents services et différents postes des soins intensifs.
Ong (2021) (93) Étude de biosurveillance Singapour Jan 2021*	Des échantillons d'air ont été prélevés dans une chambre d'isolement des infections aéroportées d'un hôpital et d'une installation d'isolement communautaire (à ventilation naturelle) hébergeant des patients ayant reçu un diagnostic positif de COVID-19, à 1 mètre de distance du patient. Les échantillons d'air ont été prélevés à l'aide d'un échantillonneur de bioaérosols BioSpot-VIVAS BSS300-P (prélevant des particules d'une taille <4,34 µm). Les échantillonneurs d'aérosols du NIOSH ont été utilisés pour valider les résultats du Biospot. L'ARN du SRAS-CoV-2 a été détecté par RT-PCR, et cultivé à	50 % des échantillons d'air BioSpot de la chambre d'isolement des infections aéroportées de l'hôpital (n=6/12) étaient positifs pour l'ARN du SRAS-CoV-2 (concentrations allant de 178,9 à 2 738,4 copies/m^3). Les échantillons positifs ont été prélevés dans les chambres où se trouvait au moins un patient symptomatique (<7 jours après l'apparition des symptômes). Les échantillonneurs d'aérosols du NIOSH ont détecté l'ARN du SRAS-CoV-2 dans les aérosols de <1 µm, 1-4 µm et >4 µm de diamètre. Seul 1 des 9 échantillons provenant de l'installation d'isolement communautaire était positif pour l'ARN du SRAS-CoV-2, avec une concentration de 978,3 copies/m3. Les cultures virales de tous les échantillons positifs étaient négatives.

	l'aide de la culture cellulaire Vero C1008.	
Dumont-Leblond (2020) (21) Étude de suivi biologique Canada Mars à juin 2020 *nouvelle*	Échantillons d'air prélevés dans les chambres d'isolement des infections aéroportées d'un hôpital du Québec où se trouvaient des patients non atteints de la COVID-19 (n = 22). Des échantillons d'air ont été prélevés (avec des filtres en gélatine de 3 µm et des filtres en polycarbonate de 0,8 µm) à l'aide d'un échantillonneur sec SASS 3100 installé à 1,5 m du chevet du patient. La contamination virale a été mesurée par RT-PCR et par la culture cellulaire Vero E6.	11 % (n = 11 sur 100) des échantillons d'air prélevés au chevet de 6 patients étaient positifs pour l'ARN viral. Ces patients présentaient de la fièvre, de la dyspnée et une toux plus élevée que les autres patients de l'échantillon. La plupart étaient de sexe masculin et ont été hospitalisés un peu plus longtemps. La charge virale moyenne du SRAS-CoV-2 dans les échantillons positifs prélevés dans les salles a été estimée à 4,86E +4 génomes viraux par heure. Aucun virus isolé dans les échantillons d'air n'a pu être cultivé.
Binder (2020) (75) Étude de suivi biologique États-Unis Avril et mai 2020 *nouvelle*	Des échantillons d'air ambiant et d'aérosols ont été prélevés dans les chambres d'hôpital de patients individuels où se trouvaient des patients atteints de la COVID-19 (n = 20, 16 symptomatiques et 4 asymptomatiques) dans un service réservé aux patients atteints de la COVID-19. Les bioaérosols ont été prélevés à l'aide d'un échantillonneur NIOSH BC 251 placé à différentes distances de la tête des patients (1, 1,4, 2,2 et 3,2 mètres). Les chambres d'hôpital vides, les couloirs, la salle de repos du personnel et les postes de travail du personnel ont été échantillonnés comme zones témoins. La contamination virale par le SRAS-CoV-2 a été mesurée	Trois échantillons prélevés dans trois des chambres de patients atteints de la COVID-19 étaient positifs pour l'ARN viral. Les échantillons avaient été prélevés à une distance variant entre 1,4 et 2,2 mètres des patients. Il s'était écoulé de 4 à 10 jours depuis l'apparition des symptômes (nez qui coule, maux de tête, fièvre, toux, difficulté à respirer, fatigue, perte d'odorat, symptômes gastro-intestinaux). Aucun virus viable n'a pu être identifié dans les échantillons de bioaérosols par culture cellulaire. Les échantillons prélevés dans d'autres régions étaient négatifs pour l'ARN du SRAS-CoV-2.

	par RT-PCR et par la culture cellulaire Vero EC6.	
Passos (2021) (76) Étude de suivi biologique De mai à août 2020 *nouvelle*	Des échantillons d'air ont été prélevés dans deux hôpitaux différents (n = 52) à l'aide de méthodes d'échantillonnage actif et passif des aérosols. L'échantillonnage actif a utilisé plusieurs modèles d'échantillonneurs d'air portatifs (AIRIDEAL 3P, MD-8 AirPort, HANDI-VOL) et types de filtres (filtres en cellulose, en PTFE ou en microfibre de quartz). La méthode passive a utilisé des boîtes de Pétri pour recueillir des particules sédimentaires. On trouvait, dans les deux hôpitaux, des patients atteints de la COVID-19 dans des services de soins intensifs spécialisés au moment du prélèvement de l'échantillon. Des échantillons d'aérosols ont également été prélevés dans plusieurs espaces publics extérieurs à l'aide d'échantillonneurs d'air à grand débit (AGV, Energética). L'ARN du SRAS-CoV-2 dans les échantillons a été détecté par RT-PCR.	Des échantillons d'air provenant de quatre zones d'échantillonnage dans un hôpital (dont les soins intensifs étaient occupés à 100 % au moment de l'échantillonnage) étaient positifs pour l'ARN viral dans les particules en suspension (taille des pores du filtre > 0,2 µm et > 0,3 µm), ainsi que dans 11 % des particules sédimentables (n = 4 sur 36). Des échantillons positifs de particules d'air en suspension ont été détectés dans la salle des soins intensifs réservée aux patients atteints de la COVID-19 (concentration de 0,33 unité génomique m^{-3} à une distance supérieure à 2 par rapport au patient), dans une salle de retrait des vêtements de protection (0,14 unité génomique m^{-3}), une salle de rangement pour les toilettes mobiles destinées aux patients et pour le linge souillé des patients (0,19 unité génomique m^{-3}). La salle de rangement profitait d'une ventilation naturelle. Des particules sédimentables positives à l'ARN du SRAS-CoV-2 ont été détectées dans des échantillons prélevés dans un couloir extérieur adjacent à l'unité des soins intensifs réservée aux patients atteints de la COVID-19. Tous les échantillons d'air extérieur et les échantillons prélevés dans l'autre hôpital (c.-à-d. L'hôpital 1) (taux d'occupation de 33 % au moment de

		l'échantillonnage) étaient négatifs pour l'ARN du SRAS-CoV-2.
Lane (2021) (65) Étude de suivi biologique Janvier 2021* *nouvelle*	Des échantillons d'air ont été prélevés dans plusieurs unités de l'hôpital, dans les chambres d'isolement des infections aéroportées, dans les postes de soins infirmiers des soins intensifs, dans les couloirs pour les familles et les visiteurs à l'extérieur de l'unité des soins intensifs, dans l'unité de médecin et dans les couloirs près des chambres des patients. Des échantillonneurs cycloniques NIOSH 251 à 2 étapes ont été utilisés pour prélever des échantillons d'air (limite de détection de 8 copies virales/m^3 d'air). Deux chambres de patients atteints de la COVID-19 ont été utilisées comme échantillons témoins positifs. L'ARN viral a été détecté par RT-PCR.	Les deux échantillons témoins positifs prélevés dans les deux chambres des patients dont la COVID-19 a été confirmée étaient positifs pour l'ARN viral. Aucun des échantillons d'air (n = 528) provenant d'une autre zone d'échantillonnage n'était positif pour l'ARN du SRAS-CoV-2.
Liu (2020) (77) Étude de biosurveillance Chine Février-mars 2020	Concentration d'ARN du SRAS-CoV-2 et distribution de la taille des aérosols dans les échantillons d'air (n = 30) provenant de plusieurs sites à l'intérieur ou à proximité d'un hôpital et d'un hôpital de campagne. Tous les échantillons d'aérosols (n = 30) ont été prélevés sur des filtres en gélatine préstérilisés (Sartorius). Trois échantillons d'aérosols de tailles différentes ont été prélevés à l'aide d'un impacteur en cascade miniature	La contamination par le SRAS-CoV-2 dans les échantillons d'air des soins aux patients était faible à indétectable. Dans le cas de l'hôpital de campagne, le plus grand ARN en suspension du SRAS-CoV-2 en aérosols a été identifié dans une salle de toilette temporaire (1 m^2) avec une faible ventilation, probablement due à la respiration du patient ou à l'aérosolisation du virus à partir des excréments et de l'urine des patients infectés.

	(tous les échantillons ont été prélevés dans les zones du personnel). L'ARN viral a été détecté par la méthode RT-PCR.	Les échantillons prélevés dans les chambres personnelles des employés de l'hôpital de campagne ont montré les plus grandes concentrations de virus. Des aérosols de 0,25 à > 2,5 µm ont été identifiés. Les auteurs émettent l'hypothèse que cela provient des surfaces des EPI et des vêtements des travailleurs de la santé. Des concentrations d'ARN viral faibles, mais détectables ont été trouvées à l'entrée d'un grand magasin et sur un site extérieur près de l'hôpital, ce qui suggère que cela pourrait être dû à un flux de circulation élevé et à la foule. Remarque : Les concentrations spécifiques du SRAS-CoV-2 dans l'air dans chaque échantillon d'aérosol par site sont fournies dans la publication.
Chia (2020) (78) Étude de biosurveillance Singapour Printemps 2020*	Détection de la contamination de l'air par le SRAS-CoV-2 dans les chambres d'isolement des infections aérogènes accueillant des patients atteints de la COVID-19, en milieu hospitalier. Des échantillons d'air ont été prélevés et la taille des aérosols a été mesurée par les échantillonneurs de bioaérosols NIOSH BC 251. L'ARN viral a été détecté au moyen d'une épreuve PCR.	66 % (n = 2/3) des échantillons d'air prélevés dans les environnements des chambres d'isolement des infections aéroportées étaient positifs pour l'ARN du SRAS-CoV-2. La plus petite fraction de taille aérodynamique qui contenait des niveaux détectables d'ARN du SRAS-CoV-2 était de 1 à 4 µm. Les concentrations totales du SRAS-CoV-2 dans l'air variaient entre $1,84 \times 10^3$ à $3,38 \times 10^3$ copies d'ARN par m^3 d'air échantillonné. Les auteurs suggèrent que la présence du SRAS-CoV-2 dans les échantillons d'air est probablement la plus élevée pendant la première semaine de la maladie, lorsque la charge virale respiratoire est élevée.

Jin (2021) (79) Étude de suivi biologique Chine Février et mars 2020 *nouvelle*	Des échantillons d'air ont été prélevés dans une unité de soins intensifs où se trouvait un seul patient ayant eu la COVID-19 et prêt à recevoir son congé, deux jours après que ce patient eut obtenu un résultat négatif au test de dépistage du SRAS-CoV-2. Des échantillons d'air ont été prélevés dans la chambre d'isolement et dans le vestiaire pour EPI du personnel. Des échantillons d'air à grand volume ont été prélevés à l'aide d'un échantillonneur d'aérosols portatif WA 400. L'ARN viral dans les échantillons a été détecté par RT-PCR.	Un seul échantillon d'air provenant de la chambre d'isolement dans l'unité des soins intensifs était positif (1 sur 7, 14,29 %) pour l'ARN viral. Les auteurs indiquent que leurs résultats laissent entendre que le virus peut être transmis par aérosol pendant des jours, même après qu'un patient ait obtenu un test négatif.
Zhou (2020) (81) Étude de biosurveillance Royaume-Uni Avril 2020	Trois à cinq échantillons d'air ont été prélevés dans plusieurs milieux hospitaliers à l'aide d'un échantillonneur d'air de Coriolis, la présence d'ARN du SRAS-CoV-2 a été quantifiée par la méthode RT-PCR, puis des cultures de cellules Vero E6 et Caco-2 ont été utilisées pour cultiver le virus.	38,7 % (n = 14/31) des échantillons d'air prélevés étaient positifs pour l'ARN viral, mais le SRAS-CoV-2 n'a pas pu être mis en culture en raison de la faible charge virale récupérée. La probabilité de contamination dans les zones publiques était plus faible que dans les zones immédiatement occupées par un patient atteint de la COVID-19 (OR 0,5 IC de 95 % 0,2-0,9).
Orenes-Piñero (2020) (81) Étude de biosurveillance Espagne Printemps 2020*	Les chercheurs mettent au point et appliquent des pièges à COVID-19 pour mesurer la capacité de transmission du SRAS-CoV-2 par les aérosols dans les établissements de soins hospitaliers. Des pièges à COVID-19 ont été placés à un mètre des patients dans les unités de soins intensifs et les chambres	Dans l'unité de soins intensifs, aucun des pièges à COVID-19 n'était positif; tous les patients atteints de la COVID-19 étaient intubés. Dans les chambres communes, deux pièges à COVID-19 étaient positifs pour le SRAS-CoV-2, tous deux se trouvaient à proximité d'un patient nécessitant une assistance respiratoire. Les auteurs concluent que c'est sans équivoque le résultat de la transmission du virus dans l'air.

	communes. L'ARN viral a été détecté par la méthode RT-PCR.	
Feng (2020) (52) Étude de biosurveillance Chine Février-mars 2020 Remarque : D'autres résultats sur l'ARN viral dans des échantillons d'air expiré sont résumés dans le tableau 4.	L'air ambiant des chambres des patients atteints de la COVID-19 en convalescence dans les unités d'isolement des hôpitaux et aux soins intensifs a été échantillonné à l'aide d'un échantillonneur du NIOSH. Des échantillons d'air (n = 12) ont été prélevés et la taille des aérosols a été mesurée. Les échantillonneurs ont également été placés sur un trépied de 1,2 m de hauteur et à 0,2 m du lit, du côté de la tête du patient, pendant 30 minutes.	L'ARN du SRAS-CoV-2 a été détecté dans un seul échantillon d'air provenant de patients atteints du SRAS-CoV-2. La concentration maximale d'ARN viral détectée dans l'échantillon d'air positif par taille de particules était de 1 112 copies/m^3 (<1 µm) et 745 copies/m^3 (>4 µm). Les auteurs ont attribué la contamination minimale de l'ARN viral dans les échantillons de l'étude à la réduction de l'excrétion virale respiratoire chez les patients aux stades ultérieurs de l'infection.
Ding (2020) (53) *Préimpression* Étude de biosurveillance Hong Kong Février 2020 Remarque : D'autres résultats sur l'ARN viral dans des échantillons d'air expiré sont résumés dans le tableau 4.	Des échantillons d'air (n = 46) ont été prélevés dans les chambres d'isolement des infections aérogènes accueillant des patients atteints de la COVID-19, dans les postes de soins infirmiers, dans les couloirs et dans les unités de climatisation d'un hôpital traitant des cas de COVID-19. Plusieurs échantillonneurs d'air ont été utilisés pour le prélèvement des échantillons, qui a été effectué à des jours différents, et l'ARN a été détecté par la méthode RT-PCR.	Un seul échantillon d'air (n = 1/46) provenant du couloir à l'extérieur d'une salle d'entreposage avec une poubelle pour les déchets médicaux avait un résultat positif faible pour l'ARN du SRAS-CoV-2. Tous les autres échantillons d'air testés dans les chambres des patients, les toilettes et les entrées d'air étaient négatifs. Les copies d'ARN pour l'échantillon faiblement positif n'ont pas été quantifiées.
Guo (2020) (82) Étude de biosurveillance Chine Février-mars 2020	Des échantillons d'air ont été prélevés dans l'unité de soins intensifs d'un hôpital (n = 40) et dans les unités de soins généraux hébergeant des patients atteints de la COVID-19 (n = 6), à différentes distances des patients	Des particules du SRAS-CoV-2 ont été identifiées dans 35 % des échantillons d'air des unités de soins intensifs, 12,5 % des échantillons d'air des unités de soins généraux et 12,5 % des échantillons d'air du bureau du médecin. Aucun virus du SRAS-CoV-2

	et du bureau du médecin (n = 8). Des échantillons d'air ont été prélevés à l'aide d'un échantillonneur avec cyclone humide SASS 2300.	n'a été identifié dans les échantillons d'air du couloir des patients. Sur la base du ou des sites de prélèvement d'échantillons d'air positifs, les auteurs concluent que les aérosols chargés de virus se concentrent à proximité et en aval des patients, et que la distance maximale de transmission des aérosols chargés de virus est de 4 mètres.
Nissen (2020) (83) Étude de biosurveillance Suède Printemps 2020*	Des boîtes de Pétri ouvertes contenant du liquide ont été placées à l'entrée d'air des salles de soins et près des filtres d'évacuation du système de ventilation d'un hôpital pendant 24 heures afin de recueillir des virus viables. L'infectivité a été évaluée à l'aide de la culture cellulaire Vero E6.	L'ARN du SRAS-CoV-2 a été détecté dans des échantillons de fluides placés dans le système de ventilation, et dans 33 % des échantillons (n = 1/3) placés près des entrées d'air des salles. La viabilité du virus isolé n'a pas pu être établie par culture cellulaire.
Zhang (2020) (84) *Préimpression* Étude de biosurveillance Chine Mars-avril 2020	L'étude a consisté à échantillonner les aérosols de l'environnement extérieur (n = 16) dans trois hôpitaux recevant des patients atteints de la COVID-19. Les échantillons d'aérosols ont été prélevés à l'aide d'échantillonneurs de bioaérosols. L'ARN viral a été quantifié par la méthode RT-PCR. Remarque : Il n'a pas été signalé que l'infectiosité du virus récupéré a été mesurée.	Le SRAS-CoV-2 a été identifié dans les aérosols échantillonnés à des concentrations de 285-1 130 copies/m^3, similaires aux niveaux de contamination observés dans les unités de soins intensifs. L'ARN viral a été identifié jusqu'à 5 mètres de distance des bâtiments de soins ambulatoires, ainsi que dans les zones de traitement des eaux usées des hôpitaux.
Aucun ARN du SRAS-CoV-2 dans les échantillons		

Dumont-Leblond (2021) (22) Étude de suivi biologique Canada Printemps 2020 *nouvelle*	Des échantillons d'air et des échantillons provenant de surfaces sans contact ont été prélevés dans 31 chambres de plusieurs établissements de soins de longue durée (n = 7) au Québec. Les échantillons d'air ont été prélevés 8 à 30 jours après l'apparition des symptômes des résidents à l'aide d'un échantillonneur IOM Multidust attaché à une pompe portable Gillian Air 5, placée à environ 2 mètres des résidents positifs au SRAS-CoV-2. Les salles échantillonnées ne comportaient aucune mesure importante d'atténuation des aérosols. L'ARN SRAS-CoV-2 a été quantifié par RT-PCR et une culture avec cellules Vero E6 a été effectuée. Remarque : la distance entre les surfaces et les patients atteints du SRAS-CoV-2 n'a pas été fournie.	Tous les échantillons d'air (n = 31) étaient négatifs, mais de l'ARN viral a pu être récupéré sur 32 % (n = 20 sur 62) des échantillons de surface sans contact, soit les cadres de porte et étagères dans les chambres (concentrations variant entre 13 et 36 612 génomes/surface). Les auteurs ont suggéré que la charge virale récupérée sur les surfaces sans contact direct était un indice de la propagation des virus dans l'air. Le virus n'a pas pu être cultivé à partir des échantillons positifs.
Song (2020) (85) Étude de suivi biologique Chine Février 2020 *nouvelle*	Des échantillons d'air ont été prélevés dans des chambres d'isolement des infections aéroportées où se trouvaient des patients atteints de la COVID-19. Des échantillons d'air ont été prélevés à l'aide du système d'échantillonnage automatique Derenda PNS 16T-3.1, à environ 1 mètre des lits des patients. L'ARN viral dans les échantillons a été mesuré par RT-PCR.	Tous les échantillons étaient négatifs pour l'ARN du SRAS-CoV-2.
Faridi (2020) (86)	Des échantillons d'air (n = 10) ont été prélevés dans des salles où se	Tous les échantillons étaient négatifs pour l'ARN du SRAS-CoV-2.

Étude de suivi biologique Iran Mars 2020 *nouvelle*	trouvaient des patients atteints de la COVID-19 présentant des symptômes aigus et critiques. Des échantillons d'air ont été prélevés dans les mini-impacteurs standards stériles à l'aide d'une pompe à vide. Les échantillonneurs d'air étaient placés de 1,5 à 1,8 m au-dessus du plancher et à environ 2 à 5 m des lits des patients. Certains patients ont toussé pendant le prélèvement de l'échantillon. L'ARN viral dans les échantillons a été mesuré par RT-PCR.	
Declementi (2020) (87) Étude de suivi biologique Italie Septembre 2020* *nouvelle*	Des échantillons d'air (n = 8) ont été prélevés dans une unité de soins non intensifs pour des patients atteints de la COVID-19, après la mise en place de processus de nettoyage et de désinfection. L'ARN viral dans les échantillons a été mesuré par RT-PCR. Remarque : Ni le modèle de l'échantillonneur, ni la présence ou l'absence de cas de COVID-19 pendant l'échantillonnage ni la distance avec les cas au moment de l'échantillonnage ne sont indiqués.	Tous les échantillons étaient négatifs pour l'ARN du SRAS-CoV-2.
Anh (2020) (88) Étude de suivi biologique Corée Mars 2020 *nouvelle*	Des échantillons d'air ont été prélevés dans les chambre d'isolement où se trouvaient des patients atteints d'une forme grave de la COVID-19 qui ont dû avoir recours à une ventilation mécanique ou à une	Tous les échantillons étaient négatifs pour l'ARN du SRAS-CoV-2.

	oxygénothérapie à haut débit. Les échantillons ont été prélevés à l'aide d'un BioSampler SKC et d'un échantillonneur pour écouvillon. L'ARN viral a été mesuré par RT-PCR.	
Masoumbeigi (2020) (89) Étude de suivi biologique Iran Septembre 2020* *nouvelle*	Un échantillonnage d'air (n = 31) a été effectué dans un hôpital où se trouvaient des patients atteints de la COVID-19; tous les patients avaient une forme grave avec toux et éternuements. Des échantillons d'air ont été prélevés dans les salles d'urgence, l'unité des soins intensifs, la salle du tomodensitomètre et la buanderie. L'échantillonnage de l'air a été effectué par un impacteur en verre (AGI) à une distance d'environ 0,5 à 4 m des lits des patients. L'ARN viral a été détecté par RT-PCR.	Tous les échantillons étaient négatifs pour l'ARN du SRAS-CoV-2.
Alsved (2020) (90) Étude de biosurveillance Suède* Printemps 2020*	ARN du SRAS-CoV-2 mesuré à partir des cas de COVID-19 (n = 2) dans les deux jours suivant l'apparition des symptômes. Des échantillons d'air ont été prélevés à 0,8 mètre du cas, alors que l'individu parlait ou chantait. Les mesures ont été effectuées dans une chambre expérimentale étanche à l'air avec des volontaires humains.	Les échantillons d'air prélevés dans un rayon de 0,8 mètre des cas de COVID-19 étaient négatifs pour l'ARN viral. Les charges virales dans les voies respiratoires des sujets au moment de l'expérience n'ont pas pu être obtenues. Les auteurs affirment que des valeurs de Ct qPCR de 22-25 ont été rapportées dans les rapports cliniques des sujets dans les 24 heures suivant l'expérience.
Cheng (2020) (91)	Des échantillons d'air ont été prélevés à moins de 10 cm de patients asymptomatiques et	Aucun virus n'a été détecté dans les échantillons d'air provenant de pièces

Étude de biosurveillance Chine Janvier-avril 2020	symptomatiques (n = 6) atteints de la COVID-19, avec ou sans masque chirurgical, dans une chambre d'isolement des infections aérogènes, afin de détecter une contamination par le SRAS-CoV-2. Les charges virales dans les échantillons de fluides respiratoires des patients ont également été testées en faisant éternuer et cracher les patients sur des filtres en gélatine dans les échantillonneurs d'air. Les charges virales ont été mesurées à l'aide de tests (non spécifiés) et par la méthode RT-PCR.	où se trouvaient des patients avec ou sans masque. À l'exception d'un patient dont la charge virale du liquide respiratoire était de 2,54 x10^4 copies/ml, les échantillons de tous les autres patients ayant éternué étaient négatifs pour l'ARN du virus. Les auteurs suggèrent que la transmission par les aérosols n'est pas le mode prédominant de transmission de l'infection dans les milieux échantillonnés. L'utilisation appropriée des EPI, la désinfection de l'environnement et l'occupation unique dans une chambre d'isolement des infections aéroportées sont les raisons des résultats observés.
Kim (2020) (92) Étude de biosurveillance Corée du Sud Mars-avril 2020	Des échantillons d'air (n = 52) ont été prélevés à deux mètres des patients atteints de la COVID-19 (n = 8), avant leur admission et les jours 3, 5 et 7 de l'hospitalisation, à l'aide d'un échantillonneur d'air portable AirPort MD8. Certains patients étaient logés dans des chambres à pression négative (par exemple, les chambres d'isolement des infections aéroportées). L'ARN a été mesuré par la méthode RT-PCR.	Tous les échantillons d'air prélevés étaient négatifs pour l'ARN viral.
Ong (2020) (93) Étude de biosurveillance	Des échantillons d'air ont été prélevés chez des patients atteints de la COVID-19 (n = 3) dans une chambre d'isolement des	Aucun échantillon d'air n'était positif pour le SRAS-CoV-2.

Singapour Janvier-février 2020	infections aérogènes à pression négative d'un centre dédié aux éclosions de SRAS-CoV-2 entre le 4e et le 11e jour de leur maladie, à l'aide de pompes de SKC Universal et d'un échantillonneur microbiologique MD8 de Sartorius. L'ARN a été mesuré par la méthode RT-PCR.	
Ma (2020) (51) *Préimpression* Étude de suivi biologique Chine Printemps 2020* Note : Des résultats supplémentaires sur l'ARN viral dans les échantillons d'haleine expirée et les échantillons d'air de la communauté sont résumés dans les tableaux 4 et 6.	Des échantillons d'air (n=26) ont été prélevés dans les hôpitaux et dans les chambres d'hôtel de quarantaine non ventilées des cas à l'aide d'un robot. L'ARN a été détecté par RT-PCR.	Aucun échantillon d'air provenant du milieu hospitalier n'était positif pour l'ARN viral du SRAS-CoV-2.

Tableau 6 : Études de suivi biologique portant sur le SRAS-CoV-2 dans l'air en milieu communautaire (n = 9)

Présence du SRAS-CoV-2 dans les échantillons de culture cellulaire		
Lednicky (2021) (23) *Préimpression* Étude de suivi biologique États-Unis Janvier 2021* *nouvelle*	Des échantillons d'air ont été prélevés dans une voiture conduite par un patient atteint de COVID-19 (légèrement symptomatique, sans toux) à l'aide d'un échantillonneur en cascade personnel Sioutas à plusieurs stades d'échantillonnage	L'ARN viral du SRAS-CoV-2 était détectable à tous les stades d'échantillonnage des aérosols avec le SIPC, à des concentrations allant de 1,24E+03 à 3,14E+04 génome/m^3 d'air.

	pour différentes tailles d'aérosols (SIPC). L'échantillonneur était fixé au pare-soleil du côté passager de la voiture, soit à environ 1 mètre du visage du sujet. Le climatiseur de la voiture était en marche pendant la course de 15 minutes. L'ARN du SRAS-CoV-2 a été détecté par la RT-PCR, la viabilité du virus mesurée par la culture cellulaire Vero E6, tout comme le séquençage du génome.	Ces résultats suggèrent que les virions sont présents dans des sécrétions respiratoires de différentes tailles. Le SRAS-CoV-2 a été mis en culture à partir des stades d'échantillonnage dans lesquels on a recueilli des particules de 0,25 à 0,50 µm.
ARN du SRAS-CoV-2 dans les échantillons		
Munoz-Price (2021) (24) Étude de suivi biologique États-Unis Printemps 2021* *nouvelle* Remarque : D'autres résultats sur l'ARN viral dans l'air ambiant dans les milieux de soins aux patients sont résumés au tableau 5.	Les échantillons d'air (n = 9) ont été prélevés auprès de ménages où l'on trouvait des cas confirmés de COVID-19. Des échantillons d'air ont été prélevés à l'aide de l'échantillonneur d'air Sartorius MD8, placé entre 0,3 et 1,8 mètre de la tête des patients. L'ARN viral dans les échantillons a été mesuré par RT-PCR.	55 % (n = 5 sur 9) des échantillons d'air prélevés auprès de trois ménages différents étaient positifs pour l'ARN viral. La probabilité de résultats positifs pour les échantillons d'air dans les ménages, comparativement aux milieux hospitaliers, a été estimée à 8,75 [IC à 95 %, 1,21 à 63,43; P = 0,058]. Le nombre médian de jours entre le dernier test positif pour le SRAS-CoV-2 et le jour de l'échantillonnage de l'air était de 3 (plage de 2,5 à 5). Parmi les ménages dont les échantillons d'air étaient positifs, l'un avait un climatiseur en marche et les trois avaient ouvert des fenêtres ou des portes immédiatement avant l'échantillonnage d'air. Soit dit en passant, la plupart des maisons étaient chaudes et humides au moment du prélèvement de l'échantillon.
Gehrke (2021) (61) *Préimpression*	Des échantillons d'air ont été prélevés dans une salle de concert et un centre commercial pendant	On a trouvé des points chauds pour la COVID-19 dans des zones non visibles

Étude de suivi biologique Allemagne Octobre 2020 à janvier 2021 *nouvelle* Remarque : Le tableau 5 résume les résultats supplémentaires sur l'ARN viral tirés des échantillons d'air prélevés en milieu hospitalier.	6 heures au moyen de pièges à froid non alimentés. L'ARN viral a été quantifié par RT-PCR dans une zone à forte transmission dans la communauté afin d'identifier les points chauds potentiels pour la transmission.	et dans des zones prédisposées à un effet de flottabilité (cheminée). Dans la salle de concert, 1 des pièges à froid sur 10 était positif pour l'ARN viral. Dans le centre commercial, 35 % des pièges qui se trouvaient au rez-de-chaussée, dans les zones de kiosques aux 2e et au 3e étages, ainsi qu'autour des escaliers mécaniques étaient positifs pour l'ARN viral (n = 5 sur 14). La section de mode du 4e étage, qui a habituellement une capacité de 25 %, était négative. La concentration virale la plus élevée (2,7 à 5,4 x 10^3 copies/ml) a été trouvée au niveau du sol entre les escaliers mécaniques. Toutefois, les mesures de suivi pour les pièges à froid placés directement sous 2 entrées et 2 sorties d'air au 3e étage (pour exclure toute contamination du système de ventilation central) étaient négatives. Les échantillons prélevés le vendredi où l'on retrouvait un plus grand nombre de clients étaient deux fois plus élevés que ceux prélevés le lundi.
Moreno (2021) (69) Étude de suivi biologique Espagne Mai à juillet 2020 *nouvelle*	Des échantillons d'air ont été prélevés dans des métros et des autobus utilisés. L'air ambiant ($PM_{2,5}$) a été échantillonné à l'aide de filtres en téflon et d'équipement de surveillance individuelle de l'environnement (PEM). Des filtres de climatisation ont également été échantillonnés. L'ARN viral dans les échantillons a été mesuré par RT-PCR.	2 échantillons d'air du métro sur 6 étaient positifs pour le SRAS-CoV-2, mais aucun des échantillons du filtre du climatiseur n'était positif. 1 échantillon d'air sur 6 provenant des autobus et 4 échantillons sur 9 provenant des filtres de climatisation étaient positifs. Les résultats du nettoyage et de la désinfection ont indiqué que ce processus a réussi la décontamination.
de Rooij (2021) (66)	Des échantillons d'air ont été prélevés dans des élevages de	En se fondant sur la contamination des échantillons, les chercheurs ont conclu

Préimpression Étude de suivi biologique Pays-Bas Avril à juin 2020 *nouvelle*	visons où on a vu des éclosions de COVID-19 (3 élevages à la fin de l'éclosion, 1 au début de l'éclosion). Des échantillons ont été prélevés dans des salles d'élevage à l'intérieur, à l'extérieur sur les lieux de l'élevage et dans des sites résidentiels avoisinants. Des échantillons d'air ont été prélevés à l'aide de filtres en téflon et en parallèle avec le prélèvement de particules PM_{10} (< 10 µm) et de poussières inhalables (< 100 µm). Des échantillons d'air ont également été prélevés sur les membres du personnel effectuant l'enquête sur le terrain. La contamination virale dans les échantillons d'air a été mesurée par RT-PCR.	que les élevages de visons étaient fortement contaminés par de l'ARN viral à l'intérieur, mais que la dispersion du virus à l'extérieur et dans les zones avoisinantes était négligeable. Élevage à un stade aigu de l'éclosion : - L'ARN du SRAS-CoV-2 a été détecté dans 62,5 % (n = 5 sur 8) des échantillons de poussière inhalables et dans 50 % (n = 4 sur 8) des échantillons de PM^{10} prélevés dans l'élevage. Tous les échantillons d'air prélevés sur les membres du personnel (n = 2) étaient positifs pour l'ARN viral. - L'ARN du SRAS-CoV-2 a également été détecté dans des échantillons prélevés à l'extérieur, soit à une distance variant entre 1,5 et 10 mètres de l'entrée ouverte de l'élevage, mais les échantillons prélevés à 20 m de l'entrée étaient négatifs. Élevage à un stade tardif de l'éclosion : - L'ARN viral a été détecté dans 9,8 % (n = 4 sur 41) des échantillons de poussière inhalables, à environ 4×10^3 copies/m^3. L'ARN du SRAS-CoV-2 n'a pas été décelé dans les échantillons de poussière inhalables prélevés à l'extérieur des espaces où se trouvaient les visons (n = 9) ou dans les échantillons de PM^{10} prélevés dans l'élevage (n = 9) ou près des espaces où se trouvaient les visons (n = 9). L'un des échantillons d'air prélevés auprès

		des membres du personnel était positif pour l'ARN du SRAS-CoV-2. - Tous les échantillons d'air provenant de sites résidentiels étaient négatifs pour l'ARN du SRAS-CoV-2.
Ma (2020) (51) *Préimpression* Étude de biosurveillance Chine Printemps 2020* Remarque : D'autres résultats sur l'ARN viral dans des échantillons d'air expiré sont résumés dans le tableau 4 et le tableau 5.	Des échantillons d'air ont été prélevés à l'aide d'un robot dans des hôpitaux et des chambres d'hôtel non ventilées utilisées pour la quarantaine. L'ARN a été détecté par la méthode RT-PCR.	Un seul échantillon d'air positif (3,8 % n = 26) a été identifié dans les toilettes non ventilées d'un hôtel utilisé pour la quarantaine.
AUCUN ARN du SRAS-CoV-2 dans les échantillons		
Wong (2020) (67) *Préimpression* Étude de suivi biologique Singapour Février et mars 2020 *nouvelle*	Des échantillons d'air (n = 6) ont été prélevés dans des chambres, des couloirs, des toilettes et des ascenseurs utilisés par les patients atteints de la COVID-19 dans des milieux communautaires (non précisés). L'ARN viral dans les échantillons a été mesuré par RT-PCR.	Tous les échantillons d'air étaient négatifs pour l'ARN viral.
Döhal (2020) (68) *Préimpression* Étude de suivi biologique Allemagne Mars 2020	L'air ambiant dans 21 foyers où se trouvaient des personnes en quarantaine (n = 15) a été prélevé par échantillonnage cyclonique à l'aide d'un échantillonneur Coriolis 154 Micro Air. L'ARN viral dans les échantillons a été mesuré	Tous les échantillons d'air étaient négatifs pour l'ARN viral.

nouvelle	par la RT-PCR et par la culture cellulaire Vero-E6. Remarque : Au moins une personne dans chaque ménage inclus dans l'étude était séropositive pour le SRAS-CoV-2 au moment du prélèvement de l'échantillon.	
Di Carlo (2020) (94) Étude de suivi biologique Italie Mai 2020 *nouvelle*	Des échantillons ont été prélevés dans un autobus de la ville dans lequel on trouvait un grand nombre de patients atteints de la COVID-19, pendant la dernière semaine de confinement et la première semaine de réouverture graduelle (environ 1 100 passagers ont pris l'autobus pendant la période de l'étude). L'air a été échantillonné à l'aide de filtres à membrane de gélatine microbiologique de 80 mm. L'ARN viral dans les échantillons a été mesuré par RT-PCR.	Aucun échantillon d'air (ou de surface) n'a été positif pour le SRAS-CoV-2. Les mesures de santé publique en place comprenaient une désinfection des mains à l'entrée de l'autobus, le port obligatoire du couvre-visage et le fait de garder les fenêtres de l'autobus ouvertes. Les auteurs affirment que ces précautions ont empêché la circulation et la détection du SRAS-CoV-2 pendant la période de l'enquête.

CHARGES VIRALES DU SRAS-COV-2 DANS LES PARTICULES RESPIRATOIRES

Un examen systématique et une méta-analyse ont permis de créer un modèle pour estimer la relation entre le virus viable du SRAS-CoV-2, les charges virales des cas et les gouttelettes chargées de virus et les émissions d'aérosols (55). Cet examen a révélé que la charge virale maximale se situait entre un jour avant et cinq jours après l'apparition des symptômes (55). Le modèle a estimé que la probabilité de trouver un virus viable dans les aérosols respiratoires expulsés par une personne ayant une charge virale maximale était ≤ 61,1 % (IC à 95 % : 51,8 à 70,4 %), et l'estimation de la probabilité était considérablement plus faible, soit 0,69 % (IC à 95 % : 0,43 à 0,95 %), lorsque la personne avait une charge virale moyenne.

Tableau 7 : Charge virale du SRAS-CoV-2 dans les particules respiratoires (n = 1)

ÉTUDE	MÉTHODE	RÉSULTATS PERTINENTS
Chen (2020) (55) *Préimpression* Analyse in silico éclairée par l'examen systématique Canada* Août 2020	Un examen systématique et une méta-analyse ont été réalisés (août 2020) pour élaborer un ensemble de données et résumer les données sur la charge virale respiratoire (rVL) du SRAS-CoV-2. Un modèle a été développé pour estimer la probabilité que les gouttelettes respiratoires et les aérosols contiennent des virus viables, en supposant différentes estimations de la charge virale et différentes activités.	La méta-analyse a montré une grande hétérogénéité des charges virales entre les individus, les études et les stades d'infection. Cela suggère que des facteurs virologiques intrinsèques sont à l'origine de la dispersion observée lors de la pandémie. De nombreux cas présentent un risque de transmission minime, alors que les individus hautement infectieux ont libéré 9,84 (IC de 95 %, 9,17-10,56,) $\log_{10}$ de virions du SRAS-CoV-2/ml via des gouttelettes et des aérosols en respirant, en parlant et en chantant. Le modèle estime que la toux a augmenté la contagiosité des cas symptomatiques. La probabilité de présence d'un virus viable dans les aérosols au pic de la charge virale a été estimée à ≤61,1 % (IC de 95 %) : 51,8-70,4 %) pour les cas les plus infectieux, et ≤ 0,69 % (IC de 95 % : 0,43-0,95 %) pour les cas ayant une charge virale moyenne.

Méthodologies :

Une analyse documentaire quotidienne (ouvrages publiés et en prépublication) est effectuée par le Groupe des sciences émergentes de l'ASPC. L'analyse a compilé les ouvrages sur la COVID-19 depuis le début de l'éclosion et est mise à jour quotidiennement. Les recherches visant à extraire les ouvrages pertinents sur la COVID-19 sont menées dans Pubmed, Scopus, BioRxiv, MedRxiv, ArXiv, SSRN et Research Square, et les résultats sont recoupés avec les ouvrages figurant sur la liste de la documentation sur la COVID de l'Organisation mondiale de la Santé et des centres d'information sur la COVID-19 gérés par Lancet, BMJ, Elsevier et Wiley. Le résumé quotidien et les résultats complets de l'analyse sont conservés dans une base de données RefWorks et dans une liste Excel consultable. Une recherche ciblée par mot-clé a été effectuée dans ces bases de données pour recenser les citations pertinentes sur la COVID-19 et le SRAS-CoV-2 à l'aide des termes de recherche suivants, soit aerosol, airborne, droplet.

Chaque référence potentiellement pertinente a été examinée pour confirmer qu'elle comportait des données pertinentes, qui ont été extraites dans la revue. Le texte intégral de la recherche potentiellement pertinente a été examiné pour confirmer sa pertinence et un synopsis de l'étude a été extrait dans la revue. La présente revue contient des recherches publiées jusqu'au 12 mars 2020.

Examen par les pairs

Ce document a fait l'objet d'un examen par les pairs dirigé par un expert en la matière et d'un examen en ce qui concerne la rédaction et la science par le Bureau de la Conseillère scientifique en chef.

Préparée par : Chatura Prematunge et Lisa Waddell. LNM, Groupe des sciences émergentes, ASPC.

Connaissances mobilisées par le Bureau de la Conseillère scientifique en chef phac.ocsoevidence-bcscdonneesprobantes.aspc@canada.ca

Evidence Snapshot:

Evidence Brief on the Risk of COVID-19 Transmission in Flight, Update 2

Context

Many changes have been implemented by airlines during the pandemic to reduce the risk of SARS-CoV-2 transmission during air travel. This evidence brief updates the literature on in-flight transmission of SARS-CoV-2, and the strategies developed to mitigate transmission during boarding, flight and disembarkation.

Key Findings

Sixty-four studies were identified in total including 29 studies published between October 2020 and April 26, 2021.

- Most in-flight transmission events occurred on flights early in the pandemic when mandatory use of face masks in flights was not yet in place. Those seated within two rows of an index case were at higher risk of acquiring SARS-CoV-2. Overall, increasing the time duration of a trip increased infection transmission risk which may be partially due to removing one's mask during meal service or walking around on longer flights.
- Multiple interventions maximally reduced the risk of transmission. Enhanced protective measures included: enhanced cleaning; universal face masks; hand hygiene; reduced flight capacities; physical distancing on embarkation and disembarkation; designated crew only areas; and quarantine areas for unwell passengers and crew.
- The risk of transmission in simulation models was higher on flights near capacity compared with those with empty middle seats that allowed for more physical distancing. Symptom checks were not always effective due to lack of compliance by passengers.
- Airplane ventilation systems quickly refresh cabin air, reducing opportunities for transmission. Environmental studies estimated that in-flight particle concentrations in the air in airplanes were lower than that of retail/grocery stores, restaurants, office spaces, homes, and other forms of transportation.

Considerations

Effective ventilation and layering multiple interventions with enhanced protective measures have significantly reduced the risk of COVID-19 transmission during air travel. Future research needs to assess both the effect of emerging variants on transmissibility risk and vaccination status of both travellers and airline staff in mitigating risk.

Evidence Snapshot:

Evidence Brief on SARS-CoV-2 Variants of Concern and Transmission in Children

Context

Several SARS-CoV-2 variants of concern (VOCs) that have acquired enhanced infectivity and transmissibility have been identified since December 2020. This review gathered evidence up to March 26, 2021 regarding the transmission of the VOCs in children and their impact on in-school transmission.

Key Findings

The evidence brief includes results of web-scraped media data of school-related COVID-19 outbreaks across Canada and nine studies on transmission of the VOCs in children. Of these, five assessed only VOC transmission in children, three assessed the impact on in-school transmission, and one evaluated both.

- There were an increasing number of VOC related school outbreaks reported in the media in Canada between January to March 2021. All published studies were on B.1.1.7 transmission in the UK during November 2020 to January 2021. There was increased transmissibility of the VOC in both adults and children but B.1.1.7 did not disproportionately affect children and youth < 20 years. Transmission in school-aged children was strongly correlated with the level of community transmission. Both a modelling study and epidemiological evidence identified that children did not drive variant transmission.
- Among children who were hospitalized, there was no evidence of more severe disease with B.1.1.7 infection. A single report estimated that children under ten are about half as likely as adults to transmit the variant similar to the original SARS-CoV-2 variant findings.
- Modelling studies found that B.1.1.7 transmission in children was inversely proportional to the stringency of public health measures other than school closures, and the stringency of public health measures was the most important determinate of epidemic trajectory.

Considerations

Community transmission appears to be the biggest predictor of VOC transmission in children and transmission patterns in schools. To date, B.1.1.7 appears to be more transmissible in children but does not appear to be more severe than the original strain and whether schools are open or closed appears to have minimal impact on the epidemic course overall. A key knowledge gap in this research is the lack of high-quality transmission studies of all the current VOCs in children and VOC transmission patterns in schools.

mars 8, 2021

Aperçu des éléments de preuve :

Synthèse en bref des données probantes sur les variants préoccupants du SRAS-CoV-2 et la transmission chez les enfants

Contexte

Plusieurs variants préoccupants du SRAS-CoV-2 qui ont acquis une plus grande infectivité et une plus grande transmissibilité ont été identifiés depuis décembre 2020. Cette synthèse en bref inclut donc les éléments de preuve disponibles jusqu'au 26 mars 2021 sur la transmission des variants préoccupants chez les enfants et l'impact sur la transmission dans les écoles.

Principales constatations

La synthèse en bref inclut les données des médias recueillis sur le Web à propos des éclosions de COVID-19 dans les écoles partout au Canada, ainsi que neuf études sur la transmission des variants préoccupants chez les enfants. De ce nombre, cinq ont évalué uniquement la transmission des variants préoccupants chez les enfants, trois ont évalué l'impact sur la transmission à l'école et un a évalué les deux.

- De janvier à mars 2021, les médias ont fait état d'un nombre croissant d'éclosions de variants préoccupants dans les écoles du Canada. Toutes les études publiées portaient sur la transmission du variant B.1.1.7 au Royaume-Uni entre novembre 2020 et janvier 2021. On a pu voir une augmentation de la transmissibilité des variants préoccupants chez les adultes et les enfants, mais le variant B.1.1.7 n'a pas touché de façon disproportionnée les enfants et les jeunes de moins de 20 ans. La transmission chez les enfants d'âge scolaire était cependant fortement corrélée avec le niveau de transmission dans la collectivité. Tant une étude de modélisation que des signes épidémiologiques ont révélé que les enfants n'étaient pas responsables de la transmission des variants.
- Parmi les enfants qui ont été hospitalisés, il n'y avait aucun signe de maladie plus grave en raison d'une infection par le variant B.1.1.7. Un seul rapport a estimé que les enfants de moins de dix ans étaient deux fois moins susceptibles que les adultes de transmettre le variant SRAS-CoV-2 que la souche originale.
- Les études de modélisation ont révélé que la transmission du variant B.1.1.7 chez les enfants était inversement proportionnelle à la rigueur des mesures de santé publique autres que la fermeture des écoles et que la rigueur de ces mesures était le déterminant le plus important de la trajectoire de l'épidémie.

Facteurs dont il faut tenir compte

La transmission communautaire semble être le plus important prédicteur tant de la transmission des variants préoccupants chez les enfants que des modes de transmission dans les écoles. À ce jour, le variant B.1.1.7 semble être plus transmissible chez les enfants, mais ne semble pas avoir de plus graves répercussions que la souche originale. Le fait que les écoles soient ouvertes ou fermées ne semble avoir qu'un impact minime sur le cours de l'épidémie dans son ensemble. L'absence d'études de grande qualité sur la transmission de tous les variants préoccupants chez les enfants et sur les modes de transmission dans les écoles représente une lacune clé de cette recherche.

Nouvelles éléments de preuve sur la COVID-19

Résumé évolutif à propos des variants préoccupants du SRAS-CoV-2

Faits saillants jusqu'au 28 avril 2021

Introduction

Les **variants préoccupants** (*variants of concern* ou VOC en anglais) du SRAS-CoV-2 sont des variants en circulation qui ont été signalés par des organisations de santé publique nationales ou internationales. Ces VOC sont préoccupants par rapport aux variants originaux du SRAS-CoV-2, car leur complément de mutations entraîne une transmissibilité et une virulence accrue (morbidité ou mortalité), des changements dans la présentation clinique de la maladie, une évasion immunitaire, une efficacité réduite des traitements, des vaccins ou des mesures de santé publique et des échecs de détection diagnostique (1, 2). L'objectif de ce résumé à jour de la littérature sur les VOC du SRAS-CoV-2 est de mettre en évidence les nouvelles données à ce sujet, leur épidémiologie et la manière dont les attributs des variants préoccupants peuvent avoir un impact sur la gestion de la pandémie. L'accent sera mis sur les changements de paramètres épidémiologiques (par exemple, les taux de transmission, les résultats cliniques de la gravité et de la mortalité, les changements dans les groupes d'âge touchés ou les proportions asymptomatiques), les impacts sur les tests de diagnostic, l'évasion immunitaire/l'efficacité des vaccins et les impacts sur d'autres mesures de santé publique.

TABLEAU 1 : VARIANTS ACTUELS PRÉOCCUPANTS (VOC)

Nom de l'OMS (05-21)	Lignée Pango	Clade de la prochaine souche	Clade GISAID	Autre nom	Première détection	Premiers échan-tillons	Mutations de pointe caractéristiques
Alpha	B.1.1.7	20I/501Y.V1	GR/501Y.V1	VOC 202012/01	Royaume-Uni	Sept. 2020	69/70del, 144del, N501Y, A570D, D614G, P681H, T716I, S982A, D1118H
Bêta	B.1.351	20H/501Y.V2	GH/501Y.V2	VOC 202012/02	Afrique du Sud	Août 2020	D80A, D215G, 241/243del, K417N, E484K, N501Y, D614G, A701V
Gamma	P.1, B.1.1.28.1	20J/501Y.V3	GR/501Y.V3	VOC 202101/02	Brésil et Japon	Déc. 2020	L18F, T20N, P26S, D138Y, R190S, K417T, E484K, N501Y,

							D614G H655Y, T1027I, V1176F
Delta	B.1.617.[21]		G/452R.V3		Inde	Octobre 2020	L452R, D614G, P681R, ± (E484Q, Q107H, T19R, del157/158, T478K, D950N)

[1] Le B.1.617.2 a été ajouté à la liste des VOC le 11 mai 2021. Un profil sera établi pour ce VOC dans la prochaine mise à jour mensuelle.

Les **variants d'intérêt** (*variants of interest* ou VOI en anglais), également appelés variants en cours d'investigation (*variants under investigation* ou VUI en anglais), sont une désignation utilisée pour signaler un variant qui a le potentiel d'être une VOC, mais qui nécessite une étude ou des preuves supplémentaires. Les indicateurs pour la désignation d'un VOI comprennent un changement phénotypique ou l'acquisition de mutations avec une implication phénotypique établie ET qui a été la cause d'une transmission communautaire/d'amas ou qui est détectée dans plusieurs pays OU qui est évaluée comme un VOI par une autorité telle que l'OMS (1, 2). Les données sur les VOI sont collectées, mais ne sont pas mises en évidence dans ce résumé. L'ensemble complet de données en format Excel est accessible ici et filtré par VOI.

Ce résumé se veut un portrait à jour des données probantes clés sur la façon dont les VOC peuvent avoir un impact sur la pandémie, y compris sur les changements dans l'épidémiologie, l'évasion immunitaire ou les échecs des tests de diagnostic.

Points clés

Au 28 avril 2021, 218 études faisaient état d'un VOC ou d'un VOI et 156 études identifiées faisaient rapport d'un B.1.1.7, P.1 ou d'un B.1.351, et elles ont été incluses dans les résumés ci-dessous. Les observations cliniques, et les estimations de prévalence ponctuelle (n=23) et les études sur les VOI n'ont pas été résumées. Des résumés généraux sont présentés dans le tableau des points clés ci-dessous, et des résumés plus détaillés de chaque VOC figurent dans les sections d'examen. Les détails des études individuelles se trouvent dans l'ensemble de données en format Excel et accessibles ici. Dans l'ensemble, la prédominance des preuves disponibles concernait le variant B.1.1.7 (142 études) par rapport au variant B.1.351 (66 études) et au P.1 (34 études).

Transmissibilité :

- Toutes les études ont montré une augmentation de la transmissibilité pour les variants B.1.1.7, B.1.351 et P.1 par rapport au variant original, bien que l'étendue soit très variable. Pour le B.1.1.7, deux études canadiennes ont rapporté une transmissibilité accrue de 34 % (3) et des taux d'attaque secondaire plus élevés de 31 % (4).

Gravité clinique :

- Les études portant sur les trois variants ont montré une augmentation du risque d'hospitalisation et d'admission en unité de soins intensifs (USI). Toutefois, ces données sont basées sur un nombre limité d'études.
- Pour les indicateurs de gravité, quelques études ont rapporté un risque d'hospitalisation stratifié par âge et une probabilité accrue dans les groupes d'âge adulte entre 20 et 59 ans. D'autres études n'ont pas signalé d'association avec l'âge. Plusieurs études ont également rapporté une proportion plus faible de conditions préexistantes parmi les cas de VOC, à l'exception de l'obésité.
- En ce qui concerne la mortalité, les données relatives au P.1 et au B.1.1.7 ont montré que le risque de mortalité était globalement inférieur à celui du variant original. Une seule étude de surveillance sur le B.1.351 n'a montré aucune différence dans l'ensemble quant aux risques de mortalité. Le risque de mortalité aurait augmenté dans certains groupes d'âge adulte.
- Par rapport au variant original, la charge virale était systématiquement de 2 à 10 fois plus élevée pour le B.1.1.7, et était plus élevée pour le P.1 et le B.1.351 que le variant original, mais plus faible que la charge virale du B.1.1.7.
- Il n'y a pas eu d'études évaluant la période infectieuse pour le P.1 et le B.1.351 et seulement une petite étude qui a trouvé que l'infection moyenne au B.1.1.7 a duré 13,3 jours contre 8,2 jours pour les autres variants. Il n'y a pas eu d'études sur la période d'incubation pour aucun des VOC.

- D'autres catégories liées à la performance diagnostique et à la recherche épidémiologique sur la diffusion et l'impact des interventions non pharmaceutiques sont résumées dans les sections approfondies sur les VOC.
    - Aucune étude évaluant les tests de diagnostic ou de détection du SRAS-CoV-2 n'a décrit des problèmes d'échec ou de performance pour la détection des VOC, en dehors de l'abandon du gène S bien caractérisé pour le B.1.1.7.
    - Peu d'études portaient sur des interventions non pharmaceutiques. Bien qu'une plus grande rigueur ait été nécessaire pour contrôler les VOC en raison d'une transmissibilité plus élevée, aucune modification des interventions individuelles n'a été nécessaire.
    - Les études sur l'introduction et la propagation des VOC dans une région géographique n'ont pas été incluses dans le tableau ci-dessous, mais des résumés sont disponibles dans les profils des VOC individuels, tout comme les résumés des modèles animaux et des études *in vitro* sur la réinfection, la protection vaccinale et l'impact potentiel des VOC sur la thérapeutique.

Les catégories de preuves dans les tableaux ci-dessous comprennent les éléments suivants s'ils sont signalés :

La **transmissibilité** comprend les changements dans la transmissibilité, les taux d'attaque secondaire et les estimations de l'avantage sélectif.

La **gravité clinique** comprend la proportion d'infections qui sont symptomatiques, la proportion de maladie grave et de mortalité, ainsi que les facteurs de risque de maladie grave ou de mortalité, la charge virale, la

période infectieuse, la période d'incubation. Il convient de noter que les facteurs de risque de maladie grave incluent des populations spéciales, par exemple les personnes enceintes, si elles sont signalées.

L'**échappement immunitaire** comprend les modifications de l'efficacité des vaccins, le risque de réinfection chez l'humain, les modèles animaux, les expériences *in vitro* ou *in silico*, ainsi que les impacts sur la thérapeutique s'ils sont signalés.

Les **échecs des tests de diagnostic/détection** sont saisis dans les sections individuelles, et ne seront inclus dans le tableau 2 que si la performance du test est préoccupante.

Autre épidémiologie comprend toutes les études qui documentent l'émergence et la propagation des VOC dans une zone géographique, les études écologiques qui examinent la propagation des VOC et les facteurs de risque pour les points chauds, et les études sur les interventions de santé publique efficaces contre les VOC, l'épidémiologie génomique comme sous-catégories.

TABLEAU 2 : RÉSUMÉ DES PREUVES CLÉS DU VOC P.1 (GAMMA) (N=34), DU VOC B.1.351 (BETA) (N=66) ET DU VOC B.1.1.7 (ALPHA) (N=142)

Catégorie	P.1 (Gamma)	B.1.351 (Bêta)	B.1.1.7(Alpha)
EFFICACITÉ DE LA TRANSMISSION			
Transmissibilité Par rapport au variant original	Quatre rapports de données de surveillance : • 27 % de plus en France (combiné P.1/B.1.351) (5) • 160 % - 100 % plus élevé au Brésil (6, 7) • Un modèle étudiant le P.1 en Italie a rapporté une transmissibilité supérieure de 12 à 39 % selon que le P.1 présente ou non une évasion immunitaire (8). Faible niveau de preuve.	Quatre rapports de données de surveillance : • 27 % plus élevé en France (combiné P.1/B.1.351) (5), • 55 % (9, 10) et 20-100 % plus élevé en Afrique du Sud (11) Faible niveau de preuve	24 études de surveillance et d'observation : • Variation relative de la transmissibilité du B.1.1.7 ($_{1-Rvoc/Variant\ original}$) entre 34 et 118 % d'une étude à l'autre, une partie de la variation étant due à l'époque (12) et au pays (plus élevée au Royaume-Uni) (10) : ○ Canada : 34 % (IC 95 % : 31-38) (3), É.-U. : 35-59 % (13, 14). ○ Royaume-Uni : de 43 à 118 % (10, 12, 13, 15-17), de 13,4 à 41,3 % dans les régions du Royaume-Uni en décembre 2020 (18). ○ Europe : France 41 -52 % (5, 19), Danemark 55 %, Suisse 54-74 % (13), (20), Norvège 24 % (21), Italie 55-57 % (22), Pays de Galles et É.-U. 65-72 % (10). ○ Israël 45 % (23). ○ Le Japon a estimé une augmentation de 60 % de la transmissibilité relative aux VOC (non spécifiés) (24). • De même, les ratios des taux d'attaque secondaire parmi les études sur la transmission par les ménages étaient de 30 à 70 % plus élevés au Canada (4), en Norvège (21) et au Danemark (25). Niveau de preuve faible à modéré

SÉVÉRITÉ CLINIQUE			
Virulence/gravité ou durée de la maladie Par rapport au variant original	Deux (2) études de surveillance : • Une proportion plus élevée de cas d'hospitalisation (p<0,001) (26). • Plus grande probabilité d'être admis à l'hôpital (aOR 2,6, 95 % CI 1,4-4,8) (26). • Probabilité plus élevée d'être admis en soins intensifs (aOR 2,2, 95 % CI 1,8-2,9) (26). • Une croissance exponentielle des cas hospitalisés a été signalée à Rio Grande do Sul et Porto Alegre (27). Faible niveau de preuve.	Une (1) étude de surveillance européenne : • Aucune différence dans la proportion de personnes symptomatiques. • Plus grande probabilité d'être admis à l'hôpital (aOR 3,6, 95 % CI 2,1-6,2) (26) • Probabilité plus élevée d'être admis en soins intensifs (aOR 3,3, 95 % CI 1,9-5,7) (26). Faible niveau de preuve.	Dix (10) études de surveillance et d'observation : • Des données contradictoires sur la prévalence de la maladie symptomatique n'ont révélé aucune différence entre les deux dans une étude et moins de cas symptomatiques (p<0,001) dans une autre (26, 28). • Cinq études ont révélé une probabilité plus élevée d'être admis à l'hôpital (aOR 1,36 - 1,7 et aHR 1,34) (26, 29-32). • Deux études ont révélé une probabilité plus élevée d'admission en soins intensifs (aOR 2,3, aHR 1,99) (26, 33). • Parmi les cas hospitalisés, il n'y avait pas d'association entre le B.1.1.7 et la maladie grave et le décès (aPR 1-02) (34). • Des taux plus élevés d'hypoxie à l'admission à l'hôpital ont été signalés dans deux études (35, 36). Niveau de preuve modéré.
Facteurs de risque sur la gravité Par rapport au variant original	Trois (3) études d'observation • Les cas de P.1 avaient une probabilité d'hospitalisation de 3,0 à 13,1 fois plus élevée dans les	Une (1) étude de surveillance européenne • Risques d'hospitalisation de 3,5 à 3,6 fois plus élevés pour les groupes d'âge 40-79 ans (26)	Cinq (5) études d'observation : • Une étude sur les cas de COVID-19 hospitalisés a rapporté une plus grande proportion de femmes (48,0 % contre 41,8 %, p=0,01), moins de patients fragiles (14,5 % contre 22,4 %, p=0,001) et une plus grande proportion de cas obèses (30,2 %

	groupes d'âge 20-79 ans (26). • L'admission en USI était 2,9 -13,9 fois plus élevée dans les groupes d'âge ≥ 40 ans (26). • Les conditions préexistantes étaient plus faibles : 27,8 % dans le P.1 contre 89 % dans le variant original, p<0,001 (26). • Les cas graves chez les personnes de moins de 60 ans sont passés de 39 % lors de la première vague à 47 % lors de la deuxième vague (37). • Deux études n'ont pas trouvé d'augmentation de la proportion de personnes hospitalisées dans aucun groupe d'âge (26, 38). Faible niveau de preuve.	• L'admission en USI des personnes âgées de 40 à 59 ans était plus élevée (aOR 8, IC 95 % 3,7-17,3). • Les conditions préexistantes étaient plus faibles (79,6 % B.1.351, contre 89 %, p<0,001) (26). Faible niveau de preuve.	contre 24,8 %, p=0,048), mais aucune différence selon l'âge ou l'ethnie (35). • Une autre étude n'a signalé aucune différence significative en ce qui concerne l'âge et le sexe des patients, ainsi que la durée médiane du séjour à l'hôpital (31). La différence d'âge était statistiquement significative dans une autre étude (37 contre 39 ans) (39). • Une étude a rapporté un ratio de probabilités d'hospitalisation 3,0 fois plus élevé chez les 20-39 ans et 2,3 fois plus élevé chez les 40-59 ans, et que les conditions préexistantes étaient plus faibles (44,8 % contre 89 % p<0,001) (26). • Une étude hospitalière réalisée en France a révélé que l'âge moyen était de 59,2 ans, en baisse par rapport à 70,7 ans, et que le nombre de patients sans comorbidité avait augmenté de 16 % à 42 % (p=0,007) (36). Niveau de preuve faible à modéré.
Mortalité	Deux (2) études observationnelles et 1 modèle prédictif :	Une (1) étude de surveillance européenne :	Neuf (9) études de surveillance et d'observation :

Par rapport au variant original	• Le P.1 présentait une probabilité de mortalité globale plus faible (aOR 0,6, IC 95 % 0,3-1,0) (26). • Taux de mortalité hospitalière plus élevé chez les jeunes adultes (38). • Le modèle prédictif a estimé que la mortalité moyenne était 1,5 (50 % CrI 1,2-1,9) fois plus élevée après l'émergence du P.1, (7). Faible niveau de preuve	• Pas de différence dans les risques de décès (26). Faible niveau de preuve.	• Trois études n'ont signalé aucune différence significative en matière de mortalité globale (2,1 vs 4,1 %) (28), (31), ou après 28 jours (OR : 0,90, IC 95 % 0,57-1,41, p=0,64) (32) • Une étude a fait état d'un risque de mortalité plus faible (aOR 0,5, IC 95 % 0,3-0,9) (26) • Cinq études ont fait état d'un risque de mortalité plus élevé : risque plus élevé de décès à 28 jours (55 %, IC 95 % : 39-72 %) (40), aHR 1,59 (IC 95 % 1,25-2,03) (33), aHR 1,67 (IC 95 % 1,34 - 2,09; P <0,0001) (34). HR 1,64 (IC 95 % 1,32 - 2,04, p <0,001) ce qui équivaut à une augmentation de 2,5 à 4,1 décès pour 1 000 cas détectés (41) et une étude écologique a estimé que le B.1.1.7 était 33 % plus mortel au Royaume-Uni (42) Niveau de preuve modéré.
Facteurs de risque de mortalité par rapport au variant original	Une (1) étude de surveillance au Brésil : • La mortalité chez les cas de COVID-19 <60 ans a augmenté de 18 % en novembre 2020 à 28 % en février 2021 (37). • La mortalité chez les personnes ne présentant aucune condition préexistante	Aucune étude	Deux (2) études de surveillance et de cohorte rétrospective : • Une étude a révélé que la mortalité était plus élevée dans les groupes d'âge plus jeunes que dans les groupes plus âgés (59,0 % chez les 1-34 ans contre 55,4 % chez les 85 ans ou plus) et qu'elle était plus élevée chez les Noirs (69,6 %), les personnes d'origine ethnique mixte ou inconnue (64,8 %), les Blancs (58,0 %) et les Asiatiques (57,6 %) (40). • Une autre étude n'a trouvé aucune augmentation de la mortalité en fonction du

	était plus élevée après l'émergence du P.1 chez les femmes (RR 5,65, IC 95 % 2,9 - 11,03; p <0,0001) et chez les 40 - 59 ans (RR 7,7, IC 95 % 5,01-11,83; p <0,0001) (37). Faible niveau de preuve.		sexe (p = 0,90), du groupe ethnique (p = 0,64) ou du groupe d'âge (p = 0,15) (33). Faible niveau de preuve.
Charge virale Par rapport au variant original	Deux (2) études de surveillance : • La charge virale des cas de P.1 était environ 10 fois plus élevée, indépendamment de l'âge et du sexe (43). • La charge virale était plus élevée (mais inférieure à celle des échantillons B.1.1.7) (5). Faible niveau de preuve.	Deux (2) études avec des résultats secondaires : • La charge virale était plus élevée (mais inférieure à celle des échantillons de B.1.1.7) (5, 44). Niveau de preuve très faible.	Treize études d'observation et analyses de surveillance : • On a toujours trouvé des valeurs de Ct plus faibles ou des charges virales estimées plus élevées. L'ordre de grandeur médian supérieur varie selon les études et la protéine cible de 2 à 10 fois la différence (5, 28, 31, 39, 44-49, 49-51). Niveau de preuve faible à modéré.
Période infectieuse par rapport au variant original	Aucune étude	Aucune étude	Une petite étude a calculé que les infections durent en moyenne 13,3 jours contre 8,2 jours pour les autres variants (47). Niveau de preuve très faible
Période d'incubation	Aucune étude	Aucune étude	Aucune étude

ÉCHAPPEMENT IMMUNITAIRE —Impact potentiel sur l'efficacité du vaccin, possibilité de réinfection			
Réinfection à partir d'une infection naturelle par rapport au variant original	Une (1) étude de surveillance au Brésil : • En supposant que 78 % de la population était déjà infectée, on estime que 28 % des cas à Manaus sont des réinfections (6). • Une (1) observation clinique de réinfection (52). Niveau de preuve faible/très faible.	Deux (2) observations cliniques de réinfection (53, 54). Niveau de preuve très faible.	Deux (2) études ont montré que le B.1.1.7 n'échappe pas à l'immunité naturelle : • Un taux de réinfection estimé à 0,7 % (IC 95 % : 0.6-0.8) (55). • Une étude britannique n'a trouvé aucune preuve que le B.1.1.7 modifiait l'étendue de la protection positive à l'infection par PCR chez les personnes séropositives (aIRR 0,40, IC 95 %0,10-1,64, p=0,20) (56). Niveau de preuve modéré.
Infection découverte après la vaccination/efficacité ou efficience du vaccin par rapport au variant original	Une (1) étude cas-témoins : • La vaccination avec au moins une dose de CoronaVac a été associée à une réduction d'un facteur 0,50 (EV ajustée, 49,6 %; IC 95 %, 11,3 - 71,4) des chances d'infection symptomatique par le SRAS-CoV-2 14 jours après la première dose (57).	Deux (2) ECR : • AstraZeneca : Efficacité de 10,4 % pour la prévention de la maladie symptomatique (58) • Novavax : Efficacité de 50-60 % pour la prévention de la maladie symptomatique (59) • Johnson and Johnson : l'efficacité était de 52 % et 64 % pour la maladie modérée et	Neuf (9) études comprenant des ECR, des cohortes et des études de surveillance : • L'efficacité du vaccin dans un ECR britannique d'AstraZeneca était de 70,4 % (CI 9 5 % 43,6 — 84,5) contre 81,5 % (67,9 - 89,4) dans les variants originaux (62). • En Israël, où 94 % des cas étaient le B.1.1.7, l'efficacité du vaccin Pfizer était >96 % 14 jours après la deuxième dose (63), mais il y avait un risque accru de percées infectieuses entre la première dose et jusqu'à 14 jours après la deuxième dose (aOR 2,4 (IC 95 %): 1,2 à 5,1) (61). • Une étude britannique n'a pas trouvé de différence dans la protection après une

	Faible niveau de preuve.	de 73 % et 82 % pour la maladie grave à 14 jours et 28 jours respectivement (60) • Aucune percée infectieuse n'a été identifiée >14 jours après la deuxième dose (principalement Pfizer) dans une étude cas-témoins menée en Israël (61) Niveau de preuve modéré.	première dose de vaccin (aIRR=1,84, IC 95 % 0,75-4,49, p=0,18) (56). Niveaux de preuve variables, allant des ECR (modérés à élevés) aux observations cliniques (très faibles).

CFR = taux de létalité, IC= intervalle de confiance, Ct = seuil de cycle, USI = unité de soins intensifs, OR = rapport des cotes, PCR = réaction en chaîne par polymérase, EV = efficacité du vaccin, aOR= rapport des cotes ajusté, aHR = rapport de risque ajusté, aPR= rapport de prévalence ajusté

Aperçu des données probantes

Les modèles d'étude inclus dans ce résumé vont des essais cliniques randomisés en double aveugle à faible risque de biais à un certain nombre de modèles d'étude par observation différents. Les études par observation offrent des preuves faibles à modérées, selon la conception spécifique de l'étude et la cohérence entre les études. Les études descriptives incluses dans ce rapport, telles que les séries de cas et les observations cliniques, les modèles prédictifs, les études écologiques, les modèles animaux et les études *in vitro*, présentent un niveau de preuve faible à très faible et ne peuvent généralement être utilisées que pour générer des hypothèses qui doivent être examinées plus avant avec un plan d'étude différent. Compte tenu de cette très grande variation, une indication du niveau de confiance des preuves est fournie pour un résultat particulier. Les plans d'étude sont fournis, mais aucune évaluation formelle du risque de biais n'a été réalisée.

Il y a plusieurs lacunes dans les connaissances ou des domaines où très peu de recherche figure dans le tableau des points clés, et des recherches supplémentaires sont nécessaires pour améliorer la confiance dans les résultats sommaires, en particulier pour le B.1.351 et le P.1.

CONTENU

P.1 (GAMMA)

L'ensemble de données en format Excel comprend les résumés des études individuelles et est accessible ici. Le profil détaillé des preuves élaboré pour le P.1 est présenté ci-dessous. Il couvre les données sur les modifications de l'efficacité de la transmission, les modifications de la gravité clinique, l'échappement immunitaire, les tests et les diagnostics, ainsi que d'autres études épidémiologiques portant principalement sur la propagation des VOC.

Tableau 3 : Profil d'évidence du P.1 (Gamma) VOC (n=34)

CATÉGORIE	RÉSUMÉ DES PRINCIPAUX RÉSULTATS	APERÇU DES DONNÉES PROBANTES
Efficacité de la transmission		

Transmissibilité par rapport au variant original	Une transmissibilité accrue par rapport au variant original : • 27 % de plus en France pour le combiné P.1 et B.1.351 (5). • 2.6 (IC 95 % : 2.4-2,8) fois plus élevée (6) et 2,0 (50 % CrI 1,7 - 2,4) fois plus transmissible avec une immunité croisée médiane estimée à 68 % (50 % CrI 54-79 %) au Brésil (7). • 1,12 (IC 95 % 1,03-1,23) fois plus transmissible avec une évasion immunitaire complète à 1,39 (IC 95 % 1,26-1,56) avec une protection croisée complète en Italie (8).	Quatre études ont fourni des estimations de la transmissibilité du P.1, notamment : deux analyses de données de surveillance du Brésil, une étude transversale de la France, et un modèle prédictif de l'Italie. Il y a peu de cohérence entre les études. L'hétérogénéité des estimations de la transmissibilité accrue peut être due à des facteurs tels que l'emplacement géographique et les moments où les estimations ont été faites. Faible niveau de preuve.
Gravité clinique		
Virulence/gravité ou durée de la maladie par rapport au variant original	• Une proportion plus élevée de cas de P.1 hospitalisés a été signalée par rapport au variant original (20 % contre 7,5 % p<0,001) (26). • Une étude a rapporté un rapport de cotes ajusté (aOR 2,6, IC 95 % 1,4-4,8) plus élevé de cas de P.1 admis à l'hôpital par rapport au variant original ou en USI (aOR 2,2, IC 95 % 1,8-2,9) (26). • Il y a eu croissance exponentielle des hospitalisations dans le Rio Grande do Sul, avec un temps de doublement moyen de 13,4 jours et un taux de croissance quotidien de 5,3 %. • Une croissance exponentielle similaire (temps de doublement de 13,3 jours, taux de croissance quotidien de 5,4 %) pour les hospitalisations a été signalée dans la ville de Porto Alegre (27).	Deux (2) études de données de surveillance en Europe et au Brésil. Faible niveau de preuve.
Facteurs de risque de gravité par rapport au variant original	• Dans l'analyse stratifiée par âge, les cas de P.1 avaient une probabilité d'hospitalisation 3,0 à 13,1 fois plus élevée dans les groupes d'âge 20-39, 40-59 et 60-79 (26). • Une étude a indiqué qu'il y a eu augmentation du nombre de personnes de moins de 60 ans parmi les cas graves dans une proportion de 39 % lors de la première	Deux (2) études provenant de pays européens et de données de surveillance du Brésil et une (1) étude écologique. Faible niveau de preuve.

	vague et de 47 % lors de la deuxième vague (37). • D'autres études n'ont pas indiqué d'augmentation de la proportion de personnes hospitalisées, quel que soit le groupe d'âge (38). • Les probabilités d'admission en USI étaient 2,9 à 13,9 fois plus élevées dans les groupes d'âge 40-59 ans, 60-79 ans et ≥ 80 ans (26). • Les conditions préexistantes étaient plus faibles : 27,8 % dans le P.1 contre 89 % dans le variant original, p<0,001 (26).	
Mortalité par rapport au variant original	• Diminution du risque de mortalité dû au P.1 par rapport au variant original dans l'analyse multivariable (aOR 0,6, IC 95 % 0,3-1,0) (26). • Une augmentation différenciée de la mortalité des jeunes adultes suggère la possibilité d'une plus grande sévérité du variant P.1 dans cette population. Les hospitalisations et les décès à l'hôpital chez les jeunes adultes étaient corrélés à des taux élevés de mortalité hospitalière >10 % (38). • Le modèle prédictif a estimé que les infections à P.1 ont un risque médian de 1,5 (50 % CrI 1,2-1,9) fois plus élevé risquant d'entraîner la mortalité dans la période suivant l'émergence du P.1, par rapport à avant (7).	Une (1) étude à partir des données de surveillance des pays européens, et des études du Brésil; une (1) étude écologique, un (1) modèle prédictif. Faible niveau de preuve.
Facteurs de risque de mortalité par rapport au variant original	La mortalité des cas de COVID-19 de <60 ans a augmenté de 18 % en novembre 2020 à 28 % en février 2021 (37). Le taux de létalité (CFR) a augmenté le plus chez les personnes âgées de 20 à 59 ans et chez les patients sans condition à risque préexistante. La proportion de patients sans condition à risque préexistante parmi les cas graves était plus élevée en février (33 %, contre 25 % auparavant). Par rapport à nov./déc. 2020, les femmes âgées de 20 à 39 ans, sans condition de risque préexistante, avaient un risque de décès 5,65 (IC 95 % 2,9 - 11,03; p <0,0001) fois plus élevé en février 2021 et	Une (1) étude à partir des données de surveillance du Brésil. Faible niveau de preuve.

	7,7 fois plus élevé (IC 95 % 5,01-11,83; p <0,0001) chez les 40 - 59 ans (37).	
Charge virale par rapport au variant original	La charge virale (mesurée par les valeurs CT) des échantillons de P.1 était inférieure à celle des échantillons de B.1.1.7 et supérieure à celle des variants originaux (5). La charge virale des cas de P.1 par rapport aux cas de variant original était environ 10 fois plus élevée dans le cas de P.1 (43). Les charges virales étaient plus élevées dans les infections à P.1, indépendamment de l'âge et du sexe (43).	Deux (2) études à partir des données de surveillance de la France et du Brésil. Faible niveau de preuve.
Période infectieuse	Aucune étude	
Période d'incubation	Aucune étude	
Échappement immunitaire - Impact potentiel sur l'efficacité du vaccin, possibilité de réinfection		
Réinfection à partir d'une infection naturelle par rapport au variant original	• On a estimé que 28 % des cas à Manaus au Brésil étaient des réinfections, étant donné que 78 % de la population était déjà infectée (6). • Des observations cliniques de réinfection par le P.1 ont également été rapportées (52).	Une (1) étude des données de surveillance du Brésil. Faible niveau de preuve. Un (1) rapport de cas : niveau de preuve très faible
Infection découverte après la vaccination/efficacité ou efficience du vaccin par rapport au variant original	• La vaccination avec au moins une dose de CoronaVac a été associée à une réduction d'un facteur 0,50 (EV ajustée, 49,6 %; IC 95 %, 11,3 - 71,4) des chances d'infection symptomatique par le SRAS-CoV-2 pendant la période de 14 jours ou plus après avoir reçu la 1re dose. Le sexe féminin (OR, 0,50; IC à 95 %, 0,38 - 0,81) et un test RT-PCR ou antigène du SRAS-CoV-2 positif au cours de la période précédant l'étude (OR, 0,38; IC à 95 %, 0,17 - 0,87) ont été associés à une probabilité réduite d'infection symptomatique par le SRAS-CoV-2 (57).	Une (1) étude cas-témoins.
Études *in vitro*	La plupart des sérums de convalescents ont montré une activité neutralisante réduite pour le P.1 par rapport au variant original ou au B.1.1.7. Certains vaccins ont montré une activité neutralisante modeste ou nulle contre le P.1 (64-66). *Note : De nombreuses études in vitro ont été identifiées et toutes n'ont pas été extraites dans cette version.*	Niveau de preuve très faible. La réponse immunitaire est complexe, et l'absence ou la réduction des anticorps neutralisants ne signifie pas un manque de protection immunitaire. D'autres recherches sont nécessaires (voir l'examen des sciences émergentes de

		l'ASPC sur l'immunité protectrice).
Tests et diagnostics		
Test et détection par rapport au variant original	Aucun échec de test n'a été signalé pour la PCR du P.1, les tests d'antigènes ou les tests sérologiques (67).	
Épidémiologie de la propagation		
Émergence des VOC au fil du temps	De nombreuses études font état de « détections » de P.1 qui n'ont pas été résumées. Trois études montrent la croissance de P.1 dans différentes régions d'Italie et du Brésil, dont une étude axée sur le personnel de santé vacciné (22, 43, 68).	Une (1) étude de surveillance, un (1) modèle prédictif et une (1) étude transversale. Faible niveau de preuve.

CFR = taux de létalité, CI = intervalle de confiance, Ct = seuil de cycle, ICU = unité de soins intensifs, OR = rapport de cotes, PCR = réaction en chaîne par polymérase, EV = efficacité du vaccin, OR= rapport de cotes, aOR= rapport de cotes ajusté

B.1.351 (BETA)

L'ensemble de données en format Excel comprend les résumés des études individuelles et est accessible ici. Le profil détaillé des preuves élaboré pour le B.1.351 est présenté ci-dessous. Il couvre les données sur les modifications de l'efficacité de la transmission, les modifications de la gravité clinique, l'échappement immunitaire, les tests et les diagnostics, ainsi que d'autres études épidémiologiques portant principalement sur la propagation des VOC.

Tableau 4 : Profil d'évidence du B.1.351 (Beta) VOC (n=66)

CATÉGORIE	RÉSUMÉ DES PRINCIPAUX RÉSULTATS	APERÇU DES DONNÉES PROBANTES
Efficacité de la transmission		
Transmissibilité par rapport au variant original	Une transmissibilité accrue par rapport au variant original : 27 % en France pour le combiné B.1.351 et P.1 (5), 55 % (9, 10) et 20-100 % (jusqu'à 175 %) en Afrique du Sud (11)	Ces chiffres ont été estimés à partir de quatre analyses de données de surveillance. Il y a peu de cohérence entre les études. L'hétérogénéité des estimations de la transmissibilité accrue peut être due à de nombreux facteurs, notamment le moment où sont prises les estimations de la pandémie. Faible niveau de preuve.
Taux d'attaque secondaire par rapport au variant original	76.9 % ($_{Reff=4}$) (69)	Une (1) enquête sur l'épidémie. Faible niveau de preuve.
Gravité clinique		
Virulence / Gravité ou durée de la maladie par rapport au variant original	Proportion symptomatique : B.1.351 (90,3 %; 28/31) par rapport aux cas de variant original (81,4 %; 547/672, p = 0,2) (26). Hospitalisations dues B.1.351 (19,3 %) par rapport au variant original (7,5 %) p<0,001 (26). Analyse multivariable : Plus grande probabilité d'hospitalisation en raison du B.1.351 par rapport aux cas de variants originaux (aOR 3,6, IC 95 % 2,1-6,2) (26). La proportion de cas de B.1.351 en USI (2,3 %) par rapport au variant original (0,6 %), p=0,001, était plus élevée que pour le variant original (aOR 3,3, IC 95 % 1,9-5,7) (26).	Une (1) étude, données de surveillance des pays européens. Faible niveau de preuve.

Facteurs de risque de gravité par rapport au variant original	Dans une analyse stratifiée par âge, les cas de B.1.351 présentaient une probabilité d'hospitalisation 3,5 à 3,6 fois plus élevée pour les groupes d'âge 40-59 ans et 60-79 ans par rapport aux cas du variant original du même âge (26). L'admission en USI était significativement plus probable pour les cas de B.1.351 (aOR 8, IC de 95 % 3,7-17,3) âgés de 40-59 ans (26). Les conditions préexistantes étaient plus faibles pour les trois VOC (79,6 % pour le B.1.351, contre 89 % pour le variant original, p<0,001) (26).	Une (1) étude, données de surveillance des pays européens. Faible niveau de preuve.
Mortalité par rapport au variant original	Aucune différence dans les chances de décès pour les cas de B.1.351 par rapport au variant original dans l'analyse multivariable (aOR 1,1, IC 95 % 0,4-3,4) (26).	Une (1) étude, données de surveillance des pays européens. Faible niveau de preuve.
Facteurs de risque de mortalité	Aucune étude	
Charge virale par rapport au variant original	La charge virale (mesurée par les valeurs CT) des échantillons de B.1.351 était inférieure à celle des échantillons de B.1.1.7 et supérieure à celle des variants originaux (5, 44).	Deux (2) études, résultats secondaires. Niveau de preuve très faible.
Période infectieuse	Aucune étude	
Période d'incubation	Aucune étude	
Échappement immunitaire - Impact potentiel sur l'efficacité du vaccin, possibilité de réinfection		
Réinfection à partir d'une infection naturelle par rapport au variant original	Deux cas de réinfection par B.1.351 ont été signalés (53, 54).	Deux (2) observations cliniques. Niveau de preuve très faible
Infection découverte après la vaccination/efficacité ou efficience du vaccin par rapport au variant original	AstraZeneca : 10,4 % d'efficacité pour la prévention de la maladie symptomatique (58). Novavax : 57,7 % d'efficacité pour la prévention de la maladie symptomatique chez les participants séronégatifs (59). Johnson et Johnson : Les estimations de l'efficacité en Afrique du Sud étaient plus faibles que dans les autres pays. L'efficacité du vaccin (EV) contre le B.1.351 était de 52 % et 64 % pour la maladie modérée et de 73 % et 82 % pour la maladie sévère à 14 jours et 28 jours respectivement (60).	Deux (2) ECR Niveau de preuve modéré, car il n'y avait qu'une seule étude par vaccin à partir d'ECR. Des essais supplémentaires sont nécessaires pour améliorer la confiance dans ces estimations.

	Aucune percée de B.1.351 n'a été identifiée >14 jours après la deuxième dose (principalement Pfizer) dans une étude cas-témoins menée en Israël (61).	
Modèles animaux	Dans des modèles animaux soumis à l'épreuve du B.1.351, des hamsters préalablement infectés ou vaccinés ont montré une protection contre la maladie clinique (70, 71).	Deux (2) modèles animaux. Niveau de preuve très faible.
Études *in vitro*	La plupart des vaccins et des sérums de convalescence ont montré une activité neutralisante réduite pour le B.1.351 par rapport au variant original ou au B.1.1.7. Dans la plupart des études, le B.1.351 a une neutralisation plus réduite que le P.1. *Il existe de nombreuses expériences in vitro et toutes n'ont pas encore été extraites.*	Niveau de preuve très faible. La réponse immunitaire est complexe, et l'absence ou la réduction des anticorps neutralisants ne signifie pas un manque de protection immunitaire. D'autres recherches sont nécessaires (voir l'examen du groupe scientifique émergent de l'ASPC sur l'immunité protectrice).
Tests et diagnostics		
Test et détection par rapport au variant original	Aucun échec de test n'a été signalé pour la PCR du B.1.351, les tests d'antigènes ou les tests sérologiques (67).	Une étude DTA a évalué les performances de ces tests. Faible niveau de preuve.
Épidémiologie de la propagation		
Émergence des VOC au fil du temps	Les études qui font état d'une « détection » de B. 1.351 n'ont pas été résumées. Deux études montrent la croissance du B.1.351 dans différentes régions d'Afrique du Sud et de Colombie-Britannique, Canada (72, 73).	Deux (2) analyses de données de surveillance. Faible niveau de preuve.

B.1.1.7 (ALPHA)

L'ensemble de données en format Excel comprend les résumés des études individuelles et est accessible ici. Le profil détaillé des preuves élaboré pour le B.1.1.7 est présenté ci-dessous et couvre les données sur les changements dans l'efficacité de la transmission et dans la sévérité clinique, l'échappement immunitaire, les tests et les diagnostics, et d'autres études épidémiologiques portant principalement sur la propagation des VOC.

Tableau 5 : Profil de preuves de B.1.1.7 (Alpha) VOC (n=142)

CATÉGORIE	RÉSUMÉ DES PRINCIPAUX RÉSULTATS	APERÇU DES DONNÉES PROBANTES
Efficacité de la transmission		
Transmissibilité par rapport au variant original	Les estimations de la transmissibilité relative accrue ($_{1\text{-Rvoc/Variant original}}$) varient entre 34 et 118 % d'une étude à l'autre, une partie de la variation étant due au moment où les données ont été tirées dans l'émergence du B.1.1.7. Une étude note une variation dans le temps (12) et la plupart des estimations du Royaume-Uni sont plus élevées que celles des autres pays (10) : • Canada : 34 % (IC 95 % : 31-38) (3). • Royaume-Uni : 50-100 % (12), 75 % (CrI 95 % 70-80 %) (15), 52 % (IC 95 % 46 - 58 %) (16), 43-90 % (gamme CrI : 38-130 %) (13), 44-55 % (IC 95 % 38-61%) (17), 83-118 % (71-140 %) à travers le Royaume-Uni (10), 13,4-41,3 % à travers les régions du Royaume-Uni en décembre 2020 (18). • Europe : France 41 % (IC 95 % 38-44) (5) et 52 % (CrI 95 % 54-66 %) (19), Danemark 55 % (CrI 45-66 %), Suisse 74 % (CrI 66-82 %) (13) et 54 % (IC 95 % 49-65 %) (20), Norvège 24 % (IC 95 % 0-52 %) (21), Italie 55-57 % (IC 95 % 45-66 %) (22), Pays de Galles et É.-U. 65-72 % (46-104 %) (10). • É.-U. : 59 % (CrI 56-63 %) (13), 35-46 % (14). • Israël : 45 % (IC 95 % 20-60) (23). • Le Japon a estimé une augmentation de 60 % de la transmissibilité relative des VOC (non spécifiés) par rapport aux variants originaux (24). Certaines études ne fournissent pas suffisamment de données pour calculer l'efficacité accrue de la transmission, mais indiquent qu'elle était plus élevée (55). Une revue de cadrage sur la transmissibilité a inclus des études jusqu'au 21 février 2021 (9).	Cette section s'appuie sur 21 études par observation, dont des analyses de données de surveillance, des études transversales, des études de cohorte rétrospectives et des études écologiques. Ces études sont considérées comme étant de qualité faible à modérée et présentent un risque de biais de sélection, d'information et de confusion qui n'ont pas été pris en compte de manière cohérente dans toutes les études. On s'accorde à dire que le B.1.1.7 est plus transmissible et il y a un chevauchement assez important dans les estimations de l'ampleur.
Avantage sélectif	Selon un modèle d'avantage sélectif, on a estimé que le B.1.1.7 présentait un avantage	Un (1) modèle prédictif. Faible niveau de preuve.

	sélectif de 0,337 (0,336-0,339) par rapport aux variants originaux au Royaume-Uni (74).	
Taux d'attaque secondaire par rapport au variant original	• Dans une étude canadienne sur la transmission domestique, le B.1.1.7 avait un taux d'attaque secondaire (SAR) qui était RR=1,31 (IC 95 % 1,14-1,49) fois plus élevé que les non VOC et le risque était accentué pour les cas de référence asymptomatiques (RR=1,91, IC 95 % 0,96-3,80) et les cas présymptomatiques (RR=3,41, IC 95% 1,13-10,26) (4). • Dans les ménages norvégiens, le B.1.1.7 était 60 % (20 % — 114 %) plus transmissible que les variants originaux et, dans l'ensemble, le SAR était de 0,13 pour le variant original et de 0,15 pour le B.1.1.7, ce qui équivaut à 16 % (-6 % — 43 %) plus infectieux (rapport des SAR), même en tenant compte de l'âge (21). • Une étude danoise a rapporté une transmission plus élevée parmi les ménages de B.1.1.7, soit 1,50 à 1,70 fois les variantes originales. Elle a constaté que la transmissibilité en fonction de l'âge suivait un modèle en forme de U. La transmission la plus faible était celle des cas primaires dans la tranche d'âge de 10 à 30 ans, la plus élevée étant celle des enfants plus jeunes, et la plus élevée étant celle des cas âgés (25).	Trois études sur la transmission au sein des ménages. Le rapport des taux d'attaque secondaire a également été fourni comme mesure d'une transmissibilité plus élevée pour le B.1.1.7 dans certaines études basées sur des études de recherche de contacts. Les résultats étaient contradictoires dans les trois études résumées.
Interventions non pharmaceutiques par rapport au variant original	• Un modèle SEIR basé sur la situation en France décrit l'incapacité des interventions non pharmaceutiques telles que le couvre-feu et les mesures de distanciation physique à réduire le Ro du B.1.1.7 sous 1, alors que les mêmes interventions ont réussi contre les variants originaux (75). • Un modèle permettant d'examiner les scénarios de quarantaine et de test pour contrôler les importations de SRAS-CoV-2 aux États-Unis rapporte que le B.1.1.7 ne modifie pas l'efficacité des stratégies de quarantaine et de test (76).	Deux (2) modèles prédictifs. Les modèles prédictifs sont d'excellents outils pour comparer les options, mais il convient de faire preuve de prudence lors de l'extrapolation des résultats au-delà des scénarios de comparaison des modèles. Faible niveau de preuve.
Gravité clinique		

Virulence/gravité ou durée de la maladie par rapport au variant original	Cinq études montrent qu'il y a eu plus de cas d'hospitalisations liés au B.1.1.7 et deux études effectuées sur la population en général, plus d'admission en USI. • Les preuves sont contradictoires quant à savoir si le B. 1.1.7 entraîne davantage d'infections asymptomatiques : La prévalence de la maladie symptomatique était la même dans une étude italienne (28). Proportion symptomatique : 72,6 % cas de B.1.1.7 (5 365/7 390) par rapport aux cas de variants originaux (81,4 %; 547/672; p < 0.001) (26). • Plusieurs études ont fait état d'un nombre plus élevé d'hospitalisations et d'admissions en USI lié au B.1.1.7 : ○ Hospitalisation de B.1.1.7 par rapport au variant original (11 % contre 7,5 % p<0,001) et probabilité plus élevée d'hospitalisation des cas de B.1.1.7 par rapport au variant original (aOR 1,7, 95 I % CI 1,0-2,9) (26); OR 1,64 (IC 95 % 1,32-2,04) (29); OR 1,58 (IC 95 % 1,50 - 1,67) (30); (OR 1,36 IC 95 % 1,16-1,60, p=0,0002) (31). Le rapport de risque pour l'hospitalisation due au variant B.1.1.7 par rapport au variant original (aHR 1,34, IC 95 % 1,07-1,66) et la durée du séjour étaient similaires dans les deux groupes p=0,07 (32). ○ L'admission en USI était de 1,4 % pour le B.1.1.7 contre 0,6 % pour le variant original, p=0,002, ce qui représente une probabilité plus élevée d'admission en USI pour le B.1.1.7 aOR 2,3 (IC 95 % 1,4-3,5) (26). Admission en soins intensifs pour le B.1.1.7 aHR : IC 1,99 95 % 1,59 - 2,49 par rapport au variant original (33). • Parmi les cas hospitalisés, il n'y avait pas d'association entre la maladie grave et le décès parmi les variants B.1.1.7 et les variants originaux, PR ajusté 1-02 (IC 95 % : 0·76–1·38) (34).	Dix (10) études sur la sévérité, parmi lesquelles des analyses de données de surveillance, des cohortes prospectives, des cohortes rétrospectives et des études transversales, dont la plupart ont été menées au Royaume-Uni. Niveau de preuve modéré.

	• L'hypoxie (70,0 % contre 62,5 %, p=0,029) et des taux respiratoires plus élevés (p=0,001) ont été signalés parmi les admissions de cas B.1.1.7 dans deux études (35, 36).	
Facteurs de risque de gravité par rapport au variant original	Il n'y avait pas d'accord entre les études pour savoir si des facteurs de risque étaient associés à la gravité du B.1.1.7, y compris l'âge et le sexe, mais plusieurs études ont rapporté que les personnes infectées au B.1.1.7 étaient moins susceptibles d'avoir des comorbidités : • Une étude réalisée aux États-Unis n'a pas signalé de différence significative en ce qui concerne l'âge et le sexe des patients, ainsi que la durée médiane du séjour à l'hôpital (31). Dans une autre étude, la différence d'âge était statistiquement significative (37 contre 39 ans) (39). • Dans les modèles stratifiés par âge, les cas de B.1.1.7/SGTF des groupes d'âge 20-39 ans et 40-59 ans avaient, respectivement, une probabilité d'hospitalisation 3,0 et 2,3 fois plus élevée que les cas du variant original (26). • Une cohorte hospitalière entre décembre 2020 et janvier 2021 en France décrit des patients plus jeunes (63 % de >65 ans, contre 50 %) avec un âge moyen de 59,2 ans contre 70,7 ans; les patients sans comorbidité ont augmenté de 16 % à 42 % (p=0,007) (36). Les conditions préexistantes étaient plus faibles avec le B.1.1.7, par rapport au variant original (44,8 % contre 89 % p<0,001) (26). • Une étude des cas de COVID-19 hospitalisés a rapporté une plus grande proportion de femmes atteintes du B.1.1.7 (48,0 % contre 41,8 %, p=0,01), moins de patients fragiles (14,5 % contre 22,4 %, p=0,001) et une plus grande proportion de cas obèses (30,2 % contre 24,8 %, p=0,048), mais aucune différence selon l'âge ou l'ethnie (35).	Cinq (5) études sur les facteurs de risque de gravité. Il s'agit notamment d'analyses de données de surveillance, de cohortes prospectives, de cohortes rétrospectives et d'études transversales, dont la plupart ont été menées au Royaume-Uni. Niveau de preuve modéré.

Mortalité par rapport au variant original	Il existe des preuves contradictoires sur l'association entre la mortalité et l'infection B.1.1.7 : • Trois études n'ont rapporté aucune différence significative dans la mortalité globale : Italie (2,1 contre 4,1 %) (28), États-Unis (31) et aucune association avec la mortalité à 28 jours au Royaume-Uni (OR : 0,90, IC 95 % 0,57-1,41, p=0,64) (32). • Le B.1.1.7 présentait une probabilité de mortalité plus faible que le variant original dans l'analyse multivariable (aOR 0,5, IC 95 % 0,3-0,9) (26). • Cinq études ont fait état d'un risque de mortalité plus élevé : risque plus élevé de décès à 28 jours (55 %, IC 95 % : 39-72 %) (40), aHR 1,59 (IC 95 % 1,25-2,03) (33), aHR 1,67 (IC 95 % 1,34 - 2,09; P <0,0001) (34). HR 1,64 (IC 95 % 1,32 - 2,04, p <0,001), ce qui équivaut à une augmentation de 2,5 à 4,1 décès pour 1 000 cas détectés (41). • Une étude écologique du Royaume-Uni estime que le B.1.1.7 est 33 % plus mortel (42)	Neuf (9) ont fait état de la mortalité; il s'agissait d'analyses de données de surveillance, d'études écologiques, de cohortes prospectives, de cohortes rétrospectives et d'études transversales, dont la plupart ont été menées au Royaume-Uni. Niveau de preuve modéré.
Facteurs de risque de mortalité par rapport au variant original	• Les données démographiques sur les décès liés au B.1.1.7 étaient similaires chez les hommes et les femmes, mais la prévalence était plus élevée dans les groupes d'âge plus jeune que dans les groupes d'âge plus âgés (59,0 % chez les 1-34 ans contre 55,4 % chez les 85 ans ou plus) (40). Il y avait également des variations selon l'origine ethnique : noire (69,6 %), mixte ou d'origine ethnique inconnue (64,8 %), blanche (58,0 %) et asiatique (57,6 %). La variation était la plus faible dans le quintile le plus défavorisé de l'indice de privation multiple (53,9 %) (40). • Aucune preuve d'une association significative entre le B.1.1.7 et le sexe (p = 0,90), le groupe ethnique (p = 0,64) ou le groupe d'âge (p = 0,15) (33).	Une analyse des données de surveillance et une cohorte rétrospective chacune. Faible niveau de preuve.

Charge virale par rapport au variant original	Plusieurs études (n=13) ont mesuré la charge virale en tant que Ct ou copies estimées/mL pour différentes protéines cibles (généralement N et ORF1ab). Ils indiquent systématiquement que les échantillons de B.1.1.7 sont plus susceptibles de présenter des valeurs Ct plus faibles ou des charges virales estimées plus élevées. L'ordre de grandeur médian supérieur varie selon les études et la protéine cible de 2 à 10 fois la différence (5, 28, 31, 39, 44-49, 49-51).	Treize études qui étaient principalement des analyses de données de surveillance, des études de cohorte ou transversales qui ont analysé les valeurs Ct de la PCR entre les échantillons du B.1.1.7 et les échantillons autres que le B.1.1.7. Cette mesure est indirecte et toutes les études sont conçues sur la base d'observations, cependant la conclusion que les cas B.1.1.7 ont des valeurs Ct plus basses était cohérente entre les études. Le niveau de preuve est donc faible à modéré.
Période infectieuse	Les infections durent en moyenne 13,3 jours, contre 8,2 jours pour les autres variants, selon une petite étude (47).	Preuve très faible, nécessite une évaluation plus approfondie avec un échantillon plus grand et une gamme de cas plus étendue.
Période d'incubation	*Aucune étude*	
Échappement immunitaire - Impact potentiel sur l'efficacité du vaccin, possibilité de réinfection		
Réinfection à partir d'une infection naturelle par rapport au variant original	Deux études estiment le taux de réinfection à 0,7 % (IC 95 % : 0.6-0,8) (55) et chez les travailleurs de la santé du Royaume-Uni, rien ne prouve que le B.1.1.7 modifie l'étendue de la protection contre toute infection positive à la PCR chez les personnes séropositives (aIRR 0,40, IC 95 % 0,10-1,64, p=0,20) (56).	Deux études de réinfection ont inclus une analyse sur le B.1.1.7 et s'accordent à dire que le B.1.1.7 n'échappe pas à l'immunité naturelle. Ces études de cohorte sont de niveau de preuve modéré.
Modèle animal de réinfection par rapport au variant original	Les hamsters infectés par le SRAS-CoV-2 original et guéris ont tous été protégés contre une réinfection par le B.1.1.7 (70, 77).	En accord avec les études humaines et les études *in vitro*, les deux modèles animaux offrent des niveaux de preuve cohérents, mais faibles, concernant la protection contre la réinfection.
Études *in vitro* avec sérums convalescents comparés au variant original	Réduction minime de la neutralisation (64) (78) (62, 79, 80). Les sérums convalescents des cas symptomatiques légers par rapport aux cas asymptomatiques avaient un pouvoir	Il existe de nombreuses études *in vitro* et cette liste n'est pas exhaustive à ce jour. Les études *in vitro* ont systématiquement montré des

	neutralisant significativement plus élevé p=0.0005 (81)	réductions minimes ou faibles de la neutralisation du B.1.1.7 par rapport au variant original. Les études *in vitro* offrent un faible niveau de preuve même si les résultats sont cohérents.
Infection découverte après la vaccination/efficacité ou efficience du vaccin par rapport au variant original	• L'efficacité du vaccin dans un ECR britannique d'AstraZeneca était de 70,4 % (IC 95 % 43,6 - 84,5) contre la COVID-19 symptomatique causé par le variant B.1.1.7 et de 81,5 % (67,9 - 89,4) contre la COVID-19 symptomatique causé par les variants originaux (62). Dans le cas d'une infection asymptomatique ou à symptôme inconnu, l'efficacité du vaccin était plus élevée pour les infections non-B.1.1.7 (69,7 %, 33,0-86,3) que pour les infections au B.1.1.7 (28,9 %, -77,1-71,4) (62). • En Israël, où 94 % des cas étaient B.1.1.7, l'efficacité du vaccin Pfizer était >96 % 14 jours après la deuxième dose (63, 82). Les infections notées entre la première dose et jusqu'à 14 jours après la deuxième dose en Israël ont entraîné un risque plus élevé ajusté d'être positif à la PCR avec le B.1.1.7 (aOR 2,4 (IC 95 % : 1,2 à 5,1) (61). • Dans une étude britannique sur les travailleurs de la santé, rien ne prouve que le B.1.1.7 modifie l'étendue de la protection après une première dose de vaccin (aIRR=1,84, IC 95 % 0,75-4,49, p=0,18) (56). D'autres études en situation réelle au Royaume-Uni n'ont signalé aucune différence dans l'efficacité du vaccin (données combinées avec AstraZeneca et Pfizer) avec le B.1.1.7 (83). • Après la vaccination BNT162b2, la probabilité ajustée d'une activité de neutralisation inadéquate contre le variant B.1.1.7 dans le groupe d'âge le plus élevé (>80) par rapport aux travailleurs sanitaires adultes était de aOR 4,4 (1,5-12,6, p<0,007) (84).	Les ECR, les cohortes prospectives, l'analyse des données de surveillance peuvent constituer des niveaux de preuve élevés et modérés, et leur généralisation dépend de la représentativité de la population de l'échantillon par rapport à la population générale. Des conclusions cohérentes entre les études améliorent la certitude des résultats. Les séries de cas et les rapports constituent des niveaux de preuve très faibles et ne doivent être utilisés que pour formuler des hypothèses en vue de recherches ultérieures.

	• Des observations cliniques et des séries de cas font état d'infections par rupture asymptomatiques liées au B.1.1.7 chez des adultes (85) et des personnes âgées (86), ainsi que chez des travailleurs de la santé au Brésil après l'administration de CronaVac (68).	
Modèle animal de vaccination par rapport au variant original	Les hamsters vaccinés avec ChAdOx1, puis exposés au B.1.1.7 n'ont pas perdu de poids, n'ont pas présenté de pathologie pulmonaire, et aucun virus n'a été détecté dans les échantillons de tissus, alors que les témoins présentaient une pathologie pulmonaire étendue (71)	Une (1) étude en accord avec les études humaines et les études *in vitro* : ce modèle animal offre des niveaux de preuve cohérents, mais faibles, concernant la protection contre la réinfection.
Étude *in vitro* des sérums injectés par rapport au variant original	• Pfizer BNT162b2 : faible perte de neutralisation (2,1 fois) (79, 87-89). • Les personnes déjà infectées ont beaucoup plus d'anticorps neutralisants après la première dose (90). Trois semaines après la seconde dose, tous les individus vaccinés ont neutralisé le B.1.1.7 (91). • Moderna mRNA-1273 : petite perte de neutralisation (2,3 fois) (89). • AstraZeneca ChAdOx1 : petite perte de neutralisation (88). • Vaccin AZD1222/Covishield après la première dose 96,1 % avaient des anticorps (92). • Les sérums du vaccin Spoutnik V ont neutralisé efficacement le variant original du B.1.1.7 (93).	Il existe de nombreuses études *in vitro* et cette liste n'est pas exhaustive à ce jour. Les études *in vitro* ont systématiquement montré des réductions minimes ou faibles de la neutralisation du B.1.1.7 par rapport au variant original. Les études *in vitro* offrent un faible niveau de preuve même si les résultats sont cohérents.
Modèle animal de la thérapeutique par rapport au variant original	Un certain nombre d'anticorps monoclonaux testés ont protégé des souris et des hamsters contre le B.1.1.7 (94).	Les modèles animaux constituent un faible niveau de preuve.
Étude *in vitro* de la thérapeutique par rapport au variant original	Perte minime d'activité : plusieurs anticorps monoclonaux (94-97), CP polyclonaux ou préparations d'anticorps hCoV-2-IG purifiés (98).	Les études *in vitro* constituent un faible niveau de preuve offrant un aperçu préliminaire de ce qui est attendu *in vivo*.

Étude *in vitro* de l'infectivité par rapport au variant original	La capacité du pseudovirus porteur de la mutation UK-N501Y à transduire ses cellules cibles par rapport au variant original a été considérablement augmentée, jusqu'à neuf fois (79).	Les études *in vitro* constituent un faible niveau de preuve offrant un aperçu préliminaire de ce qui est attendu *in vivo*.
Tests et diagnostics		
Test et détection	La PCR est efficace pour détecter et distinguer le variant (67, 99-104). Détection du B.1.1.7 dans les eaux usées dans des proportions aussi faibles que 0,1 % du SRAS-CoV-2 (105). De multiples études font état de tests fiables pour la détection rapide des variants (67, 105).	Huit études, cinq études sur l'exactitude des tests de diagnostic, deux analyses de données de surveillance qui décrivaient également un nouveau test ou un ensemble d'amorces, et une étude *in silico* concevant des amorces. Comme elles décrivent toutes des tests différents, les études sont considérées comme individuelles et ne peuvent être résumées ensemble. Faible niveau de preuve.
Épidémiologie de la propagation		
Émergence des VOC au fil du temps	Trois études canadiennes détaillent que les cas de B.1.1.7 étaient initialement regroupés dans deux régions et ont rapidement augmenté (73). De même, deux études réalisées en Ontario ont documenté l'augmentation rapide du B.1.1.7 (3, 106). Des études ont été retenues dans de nombreux pays du monde, la plupart décrivent la première détection du B.1.1.7 à la mi-décembre ou à la fin décembre, suivie d'une augmentation rapide du variant sur 3,5 à 10 semaines. On a constaté qu'elle était devenue la souche dominante dans plusieurs études. Une étude israélienne a documenté un plateau et un déclin dans le groupe d'âge >60 ans, alors que >50 % de la population avait été vaccinée (1 dose Pfizer> 14 jours) (23). Les États-Unis ont documenté plusieurs introductions de B.1.1.7 dans le pays (14). Plusieurs études documentent la détection du B.1.1.7 dans les eaux usées (105, 107-109).	Quarante-trois études rendent compte de l'émergence et de la propagation du B.1.1.7 dans un pays ou une région au fil du temps. La plupart de ces études sont basées sur des données de surveillance, des cohortes prospectives souvent constituées de travailleurs de santé, des cohortes rétrospectives de dossiers hospitaliers, des études longitudinales et des études écologiques. Les rapports de prévalence ponctuelle ou de cas de voyageurs infectés ont été exclus de ce résumé.

Attribution au variant B.1.1.7	On a constaté qu'une augmentation de 0,1 de la proportion du B.1.1.7, en considérant la période de pré-pic, était associée à une augmentation de 35,8 % de la hauteur du pic de la deuxième vague. Au cours de la période du 1er janvier au 25 février 2021, une augmentation de 0,1 de la proportion du B.1.1.7 a été liée à une augmentation de 15,3 % du nombre cumulé de décès au cours de cette période (110).	Un modèle utilisé pour estimer la charge supplémentaire de COVID-19 due à l'augmentation de la forme physique du B.1.1.7. Preuve de faible niveau.
Facteurs de risque de propagation	Une étude écologique menée dans les régions de Toronto et de Peel, en Ontario, a montré que le taux de croissance du B.1.1.7 (11,3 %, 19,8 % et 30,8 %), l'ensemble des cas (19,0 %, 32,7 % et 48,3 %) et les cas de VOC (18,4 %, 30,8 % et 50,8 %) étaient positivement corrélés avec la proportion de travailleurs essentiels (30,4 %, 47,9 % et 63,2 %) et le revenu médian (33 000 $, 45 000 $ et 60 000 $ CAN) de la communauté, respectivement (111).	Une étude écologique est une preuve de faible niveau.
Analyse génomique de la propagation	Les résultats ne suggèrent pas que les mutations canoniques du VOC B.1.1.7 ont évolué indépendamment dans différents endroits, et indiquent une origine et une propagation du VOC B.1.1.7 à partir du Royaume-Uni (112).	Une (1) étude des données de surveillance génomique; faible niveau de preuve.

Méthodes :

Une analyse quotidienne de la littérature (publiée et prépubliée) est effectuée par le Groupe des sciences émergentes de l'ASPC. La littérature sur la COVID-19 compilée depuis le début de l'épidémie est mis à jour quotidiennement. Les recherches pour retrouver la littérature pertinente sur la COVID-19 sont effectuées dans Pubmed, Scopus, BioRxiv, MedRxiv, ArXiv, SSRN, Research Square et croisées avec les centres d'information sur la COVID-19 gérés par Lancet, BMJ, Elsevier, Nature et Wiley. Le résumé quotidien et les résultats de l'analyse complète sont conservés dans une base de données Refworks et dans une liste en format Excel pouvant être consultée. L'un des objectifs est d'identifier les études sur les variants préoccupants ou faisant l'objet d'une étude. Les études ainsi identifiées figurent plus en détail dans notre base de données VOC/VOI, et les résultats sur les VOC sont extraits dans cette revue. Une vérification croisée des articles pertinents est également effectuée dans les bases de données à l'aide d'une recherche par mots clés ciblés. Ce tableau évolue au fur et à mesure que les preuves évoluent.

Variant préoccupant (VOC)	Termes de recherche
B.1.1.7, 202012/01, 501Y.V1, variant Kent (Mutations : Δ69/70, Δ144Y, (E484K*), (S494P*), N501Y, A570D, D614G, P681H)	B.1.1.7 OU 202012/02 OU 501Y.V1

* de nouveaux variants avec des mutations ont été signalés et sont classés dans la catégorie B.1.1.7 + E484K	
B.1.351, 501Y.V2, 20H/501.V2, Variant sud-africain (mutations : K417N, E484K, N501Y, D614G)	B.1.351 OU 501Y.V2
P.1, B.1.1.28.1, 501Y.V3, 20J/501Y.V3, variant du Brésil (mutations : K417N/T, E484K, N501Y, D614G)	P.1 OU B.1.1.28 OU 501Y.V3
Nouveau VOC au Royaume-Uni : 202102/02, B.1.1.7 avec mutation E484K (nom?)	Voir B.1.1.7
Variant en cours d'examen	
É.-U. : B.1.429 et B.1.427, 20C/S:452R, (mutations : L452R, D614G et S13I, W152C en 429 uniquement)	B.1.429 et B.1.427, 20C/S:452R, CAL.20C, L452R
P.2, B.1.1.28.2, au Brésil B.1.1.33	P.2 OU B.1.1.28 OU B.1.1.33
Royaume-Uni : A.28.1	A.28.1
Royaume-Uni, Mexique, Nigeria : B.1.525	B.1.525
Royaume-Uni : B.1.318	B.1.318
Russie : B.1.317	B.1.317
New York : B.1.526	B.1.526
Autres aux États-Unis : B.1.426, recombinant B.1.1.7 + B.1.429	B.1.426 et autres capturés avec la chaîne du B.1.429
P.3, VUI-21MAR-02 nommé aux Philippines (et possède les mutations E484, N501Y, P681H, LGV141-143)	P.3
B.1.617 Inde, sous-lignages : B.1.617.1 B.1.617.2 B.1.617.3 (double mutant E484Q et L452R)	B.1.617
B.1.618 Inde (triple mutant)	B.1.618

Cette revue contient les recherches publiées jusqu'au 28 avril 2021.
Chaque référence potentiellement pertinente a été examinée pour confirmer qu'elle contenait des données pertinentes et les données pertinentes ont été incluses dans l'examen.

Révision par les pairs

Le présent document a fait l'objet d'un examen par les pairs, par un expert en la matière, ainsi que d'un examen rédactionnel et d'un examen des aspects scientifiques et politiques par le Bureau du directeur scientifique.

Préparé par : Lisa Waddell et Kusala Pussegoda, LNM, Groupe des sciences émergentes, ASPC.

Connaissances mobilisées par le Bureau de la conseillère scientifique en chef phac.ocsoevidence-bcscdonneesprobantes.aspc@canada.ca

Subject: Ivermectin to treat people infected with COVID-19

The Honourable
Patty Hajdu
Member of Parliament
Minister of Health
Government of Canada

Dear Minister Hajdu,

With the backdrop of shocking death rates in Canada, even more shocking 500 daily deaths in California alone, and now a new variant of COVID-19 that has a huge increase in transmission, pretty much everybody knows that we are literally in a Global biological war. So when it came to my attention that there is the potential for a simple drug treatment in the form of oral tablets to treat people who have tested positive for COVID-19 I felt compelled to write to you.

My question is: Can Ivermectin (Stromectol) be used to treat COVID-19 or ANY coronavirus? You might find that the answer sounds extremely encouraging, and with emergency approval of its use in Canada for 'essential' working adults, we will have made a major step to help fight Covid-19 and thus ease, in a major way, the ongoing spread of the virus.

World Health Organization officials are predicting that the "destiny" of the COVID-19 virus is to become endemic, suggesting it could continue to spread through the population at a steady rate despite a global vaccination effort, and may never go away.

Several senior WHO officials also warned that the development of COVID-19 vaccines is no guarantee that the virus will be eradicated, proposing that a more realistic goal would be to reduce the threat of transmission to more manageable levels. This must be the ultimate goal in this war.

Ivermectin appears to be able to meet that goal. Ivermectin is a medication used to treat many types of parasite infestations. It can be taken by mouth or applied to the skin for external infestations. Ivermectin is used to treat infections in the body that are caused by certain parasites. The dose of this medicine will be different for different patients. Ivermectin is usually given as a single dose. To effectively treat your infection, you may need to take ivermectin again several months to a year after your first dose.

Ivermectin was discovered in 1975 and came into medical use in 1981. It is already on the WHO list of Essential Medicines with over 4 billion doses administered. Ivermectin is an FDA-approved anti-parasitic agent.

Ivermectin is currently being investigated as a treatment for coronavirus SARS-CoV-2, which is the virus that causes COVID-19. The trials so far have shown ivermectin reduces the number of cell-associated viral DNA by 99.8 % in 24 hours. Further studies are needed to determine the effectiveness of this medicine in humans with COVID-19.

Ivermectin has been trialled in treating the coronavirus SARS-CoV-2, which is the virus that causes COVID-19.
An in vitro trial has shown ivermectin reduces the number of cell-associated viral RNA by 99.8 % in 24 hours. An in vitro study is when they study cells in a laboratory and not in a living organism.
More studies are now needed to be done using ivermectin on people or animals to see how well ivermectin works against COVID-19. This is in vivo testing.

How does Ivermectin work on COVID-19?

- For the SARS-CoV-2 virus to make you sick, it has to first infect your cells.
- Then while inside the cell, the virus makes heaps of copies of itself, so it can spread around your body.
- The virus also has ways of reducing the way your body fights the infection.
- During the infection of the cell, some viral proteins go into the cell nucleus, and from here they can decrease the body's ability to fight the virus, which means the infection can get worse.
- To get into the nucleus the viral proteins need to bind a cargo transporter which lets them in.
- Ivermectin can block the cargo transporter, so the viral proteins can't get into the nucleus. This is how the scientists believe Ivermectin works against SARS-CoV-2 virus.
- By taking Ivermectin, it means the body can fight the infection like normal, because its antiviral response hasn't been reduced by the viral proteins.

About the FLCCC Alliance

The Front Line COVID-19 Critical Care Alliance was initially formed as a working group under "emergency" conditions of the early COVID-19 pandemic in response to multiple early reports of COVID patients with an inexplicably high need for prolonged mechanical ventilation and an excessive mortality associated with the prevailing "supportive care only" recommendations disseminated by the majority of national and international health care organizations.

In October 2020, the FLCCC Alliance identified, based on a review of the recent and rapidly emerging clinical trials evidence, that ivermectin has highly potent real-world, anti-viral, and anti-inflammatory properties against SARS-CoV-2 and COVID-19. This conclusion is based not only from multiple in-vitro and animal models, but from numerous clinical trials from centres and countries around the world showing repeated, consistent, large magnitude improvements in clinical outcomes when ivermectin is used not only as a prophylactic agent but also in mild, moderate, and even severe disease states. Further, data from large "natural experiments" that appear to have occurred when various regional health ministries and governmental authorities within South American countries initiated "ivermectin distribution" campaigns which then led to temporally associated decreases in case counts and case fatality rates.

Dr. Pierre Kory of the FLCCC Alliance calls on National Health authorities to immediately review medical evidence showing the efficacy of ivermectin for the prevention of COVID-19 and as an early outpatient treatment.

The FLCCC believes that their Critical Care team's testimony will help to immediately alter the trajectory of this pandemic. Take a closer look at the data and publish their findings, or those of now dozens of studies (and more to come) on the efficacy of Ivermectin in the prophylaxis and treatment of #COVID-19. The FLCCC Urges policymakers to take action.

They realize some people won't take the vaccine and not everybody responds to the vaccine. A person can still spread the virus after having received the vaccine. Ivermectin has been tested and appears effective.They take 12mg /70 kg bodyweight 1day and repeat in 3 days. Wait one month and repeat till the pandemic is under control.

When Ivermectin was used in a nursing home for scabies outbreak in France they found by accident nobody got COVID. The drug can be taken before during and after covid for those lasting symptoms. It is not 100% but it seems more effective than what they have now. It could take over a year for enough vaccine to be available, and you can get COVID again,

Again, the World Health Organization even says that COVID-19 may very well become Endemic, meaning that this virus will NEVER go away. This is an unimaginable prospect that requires everyone's attention now. Ivermectin appears to allow the world to get back on its feet, unless we think that every single living person on the planet will have been vaccinated. Realistically this never going to happen. The world needs a drug that can effectively treat the COVID-19 virus, including the seasonal flu virus, to prevent and mitigate the spread.

The data shows the ability of the drug Ivermectin to prevent COVID-19, to keep those with early symptoms from progressing to the hyper-inflammatory phase of the disease, and even to help critically ill patients recover. I ask that you urgently review the latest data and then issue guidelines for physicians, nurse-practitioners, and physician assistants to prescribe Ivermectin to battle COVID-19.

Please forward my comments to those who can work with Merck Canada, the makers of Stromectol (Ivermectin)Tablets , to start work on an effective oral dose to treat CANADIANS who have been infected with COVID-19 ASAP.

From my own perspective, this past year, I've heard and read about the COVID-19 virus thousands of times with sky high numbers of people infected and dead. Our Health Care system seems on the verge of collapse today. It is without a doubt a TOTAL DISASTER. Now all I am hearing about is catastrophic economic damage for small businesses and VACCINE, VACCINE, VACCINE thousands of times. Sounds like sheer panic to me, with politicians claiming that there is a light at the end of the tunnel or the end is in sight. What end, and how long is this tunnel? Politicians efforts to reassure the population that everything will be under control soon does not resonate with me at all. In fact, I believe the opposite is true. And I am a normally an optimistic retiree who is saving money right now. Surely we cannot keep shutting down our economies. So, the point is that vaccines

and human behaviour alone is not getting us to where we want and need to be, a FULL RECOVERY. The Government and medical scientists need to come up with a multi-pronged medical solution to end this war. As a relatively rich nation we are in a position where we can make this happen.

The I-MASK+ protocol will revolutionize the treatment of COVID-19"

The Front Line COVID-19 Critical Care Alliance has now developed a prophylactic and early outpatient combination treatment protocol for COVID-19 called I-Mask+. This protocol is centred around the use of Ivermectin, a well-known anti-parasite drug with recently discovered anti-viral and anti-inflammatory properties and a rapidly growing published medical evidence base demonstrating its unique and highly potent ability to inhibit SARS-CoV-2 replication.

Copy of the prophylaxis & Treatment Protocols for COVID-19 (Updated Dec 18, 2020) is in this link:

https://covid19criticalcare.com/wp-content/uploads/2020/11/FLCCC-Ivermectin-in-the-prophylaxis-and-treatment-of-COVID-19.pdf

PLEASE, PLEASE, get working TOGETHER on the emergency approval of Ivermectin drug for COVID-19 in Canada. I know we have all the scientific expertise and other resources we need. I am sure Dr. Kory will be happy to work with you.

Thank you,

[redacted]

Can IDPCB take care of this and talk to the therapeutics task force secretariat as to whether they can review/ discuss ivermectin?

I don't know who at PHAC is linked to the work of this task force but Kim would know.

Non urgent issue.

There seems to be an upswing of emails on ivermectin. Definitely a lot of enthusiasts (reminds me of the surge sometime back on hydroxy chloroquine) .

Do you know why there is a current blip in interest? Do we have lines developed on this topic?

Santé Canada Health Canada

Avis

L'ivermectine n'est pas homologuée pour la prévention ni pour le traitement de la COVID-19 et peut entraîner de graves problèmes de santé

Résumé

Produit : L'ivermectine (pour usage vétérinaire ou humain), un agent antiparasitaire (comprimé, pâte, solution orale [soluté buvable], solution injectable, prémélange médicamenteux ou préparation topique).
Problème : Des consommateurs achètent de l'ivermectine à usage vétérinaire pour la prévention ou le traitement de la COVID-19.
Ce qu'il faut faire : N'utilisez pas d'ivermectine à usage vétérinaire pour prévenir ni traiter la COVID-19. Si vous avez acheté de l'ivermectine dans ce but, débarrassez-vous-en immédiatement. Consultez un professionnel de la santé si vous avez pris ce produit et que vous avez des préoccupations relatives à votre santé.

Problème

Santé Canada a reçu des signalements préoccupants concernant l'utilisation d'ivermectine à usage vétérinaire pour prévenir ou traiter la COVID-19. Les Canadiennes et les Canadiens ne devraient jamais consommer de produits de santé destinés aux animaux en raison des possibilités de graves risques de ces produits pour leur santé.

C'est pourquoi Santé Canada avise la population canadienne de ne pas prendre d'ivermectine (pour usage vétérinaire ou humain) pour la prévention ou le traitement de la COVID-19. Il n'existe pas de données probantes montrant que l'utilisation contre la COVID-19 d'ivermectine (pour usage vétérinaire ou humain) est sûre et efficace. La vente d'ivermectine à usage humain n'est permise au Canada que pour le traitement chez les gens d'infestations par vers, un type d'infection parasitaire.

L'ivermectine à usage vétérinaire peut être dangereuse pour les humains, surtout à dose élevée, et peut entraîner de graves problèmes de santé, comme des vomissements, de la diarrhée, une hypotension artérielle, des réactions allergiques, des étourdissements, des convulsions ou un coma, et même la mort. Les produits d'ivermectine destinés aux animaux contiennent des concentrations d'ivermectine plus élevées que les produits d'ivermectine destinés aux humains.

Le Ministère a connaissance de multiples signalements de personnes qui ont eu besoin d'aide médicale ou qui ont dû être hospitalisées après la prise d'ivermectine destinée aux chevaux (en anglais seulement).

Santé Canada suit de près tous les traitements curatifs envisagés contre la COVID-19, y compris les traitements faisant l'objet d'essais cliniques à l'international. Santé Canada n'a pas reçu à ce jour de présentation de médicament ni de demande d'essai clinique concernant l'utilisation d'ivermectine pour prévenir ou traiter la COVID-19.

Santé Canada encourage les fabricants de médicaments à faire des essais cliniques pour tout médicament qui pourrait être utile dans le traitement de la COVID-19; il s'agit d'une occasion pour le milieu des soins de santé de recueillir de l'information sur l'efficacité des traitements de même que les risques connexes.

Si un fabricant présentait à Santé Canada une demande concernant l'utilisation d'ivermectine pour la prévention ou le traitement de la COVID-19, le Ministère ferait une évaluation scientifique des éléments probants afin de déterminer la qualité, l'innocuité et l'efficacité de ce médicament.

Le Ministère continuera de suivre la situation et prendra les mesures qui s'imposent en temps opportun s'il obtient de nouveaux renseignements, dont de l'information sur des activités de publicité ou de vente illégales concernant l'ivermectine. Santé Canada communiquera aussi toute information relative à l'innocuité de l'ivermectine aux professionnels de la santé et aux consommateurs.

Santé Canada a déjà mis la population canadienne en garde contre les produits de santé assortis d'allégations fausses ou trompeuses sur leur capacité à traiter ou à guérir la COVID-19. Pour en savoir plus sur les vaccins et les traitements homologués par Santé Canada, consultez Canada.ca.

Contexte

La vente d'ivermectine (un médicament sur ordonnance) est permise au Canada pour le traitement chez les humains d'infestations par vers, un type d'infection parasitaire, en particulier l'anguillulose et l'onchocercose intestinales. L'ivermectine ne devrait être utilisée que pour cette indication et sous la supervision d'un professionnel de la santé. Une version pour usage vétérinaire de ce médicament est offerte pour le traitement d'infections parasitaires chez les animaux. Les humains ne devraient jamais utiliser la version pour usage vétérinaire de ce produit.

Ce que vous devriez faire

- Si vous avez acheté de l'ivermectine à usage vétérinaire pour prévenir ou traiter la COVID-19, arrêtez d'utiliser le produit et débarrassez-vous-en de l'une ou l'autre des façons ci-dessous.
    - Respectez les directives municipales ou régionales concernant l'élimination des produits chimiques et autres déchets dangereux.
    - Rapportez le produit au point de vente pour qu'il soit correctement éliminé.
- Consultez un professionnel de la santé si vous avez pris de l'ivermectine et que vous avez des préoccupations relatives à votre santé.
- Signalez tout effet secondaire de ce produit directement à Santé Canada.
- Faites une plainte à Santé Canada si vous avez de l'information concernant la publicité ou la vente illégale d'ivermectine ou de tout autre produit de santé au moyen du formulaire de plainte en ligne.

Health Canada Santé Canada

Advisory

Ivermectin not authorized to prevent or treat COVID-19; may cause serious health problems

Summary

Product: Ivermectin (veterinary or human versions), an antiparasitic agent (tablets, paste, oral solution, injectable solution, medicated premix or topical).
Issue: Consumers, are purchasing veterinary ivermectin to prevent or treat COVID-19.
What to do: Do not use veterinary ivermectin for the prevention or treatment of COVID-19. If you have purchased ivermectin for this purpose, discard it immediately. Consult a healthcare professional if you have used this product and have health concerns.

Issue

Health Canada has received concerning reports of the use of veterinary ivermectin to prevent or treat COVID-19. Canadians should never consume health products intended for animals because of the potential serious health dangers posed by them.

In this light, Health Canada is advising Canadians not to use either the veterinary or human drug versions of Ivermectin to prevent or treat COVID-19. There is no evidence that ivermectin in either formulation is safe or effective when used for those purposes. The human version of ivermectin is authorized for sale in Canada only for the treatment of parasitic worm infections in people.

The veterinary version of ivermectin, especially at high doses, can be dangerous for humans and may cause serious health problems such as vomiting, diarrhea, low blood pressure, allergic reactions, dizziness, seizures, coma and even death. Ivermectin products for animals have a higher concentrated dose than ivermectin products for people.

The Department is aware of multiple reports of patients in the U.S. who have required medical support and been hospitalized after using ivermectin intended for horses.

Health Canada is closely monitoring all potential therapeutic treatments for COVID-19, including treatments being studied in international clinical trials. To date, Health Canada has not received any drug submission or clinical trial application for ivermectin for the prevention or treatment of COVID-19.

For drugs that have the potential to be helpful in treating COVID-19, Health Canada encourages drug manufacturers to conduct clinical trials. This would provide an opportunity for the healthcare community to collect information on the effectiveness of the treatment and its associated risks.

Should a manufacturer provide a submission to Health Canada related to the use of ivermectin to prevent or treat COVID-19, Health Canada would conduct a scientific evaluation of the evidence to determine the drug's quality, safety and effectiveness.

Health Canada will continue to monitor the situation and will take appropriate and timely action should new information become available, including any information regarding the illegal advertising or sale of ivermectin. Health Canada will also communicate any new safety information to healthcare professionals and consumers.

Health Canada has previously warned Canadians about products making false and misleading claims to treat or cure COVID-19. For information on Health Canada authorized vaccines and treatments, visit Canada.ca.

Background

Ivermectin, a prescription drug product, is authorized for sale in Canada for the treatment of parasitic worm infections in humans, specifically intestinal strongyloidiasis and onchocerciasis, and should only be used for this purpose, under the supervision of a healthcare professional. A veterinary version of this medication is available to treat parasitic infections in animals. People should never use the veterinary version of this product.

What you should do:

- If you have purchased ivermectin for the prevention or treatment of COVID-19, stop using it and discard it:
  - Follow municipal or regional guidelines on how to dispose of chemicals and other hazardous waste; or
  - Return the product to the point of sale for proper disposal.
- Consult a healthcare professional if you have used ivermectin and have health concerns.
- Report any side effects from this product directly to Health Canada.
- Submit a complaint to Health Canada should you have any information regarding the illegal advertising or sale of ivermectin or any other health product using its online complaint form.

IVERMECTIN
BACKGROUNDER (January 4, 2021)

Ivermectin

- Ivermectin is an antiparasitic-drug approved for use in Canada in both people and animals.
- The Merck manufactured drug stromectol (ivermectin) was authorized by Health Canada in September 2018 to treat intestinal strongyloidiasis and onchocerciasis (parasitic worms), and proven or suspected microfilaremia in patients with lymphatic filariasis caused by Wuchereria bancrofti.
- Ivermectin is widely available due to its inclusion on the WHO model list of essential medicines.
- Before the 2018 Notice of Compliance, the drug was only accessible in Canada through the Special Access Program.

COVID-19 and Clinical Trials

- Ivermectin is not approved for use in Canada or in the USA for the prevention or treatment of COVID-19. In April 2020, the USA FDA issued guidance not to use it to prevent or treat COVID-19.
- Completed clinical trials to test the use of ivermectin as a therapy to treat COVID-19 to date have had negative results (Camprubi et al, Public Library of Science, November 11, 2020). Several additional clinical trials are underway.
- A recent Australian article in Antiviral Research noted the positive impacts ivermectin had as an inhibitor of COVID-19 in vitro. It notes that more research is needed, and their work does not mean it should be used in humans.
- In Latin America, countries such as Peru, Bolivia, and Guatemala, ivermectin is over-the-counter, and has been been popularly used as a preventative against COVID-19. Its use there is so widespread that it may make clinical trials in those countries difficult.
- There are currently no authorized COVID-19 ivermectin clinical trials in Canada.

Therapeutics Task Force

- At the last TTF meeting (December 11, 2020), the TTF was asked to investigate ivermectin given recent attention to its potential utility in COVID-19 treatment.

- TTF members had a brief discussion about ivermectin, including both research studies and clinical trials, as well as its use in practice. Members found that its use as either a prophylactic or treatment lacked evidence of effectiveness. They concluded that it was not a promising therapy and that it required further investigation.
- Health Canada and Public Health Agency of Canada officials continue to be in dialogue with the TTF about further evidence, if additional clinical data emerges.
